The thickness of the oxide films formed anodically in a given time on aluminum in 3 percent ammonium tartrate increases linearly with the applied voltage. Layers produced in 30 sec. have a thickness of 12.2A-units per volt. After 30 sec. their thickness increases very little with the duration of the anodic treatment.[6] Such layers are amorphous and show no evidence of pores or grain structure. Films only 100 to 150A in thickness can be prepared. They are, therefore, suitable as temperature resistant support films for electron diffraction and electron microscope investigations.[7] Supporting membranes with extremely smooth surfaces can be prepared on electrolytically polished pure aluminum or on thick evaporated aluminum layers that have been stripped from a glass surface.

Diffusional Viscosity of a Polycrystalline Solid

CONYERS HERRING
Bell Telephone Laboratories, Murray Hill, New Jersey
(Received December 23, 1949)

According to a suggestion of Nabarro, any crystal can change its shape by self-diffusion in such way as to yield to an applied shearing stress, and this can cause the macroscopic behavior of a polycrystalline solid to be like that of a viscous fluid. It is possible that this phenomenon is the predominant cause of creep at very high temperatures and very low stresses, though not under more usual conditions. The theory underlying it is developed quantitatively, and calculations of rate of creep, or equivalently of effective viscosity, are given for aggregates of quasi-spherical grains and for wires composed of cylindrical grains. Allowance is made for the effect of tangential stress relaxation at the grain boundaries. It is suggested that mosaic boundaries and boundaries between grains of nearly the same orientation may be unable to serve as sources or sinks of the diffusion currents, in which case the creep rate will depend only on the configuration of grain boundaries having a sizable orientation difference. Numerical comparison of the theory with experiments on the high temperature creep of wires favors this view, but is not entirely satisfactory. Suggestions for further experiments are made.

NABARRO[1] has recently pointed out that self-diffusion within the grains of a polycrystalline solid can cause the solid to yield to an applied shearing stress, the yielding being caused by a diffusional flow of matter within each crystal grain away from boundaries where there is a normal pressure and toward those where there is a normal tension, as shown in Fig. 1. This yielding is macroscopically describable by an effective viscosity proportional to the square of the linear dimensions of the grains. This phenomenon, which occurred independently to the present writer, provides a possible explanation for the quasi-viscous behavior which has been observed for foils and wires which are suspended with a very slight load and held at an elevated temperature.[2] It may also be important in other types of sintering phenomena. The purpose of the present note is to clarify certain points in the theory underlying this "diffusional viscosity" and to attempt a more refined quantitative calculation of its magnitude for several experimentally realizable situations.

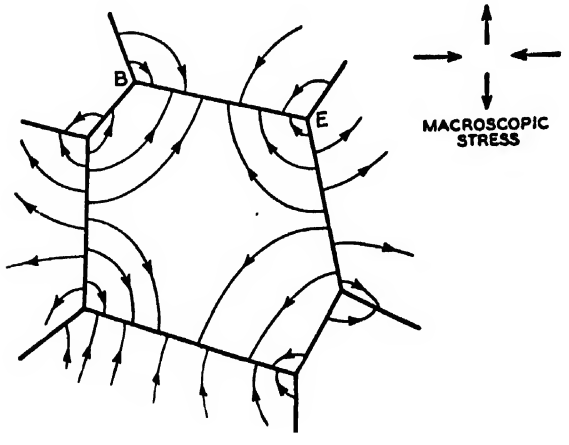

FIG. 1. A typical grain of a polycrystalline solid, showing the self-diffusion currents to be expected when the solid is subjected to a shearing stress.

1. BASIC THEORY

Let us consider first the simplest case of stress-motivated diffusion, namely self-diffusion in a single crystal of the cubic class containing only one type of atom and held at uniform temperature. In the absence of pressure gradients the diffusive flux of atoms, due to migration of lattice vacancies or interstitial atoms, will be proportional to the gradient of the concentration of these lattice defects; in the presence of pressure gradients, however, it tends to be energetically advantageous to move the lattice defects in whichever direction will relieve the inequality of pressure. It is easily shown that the effects both of concentration gradients and of pressure gradients are correctly given by writing the diffusive flux $\mathbf{j}$ (atoms per unit area per unit time) as proportional to the gradient of a chemical potential.[3,4] If n_l is the number of lattice sites per unit volume, D the self-diffusion coefficient, and T the absolute temperature,

$$\mathbf{j}=-(n_l D/kT)\nabla(\mu-\mu_h), \qquad (1)$$

where $(\mu-\mu_h)$ is the work per atom required for the reversible addition of a small quantity of material to the given region of the crystal, the material added being placed interstitially in the lattice or used to fill lattice

[3] It has long been recognized that it is more appropriate to write the diffusion equations for multi-component systems with chemical potentials, or their equivalents, rather than with concentrations, and this fact has recently been the subject of a number of papers in the metallurgical literature. The most recent, and probably the most satisfactory, of these is that of J. Bardeen, Phys. Rev. 76, 1403 (1949).

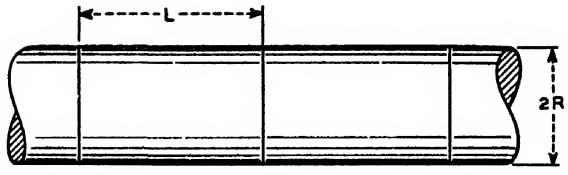

FIG. 2. Section of a wire with equally spaced transverse grain boundaries.

vacancies. This work is represented as a difference of two chemical potentials, μ and μ_h, to emphasize the fact that the change in question alters both the number of atoms and the number of lattice defects; however, in this paper only the difference of these quantities will appear.

Since any divergence of $\mathbf{j}$ within a single crystal would rapidly alter the concentration of lattice defects in such direction as to reduce $|\nabla\cdot\mathbf{j}|$, it will be safe to assume that in any continuing change $\nabla\cdot\mathbf{j}\propto\nabla^2(\mu-\mu_h)=0$. Thus the diffusion currents are completely determined if the values of $(\mu-\mu_h)$ on the boundary of the crystal are known. Now if the transfer of atoms from the interior to lattice sites at the boundary can occur easily, i.e., if the surface of the crystal is free to grow or recede with an accompanying change in the number of lattice defects in the interior, the boundary values of $(\mu-\mu_h)$ can be determined from the condition that the free energy of the crystal and its surroundings be a minimum with respect to transfer of atoms between any portion of the surface and the volume immediately beneath this portion. In reference 4 the boundary values of $(\mu-\mu_h)$ are determined in this way for the free surface of a crystal, and for grain boundaries where the interfacial tension between the grains is important; here we shall consider the simpler case where surface free energies can be neglected in comparison with the effects of externally applied forces. In intermediate cases the two effects have merely to be added.

Assuming that the surface-volume equilibrium just mentioned is realized at a grain boundary, the work involved in adding δN atoms to a crystal grain in the form of a hump on its surface must turn out to be the same, to the first order in δN, as the work involved in putting δN atoms into the interior just below the same surface region, holding the position of the surface fixed and placing the new atoms in interstitial positions or in places formerly occupied by lattice vacancies. The latter work is $(\mu-\mu_h-\mu_0)\delta N$, where μ_0 is the chemical potential of the source from which the δN atoms are obtained, say a piece of the same substance in equilibrium at the same temperature as the crystal being considered and at zero stress. The other process, formation of a surface hump, involves an amount of work $(\delta F-\mu_0\delta N-p_{zz}\delta v)$, where δF is the free energy of the hump itself, δv its volume, and p_{zz} is the normal traction on the surface, i.e., the zz component of the stress-tensor, where the z axis is chosen normal to the surface. Now to the first order in the stresses, $\delta F=\mu_0\delta N$, so equating the two amounts of work gives

$$\mu-\mu_h=\mu_0-p_{zz}\Omega_0, \tag{2}$$

where $\Omega_0=\delta v/\delta N$ is the atomic volume. This is the generalization of Nabarro's result regarding the effect of normal stress on vacancy concentration at the surface.

One can easily generalize Eqs. (1) and (2) to noncubic crystals or to crystals containing more than one kind of atom, provided the composition is uniform. In the multi-component case, however, care must be exercised in attempting to relate the D occurring in (1) to diffusion coefficients measured in other ways. Although a detailed discussion of diffusion in multi-component systems would be beyond the scope of this paper, an attempt has been made in the Appendix to indicate the type of analysis which must be used in applying the present equations to such things as substitutional solid solutions.

2. SPECIFIC CALCULATIONS

The rate of yielding of any given specimen to applied forces obviously depends on the detailed distribution of the sizes and shapes of its crystal grains, and on whether or not the grain boundaries are able to sustain shearing stresses for times as long as are required for appreciable diffusional transport to take place. It has been established in a number of cases that shearing stresses across metallic grain boundaries are rapidly relaxed at high temperatures;[5,6] it seems likely that this relaxation is a general property of grain boundaries, and that until this relaxation has become complete, the rate of creep due to it will usually be much faster than that due to diffusional viscosity. Although it is thus much more reasonable to compute the diffusional viscosity on the assumption of relaxed tangential stresses, we shall give calculations for both relaxed and unrelaxed tangential stresses, to show how much difference this factor makes. Both these calculations will be made assuming uniform, roughly spherical grains of a size small compared with that of the specimen; to show the way in which the rate of yielding is affected by having grains comparable with the dimensions of the specimen, some calculations will then be given for the rate of elongation of a wire consisting of roughly cylindrical grains end to end. Most of these cases are of course too idealized to apply accurately to any actual case, but it is hoped that they will sometimes be fair approximations to the truth.

Equal Quasi-Spherical Grains, No Grain Boundary Flow

If a crystal made up of grains such as that of Fig. 1 were suddenly subjected to a shearing stress, the initial diffusion currents would be very large in the neighborhoods of all sharp edges, such as E in the figure. This means that any grain boundary such as BE which is

[5] T. S. Kê, Phys. Rev. 71, 533 (1947); J. App. Phys. 19, 285 (1948); 20, 274 (1949).
[6] King, Cahn, and Chalmers, Nature 161, 682 (1948).

subjected to a normal tension will have more extra matter squeezed in at its edges than at its center. This will increase the tension at the center and decrease that at the edges, and a situation will very soon be reached where the normal flux is fairly uniform over each facet of the boundary. This suggests that for a crystal made up of nearly spherical grains all of the same size and having nearly isotropic elastic properties the rate of yielding can be fairly well approximated by that of a sphere acted on by such surface tractions as will produce a uniform shearing stress in its interior.

We shall assume for simplicity that the equations of Section 1 for a cubic crystal apply. Let the macroscopic stress-tensor be $\bar{p}_{\mu\nu}$. This must in all cases equal the volume average of the microscopic stress; in the present case we assume the stress in the interior of the sphere to be constant and equal to $\bar{p}_{\mu\nu}$. We assume $\bar{p}_{\mu\nu}$ to be a pure shear, so that

$$\sum_{\mu} \bar{p}_{\mu\mu}=0.$$

At a point of the surface of the sphere with coordinates x_μ the normal traction is

$$p_{rr}=\sum_{\mu,\nu} \bar{p}_{\mu\nu}x_\mu x_\nu/R^2,$$

where R is the radius of the spherical grain, so that

$$\sum_{\mu} x_\mu^2=R^2.$$

Inserting this into the boundary condition (2) it is easily seen that since $\nabla^2(\mu-\mu_h)=0$ the chemical potential in the interior must be given by

$$\mu-\mu_h=\mu_0-\Omega_0\sum_{\mu,\nu} \bar{p}_{\mu\nu}x_\mu x_\nu/R^2. \tag{3}$$

The normal flux at the boundary is, by (1)

$$j_n=(dr/dt)/\Omega_0=(2D/kT)\sum_{\mu,\nu} \bar{p}_{\mu\nu}x_\mu x_\nu/R^3 \tag{4}$$

since $n_l\Omega_0=1$. This may be compared with the rate of normal displacement of the boundary in a uniform shear of strain rate $\dot{u}_{\mu\nu}$:

$$dr/dt=\sum_{\mu,\nu} \dot{u}_{\mu\nu}x_\mu x_\nu/R. \tag{5}$$

Comparison of (4) and (5) shows that our assumptions are consistent with a uniform shear of all the grains of the crystal at a rate

$$\dot{u}_{\mu\nu}=(2D\Omega_0/kTR^2)\bar{p}_{\mu\nu}. \tag{6}$$

Viscous flow is defined, for the present case where $\bar{p}_{\mu\nu}$ is a pure shear, by the macroscopic relation $2\dot{u}_{\mu\nu}=\bar{p}_{\mu\nu}/\eta$, which with (6) gives for the effective viscosity of the polycrystalline solid

$$\eta=kTR^2/4D\Omega_0=(3/32\pi)^{\frac{1}{3}}(kT/D\Omega_0)V_g^{\frac{1}{3}}, \tag{7}$$

where V_g is the volume of a grain.

Equal Quasi-Spherical Grains, Tangential Stress Relaxed at Boundaries

For this case we must find a distribution of normal tractions over the surface of a sphere which will make the volume average of the stress-tensor in the interior equal the macroscopic stress-tensor $\bar{p}_{\mu\nu}$. Now from the equilibrium condition that the divergence of the stress-tensor must vanish we have, if $d\tau$ runs over the volume of the sphere and dS over its surface

$$0=\int x_\mu \sum_\alpha \partial p_{\alpha\nu}/\partial x_\alpha d\tau$$

$$=-\int p_{\mu\nu}d\tau+\int x_\mu \sum_\alpha p_{\alpha\nu}n_\alpha dS, \tag{8}$$

where $\mathbf{n}$ is the unit outward normal. For the present case

$$\sum_\alpha p_{\alpha\nu}n_\alpha=p_{nn}n_\nu,$$

so this gives

$$\bar{p}_{\mu\nu}=(3/4\pi R^4)\int x_\mu x_\nu p_{nn}dS. \tag{9}$$

If p_{nn} is represented by a series of spherical harmonics, (9) will determine the coefficients of the harmonics of order 2 (the lowest order consistent with the conditions of the problem) but will leave the higher order terms arbitrary. In an actual crystal grain these higher order terms will probably be no larger than is required to take account of the departure of the grain boundary configuration from spherical symmetry, and it is therefore proper to neglect them in the present approximation, the more so as they make no contribution to the over-all shear rate. Let us therefore set $p_{nn}=A(x_1^2-x_2^2)/R^2$, a form which can always be realized for the contribution of the second order spherical harmonics by proper choice of the coordinate directions x_1 and x_2. Insertion of this into (9) gives $\bar{p}_{11}=-\bar{p}_{22}=2A/5$, all other $\bar{p}_{\mu\nu}=0$. The chemical potential in the interior of the sphere is given by

$$\mu-\mu_h=\mu_0-(5/2)\bar{p}_{zz}\Omega_0(x^2-y^2)/R^2. \tag{10}$$

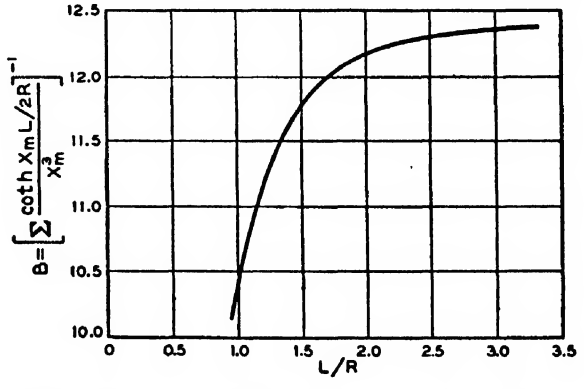

FIG. 3. Plot of the coefficient B occurring in Eq. (18) against the ratio of the length L of the grains to the radius R of the wire.

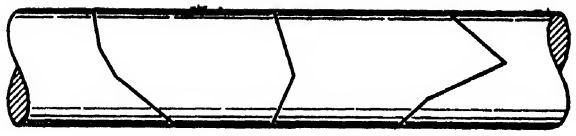

FIG. 4. Wire with irregular grain boundaries.

This is of the same form as (3) except for the factor 5/2. Repeating the argument leading to (7) gives

$$\eta = kTR^2/\tfrac{1}{10}D\Omega_0 = \tfrac{1}{10}(3/4\pi)^{\frac{1}{3}}(kT/D\Omega_0)V_a^{\frac{1}{3}}, \quad (11)$$

which is smaller than (7) by a factor $\frac{2}{5}$.

Wire with "Bamboo-Like" Grain Structure

Fine metal wires often consist of crystal grains occupying the entire cross section of the wire and having lengths which may be of the same order as the diameter of the wire or may be many times larger. In the experiments cited in reference 2 this type of grain structure characterized both the copper wires used by Udin, Shaler, and Wulff and the gold wires used by Alexander, Kuczynski, and Dawson.* A model which approximates the condition of these wires and for which the associated potential theory problem is easily solved is that of a wire with a "bamboo-like" grain structure, i.e., a cylinder of radius R with plane grain boundaries normal to the axis of the cylinder, uniformly spaced a distance L apart, as shown in Fig. 2.

For this model it is obvious from symmetry that when a longitudinal tension or compression is applied, the diffusion currents in the quasi-steady state will be such as to make the normal flux away from or into each grain boundary a constant over its area. This will of course require that the normal traction p_{nn} across a grain boundary vary with distance from the center of the wire; however, the integral condition

$$\int p_{nn}dS = F$$

must always be obeyed, where dS runs over the area of a grain boundary, and F is the force applied at the ends of the wire. For simplicity we ignore surface tension effects for the present; this is legitimate in computing the change in rate of stretching with a change in the load. In such case the boundary conditions on $(\mu-\mu_h)$ are:

$$f \equiv \mu-\mu_h-\mu_0 = 0 \quad \text{on the cylindrical surface} \quad (12)$$

while over the end boundary of each grain

$$\partial f/\partial z = \text{constant} \quad (13)$$

$$\int f dS = -F\Omega_0 \quad (14)$$

where z is the coordinate in the direction of the axis of the cylinder. The determination of f involves the same problem, therefore, as the determination of the potential due to an infinite series of uniformly charged disks placed inside a conducting cylinder. Using standard methods[7] the solution is easily shown to be

$$f = -\frac{F\Omega_0}{2\pi R^2}\frac{\sum_m [\coth(X_mL/2R)\cosh(X_mz/R)-\sinh(X_mz/R)]J_0(X_mr/R)/X_m^2J_1(X_m)}{\sum_m \coth(X_mL/2R)/X_m^3} \quad (15)$$

where the J's are Bessel functions, X_m runs over the roots of $J_0(X_m)=0$, and r is the distance from the axis of the cylinder, and where z ranges from 0 on one of the grain boundaries to $L/2$ midway between this boundary and the next. Each grain elongates or contracts at a rate

$$dL/dt = -(2\Omega_0/\pi R^2)\int j_z dS,$$

the integration being over the disk of radius R in the plane $z=0$. Using (1) and (15) we find

$$dL/dt = (D\Omega_0/2\pi R^3kT)BF, \quad (16)$$

where

$$B = [\sum_m \coth(X_mL/2R)/X_m^3]^{-1} \quad (17)$$

is a function of L/R plotted in Fig. 3. Its asymptotic value for $L \gg R$ is $B_\infty = 12.37$, and it does not begin to depart seriously from this value until L/R has become smaller than any value likely to be encountered frequently in wires whose crystal grains occupy the whole cross section.

In the present case the deformation of the wire cannot legitimately be described as viscous, because the grain size equals or exceeds the diameter of the specimen; however, it is interesting for comparative purposes to compute the viscosity η which a viscous filament of the same diameter would have to have in order to elongate at the same rate under the same load. For such a filament we have $F = \pi R^2 \cdot 3\eta d\ln L/dt$, and this agrees with (16) if

$$\eta = 2kTRL/3BD\Omega_0. \quad (18)$$

Wire with Irregular or Slanting Grain Boundaries, Tangential Stresses Relaxed

It is easy to show that if the grain boundaries are not normal to the axis of the wire as in Fig. 2, but are of the type shown in Fig. 4, the rate of yielding of the wire will

* I am indebted to the authors of these two papers for discussions of unpublished details of their work, including opportunities to examine photomicrographs of their wires, and for the statistics on mean grain lengths which have been used in Table I.

[7] See for example, W. R. Smythe, *Static and Dynamic Electricity* (McGraw-Hill Book Company, Inc., New York, 1939), Chapter 5.

be greater than that given by (16) for the same grain size, if the tangential stresses vanish at the grain boundaries. This is most easily seen by noting that a given dL/dt requires a given total normal flux integrated over the grain boundary,† regardless of its shape or inclination; in the electrostatic analogue this means a given total charge. The potential produced by this given charge, averaged over the grain boundary, will be numerically smaller when the grain boundary is oblique than when it runs normally across the wire as in Fig. 2. This potential is proportional to the normal stress across the grain boundary. It is easy to see that when the normal tractions are resolved along the axis of the wire, equal mean normal stresses will give equal values of the force F tending to elongate or compress the wire; therefore F will be less for Fig. 4 than for Fig. 2, when dL/dt is the same.

The calculations of the preceding section suggest some approximations which can be used to make a crude quantitative estimate of this effect. The same methods which were used to obtain (15) can be applied to calculate the potential due to a uniformly charged flat ring of any inner radius, r_1, and outer radius r_2, placed inside a grounded conducting cylinder. The potential problem for a grain boundary consisting of a series of ring-like steps, as shown in Fig. 5, can therefore be solved, and if the steps are not taken too large, this solution can probably be regarded as typical of irregular grain boundaries of the same average inclination. Ignoring interactions between the two ends of a grain, which Fig. 3 shows to be quite small, the force F required to produce a given elongation dL/dt at a single grain boundary of the sort described comes out to be

$$F=\frac{2\pi R^3kT}{D\Omega_0}\times\left[\sum_m\frac{\sum_{i,j}\{m,i\}\{m,j\}\exp(-|z_i-z_j|X_m/R)}{X_m^5[J_1(X_m)]^2}\right]\frac{dL}{dt}, \quad (19)$$

where i and j label the various rings, the ith ring having inner radius r_{i1} and outer radius r_{i2} and longitudinal coordinate z_i, and where

$$\{m,i\}=(X_mr_{i2}/R)J_1(X_mr_{i2}/R)-(X_mr_{i1}/R)J_1(X_mr_{i1}/R).$$

Now for large L the series in (17) differs from its leading term by only about 10 percent, so it is probably legitimate, in an approximation which replaces the grain boundaries of Fig. 4 by those of Fig. 5, to set the ratio of (19) to the F_0 given by (16) equal to the ratio of the first terms of the respective summations on m. This gives

$$F/F_0\approx\sum_{i,j}\{1,i\}\{1,j\}/X_1^2[J_1(X_1)]^2. \quad (20)$$

Some values computed from this formula for typical grain boundaries are given in Fig. 5.

The conclusion from this analysis is that the equivalent viscosity of a wire with irregular grain boundaries may be as much as two to three times smaller than the value given by (18) for flat-ended grains of the same length.

3. GRAIN BOUNDARIES *VERSUS* MOSAIC BOUNDARIES

The calculations of the preceding section have assumed the existence of certain "grains," at whose boundaries diffusion currents of lattice defects can converge or diverge, the boundary concentration of lattice defects being in equilibrium with the normal stress. It is conceivable that these properties might be possessed by crystal grains in the usual sense of the term, by mosaic blocks within a "single crystal," or, perhaps, by neither. In the present section it will be suggested as particularly likely that the condition of equilibrium just mentioned is attained, at sintering temperatures, on most ordinary grain boundaries, but is not attained on the boundaries of mosaic blocks. The experimental evidence discussed in the next section, though not entirely satisfactory, tends to favor this suggestion.

The boundaries of mosaic blocks have been pictured as consisting of rows of identical parallel dislocations spaced apart by a distance of the order of 10^3 atomic spacings.[8] Although it is not known whether the usual mosaic structure of single crystals consists of blocks bounded by such rows of dislocations, or merely of an irregular tangle of dislocation lines, it can hardly be doubted that the structure can be described in terms of dislocations; moreover, there seem to be good prospects for accounting quantitatively for many of the properties of grain boundaries, at least when the orientation difference between the grains is small, by picturing the boundaries as arrays of dislocations.[9] It is therefore

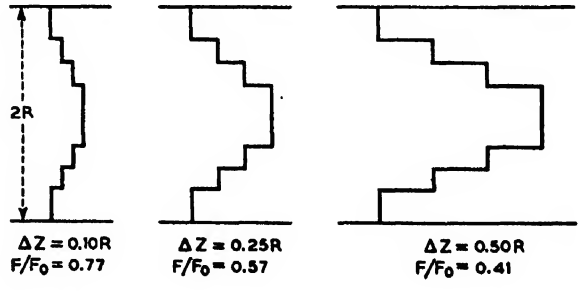

FIG. 5. Representation of irregular grain boundaries by successions of ring-like steps of height Δz at radii $0.3R$, $0.5R$, and $0.7R$. The quantity F/F_0 shown for each case is the approximate ratio of the force required to produce a given rate of elongation of the grain shown to the force required to produce the same rate of elongation of one of the flat-ended grains of Fig. 2.

† In accordance with the discussion given in Section 4, it is assumed that for sufficiently small stresses no "offsetting" of the grains will occur.

[8] J. M. Burgers, Proc. Phys. Soc. 52, 23 (1940); J. S. Koehler and F. Seitz, J. App. Mech. 14, A217 (1947).

[9] W. Shockley and W. T. Read, Phys. Rev. 75, 692 (1949); W. T. Read and W. Shockley, Phys. Rev. 78, 275 (1950).

legitimate to wonder what difference, if any, there is between the behavior of grain boundaries and that of mosaic boundaries.

In a well-annealed crystal the configurations of the dislocation arrays describing the mosaic structure must be such as to make the elastic free energy a minimum with respect to small displacements of any of the dislocation lines. Application of a small stress will affect the dislocations in two ways: a shearing stress on the slip plane of a dislocation will tend to move it in this plane, while a normal stress across a plane perpendicular to the slip vector will tend to move the dislocation in a direction not lying in the slip plane. Motion of the latter type requires the creation or annihilation of lattice defects, and will cease when the chemical potential of the lattice defects in the neighborhood of the dislocation has changed by an amount sufficient to compensate for the change in stress. An isolated dislocation line would thus affect the potential $(\mu-\mu_h)$ of the diffusion problem in much the same way as a wire held at a certain potential would affect an electrostatic problem. However, in an array of reasonably well-separated dislocations it seems likely that the freedom of motion of each dislocation will be impeded by the stress-fields of neighboring dislocations, and that within a short time after application of a small stress a new elastic equilibrium will be reached and all motion of the dislocations will cease, and concomitantly $(\mu-\mu_h)$ will become essentially constant over mosaic dimensions.

One aspect of this speculation can be given a rough check. The distance which each dislocation will move, in coming to a new position of equilibrium after application of a small stress σ, may be expected to be of the order of magnitude of $\sigma d/\sigma_0(d)$, where d is a length of the order of the spacing between dislocations and $\sigma_0(d)$ is the stress at a distance d from an isolated dislocation line. The resultant shearing strain of the whole specimen should therefore be of the order of this quantity times a/d^2, where a is the lattice constant. Since $\sigma_0(d)$ is of the order of $Ga/2\pi(1-p)d$, where G is a shear constant and p a Poisson's ratio,[10] the resulting shear is of order $2\pi(1-p)\sigma/G$. This gives values two or three orders of magnitude smaller than the total strains observed in the wire experiments of reference 2, which were of the order of 10^{-2}.

It is therefore not implausible to suppose that motion of dislocations may be of negligible importance in these experiments, and that the diffusion currents are divergenceless except at grain boundaries separating two crystals having a sizable difference of orientation $\Delta\theta$. By "sizable" is meant an orientation difference large enough so that the grain boundary can no longer be viewed as an array of dislocations spaced many lattice constants apart. If this speculation should turn out to be true, it would imply the existence of a critical value of $\Delta\theta$ below which growth of the two crystals normal to the grain boundary cannot take place freely, but above which it can. In such case any grain boundaries separating grains with less than the minimum $\Delta\theta$ should not be counted as grain boundaries in comparing the present theory with observations. There may conceivably be many such boundaries in wires whose grains have a strong tendency to crystallize with a certain crystallographic direction along the axis of the wire. For two grains with such a common axis need only a relative rotation about the wire axis to bring their orientations into coincidence, and it is possible that at sintering temperatures the natural desire of the grain boundary to decrease its interfacial tension may bring about such a rotation, at least until the orientation difference becomes small enough so that further changes of configuration cannot take place freely.

[10] See for example, J. S. Koehler, Phys. Rev. **60**, 397 (1941).

4. RELATION OF THEORY TO EXPERIMENT

Most of the present section will be devoted to a discussion of experiments on the longitudinal creep of wires at high temperatures, as measured by Udin, Shaler, and Wulff[2] for copper and by Alexander, Kuczynski, and Dawson[2] for gold. In these experiments an attempt was made to find what value of the applied tension would just suffice to prevent the wires from shrinking under the action of their surface tension, and thus to measure the latter quantity. The stresses used in these experiments were therefore below the range used in most ordinary creep experiments (about 1 to 100 g/mm^2), while the extensions were relatively large, of the order of 10^{-3} to 10^{-2} and more. It is therefore not unreasonable to attribute the creep in these high temperature experiments to mechanisms quite different from those operative in most of the previous creep experiments in the literature, although it is of course quite conceivable that the mechanisms may be the same, the thresholds being lower and the rates faster at the higher temperatures. The latter possibility is supported by the fact that Miller[11] has observed an apparently unlimited creep for single crystals of zinc under stresses of only 2 or 3 g/mm^2, even at room temperature; however, it would be risky to conclude from this that the experiments of reference 2 involve the same mechanisms as room-temperature creep in single crystals, and the following discussion will explore the alternative that the diffusion mechanism discussed in the previous sections plays a major role. As Nabarro has shown,[1] the latter mechanism does not seem to be the major one in creep experiments such as those of Chalmers[12] on single crystals of tin.

Offsetting and Kinking

Besides the diffusion effect and the possible effect of ordinary creep within the individual crystal grains, there are at least two other effects which may influence the changes in length which are observed for fine wires

[11] R. F. Miller, Trans. A.I.M.E. **122**, 176 (1936).
[12] B. Chalmers, Proc. Roy. Soc. **A156**, 427 (1936).

suspended at high temperatures. One of these is "offsetting" of adjacent grains, as shown in Fig. 6. This is known to occur for polycrystalline wires suspended at high temperatures under tension of sufficient magnitude.[13] However, it is easy to see that it cannot occur if the tension is below a certain limit, and that it cannot contribute to the shrinking of wires suspended with no load. For, referring to Fig. 6, consider a lateral offset of amount AB along a grain boundary whose normal makes an angle θ with the axis of the wire. This enables the wire to yield to the applied tensile force F by a distance $\langle AB\rangle \sin\theta$; however, it exposes an area of new surface represented by AB and CD. The surface free energy thus increases by $2R\cdot\langle AB\rangle\cdot(2\bar{\gamma}-\gamma_b)$ where $\bar{\gamma}$ is an average surface tension for the regions AB and CD, and γ_b is the specific free energy of the grain boundary. Thus the over-all free energy will be lowered by the offset if and only if

$$F>2R(2\bar{\gamma}-\gamma_b)\csc\theta. \tag{21}$$

This is somewhat larger than the force $\pi R\bar{\gamma}'$ necessary to prevent shortening of a long grain under its own surface tension. We may therefore conclude that offsetting will not occur in the lower range of stresses employed in the wire experiments of reference 2, but that it may well occur in the higher part of the stress range.

The other possible perturbing effect, which will be called "kinking," consists in the development of a slight angle between the axes of adjacent grains of the wire. This could be produced by a relative rotation about an axis normal to the wire axis. Such a rotation might be motivated by a dependence of the free energy of the grain boundary on the relative orientations of the grains; it would of course require that material be removed from the portions of the grains which move toward each other, and added to the portions which move apart. If this transport of matter takes place by diffusion, one can estimate the order of magnitude of the rate of change of orientation by the methods described in reference 4. This estimate, the details of which will not be given here, shows that for the wires of reference 2 the rate of kinking due to this cause ought to be too small to produce a perceptible shortening, though possibly not too small to give a measurable angle of kink.

Kinking might conceivably also be caused by a relative rotation of two grains about the normal to a plane grain boundary, if this normal were a trifle inclined to the axis of the wire. The motivation could again come from an anisotropy of the grain boundary energy; for this process, however, no transport of matter would be required, and its rate might be faster than that of the process described in the preceding paragraph.

Calculated *versus* Observed Creep Rates

Table I gives a comparison of the observed rates of creep of the wires of reference 2, expressed in terms of equivalent viscosities, with rates calculated from (18) and (20). Since the least accurately known of the experimental data are the lengths L of the crystal grains, the comparisons are made on this quantity.

Ideally, if the diffusion hypothesis is the correct one, it should be possible to get a fairly accurate check between theory and experiment. For, with one possible exception, all the quantities on the right of (18) can be measured fairly accurately, the most uncertain being D, and even this can be measured to an accuracy of 20 percent or better if the temperature can be accurately reproduced. The possible exception is the mean length L of the grains: if, following the possibility suggested in Section 3, it turns out that growth can occur at grain boundaries where the orientation difference is large but not at those where it is small, then the value of L to be inserted into (18) will be larger than the value L' measured metallographically, by an amount which it may be hard to establish. The correction factor F/F_0 will in many cases be close to unity, since both theory and observation agree that grain boundaries usually prefer to align themselves normal to the wire axis; if for any reason the boundaries are not transverse, a reasonable estimate of F/F_0 can be made from Fig. 5.

A number of experimental uncertainties in the present examples make the accuracy of the comparison of theory and observation fall somewhat short of this ideal. Besides the uncertain possibility that L may be appreciably greater than L', the value of L' itself is somewhat uncertain. The values given in the table were taken from photomicrographs of short sections of the wires after etching; however, since regions of long grains may alternate with regions of short grains, many such samples must be measured to get a reliable measure of the mean length of all the grains in the specimen. Moreover, the grain structure may change appreciably during the experiment. In this connection it is interesting to speculate that a relative axial rotation of neighboring grains, resulting ultimately in making the orientation difference too small for growth to occur, might conceivably cause the effective L to increase with time. This would lead to a creep rate decreasing with time, as was observed by Alexander, Kuczynski, and Dawson.[2]

A moderate error in the temperature, or rather, in the relative temperature scales of the creep and diffusion measurements, can produce an appreciable error in D. Dr. Alexander has informed the author that the temperature listed in the table as 1050° may have been closer to 1025°; a temperature lowering of this amount would

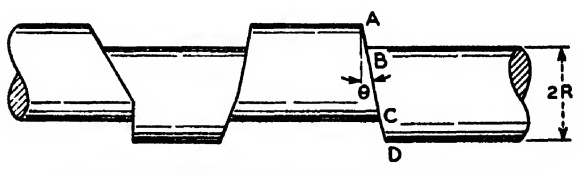

FIG. 6. Illustration of offsetting for a wire suspended under tension.

$(L/R)(F/F_0)$, calculated	1.0	0.24	9.6 to 16
L'/R, observed	4	2	2

* The observed η-values for copper were taken from lines drawn by Udin, Shaler, and Wulff averaging their measurements at different temperatures. Their values must be multiplied by 2 because of an error in a formula, derived by Frenkel, by which they reduced their observations.

L is the average spacing between grain boundaries at which growth can occur, while L' is the average spacing between observable boundaries.

F/F_0 is the correction factor to be applied to (18) due to departure of the grain boundary shapes from the ideal transverse planes of Fig. 2; according to (20) this factor is probably between $\frac{1}{2}$ and 1.

The next to the last line of the table was computed by equating the observed viscosity η to the product of F/F_0 by the right of (18) taking B to be 12.2, and solving for $(L/R)(F/F_0)$.

† See reference 2.

‡ The self-diffusion coefficient tabulated for copper is close to the values measured by Steigman, Shockley, and Nix, Phys. Rev. **56**, 13 (1939); M. S. Maier and H. R. Nelson, Trans. A.I.M.E. **147**, 39 (1942); and Raynor, Thomassen, and Rouse, Trans. Am. Soc. Metals **30**, 313 (1942). That for gold was obtained by extrapolating the data of H. A. C. McKay, Trans. Faraday Soc. **34**, 845 (1938).

lower D, and therefore the calculated $(L/R)(F/F_0)$, by a factor of about 1.5.

If the diffusion of a radioactive tracer isotope occurs largely or predominantly by simultaneous interchange of positions by neighboring atoms, the D to be used in the present calculations will of course be less than that measured in the tracer experiment, perhaps very much less.

Remarks on Future Experiments

The comparisons given in Table I, though not very satisfactory, do at least show that the creep observed in the experiments of reference 2 is of the same order of magnitude as that predicted on the hypothesis that it is due to diffusion currents flowing between the free surface and the grain boundaries and that it is therefore distinctly slower than that which would be predicted by an analogous theory in which the diffusion currents converge on the boundaries of mosaic blocks with dimensions of the order of 10^{-4} cm. However, an obvious direct check of the hypothesis that grain boundaries are essential could be made by performing the same experiments with single crystal wires, or with wires having a very large L/R ratio. In such an experiment it would be desirable to check the orientations of different parts of the "single crystals" by x-ray methods, to detect the possible presence of a polycrystalline structure with grain orientations differing by only a few degrees.[14]

Several items may be mentioned which would facilitate the interpretation of future experiments with the usual polycrystalline wires. Grain lengths should be measured over the whole length of the wire, and if possible the distribution of orientation differences between adjacent grains should be checked. Checks should also be made to find out whether the sizes and orientations of the grains change appreciably during the experiment, and whether changes in the creep rate with time are permanent or recoverable. Offsetting and kinking should of course be watched for, though according to the discussion above they are not expected to play a major role in the stress range of most interest.

Diffusional viscosity should not be very greatly affected by small amounts of impurities, once the effect of these impurities on the grain structure has been allowed for. This could easily be checked.

An interesting consequence of the theory of this paper is that the cylindrical surfaces of the wires used in experiments such as those of reference 2 ought to develop shallow depressions along the grain boundaries when they lengthen with time, and ridges when they shrink. This is because the diffusion currents tend to be especially strong at the parts of the surface near the grain boundaries. Use of polished wires would facilitate detection of this effect.

In conclusion, it should be pointed out that the phenomenon of diffusional viscosity, if it turns out to be the predominant cause of creep under very low stresses at sintering temperatures, should be very important in all kinds of sintering processes. This is especially true with regard to the final stages of sintering: the shrinking down of the cavities requires an overall contraction of the specimen, and this can easily be achieved if the crystal grains are free to slide on each other tangentially and to grow or recede normally to their boundaries. In the absence of such processes and of plastic flow within the crystals, the only mechanism which could shrink the cavities would be a diffusion of material from the outer boundary of the specimen, as postulated in the theory of Pines.[15] The latter process obviously gives a rate of densification much slower than the former process, and one which decreases rapidly with increasing dimensions of the specimen.

APPENDIX

In a cubic crystal containing various kinds of atoms, the general expression for the diffusive flux of the ith kind of atom is

$$\mathbf{j}_i = -(n_L/kT)\sum_k D_{ik}\nabla(\mu_k-\mu_h), \qquad (A)$$

where n_L is the number of unit cells in unit volume. Immediately after stresses are applied, the currents of the different species will in general be widely different; however, before any macroscopically recognizable transport of material has occurred concentration gradients will be set up in such directions as to tend to equalize these differences in currents, and if the stresses are small a quasi-steady state will very soon be reached in which $\mathbf{j}_i = X_i\mathbf{j}$, where X_i is the fractional concentration of the ith species and $\mathbf{j} = \sum \mathbf{j}_i$. It will be shown that $\mathbf{j}$ can be expressed in terms of the gradient of a single harmonic function. Equating (A) to $X_i\mathbf{j}$ and solving for $\nabla(\mu_k-\mu_h)$,

$$\nabla(\mu_k-\mu_h) = -(kT/n_L)\mathbf{j}\sum_i (D^{-1})_{ki}X_i, \qquad (B)$$

[14] Such structures have been observed in a "single crystal" of aluminum by P. Lacombe, "Report of a Conference on Strength of Solids" (The Physical Society, London, 1948), p. 91.

[15] B. Y. Pines, J. Tech. Phys., U.S.S.R. **16**, 737 (1946). I am indebted to Dr. G. C. Kuczynski for a translation of this paper.

where D^{-1} is the reciprocal of the matrix D. Now define μ_{0k} at each point of the crystal as the value of μ_k corresponding to the composition occurring at that point but at zero stress. Then by the Gibbs-Duhem relation, $\sum X_k \nabla \mu_{0k} = 0$. Moreover, if the stresses are small ($\mu_k - \mu_k - \mu_{0k}$) will be a small quantity of the first order in the stresses. Multiplying (B) by X_k and summing gives

$$-(kT/n_L)\mathbf{j} \sum_{i,k} (D^{-1})_{ki} X_i X_k = \sum_k X_k \nabla(\mu_k - \mu_k - \mu_{0k})$$

$$\approx \nabla \sum_k X_k(\mu_k - \mu_k - \mu_{0k}) \quad \text{(C)}$$

if we neglect quantities of the second order in the stresses, since ∇X_k is a small quantity of the first order. Thus we can write, in formal analogy to (1),

$$\mathbf{j} = -(n_L D'/kT)\nabla f \quad \text{(D)}$$

with

$$f = \sum_k X_k(\mu_k - \mu_k - \mu_{0k}) \quad \text{(E)}$$

and

$$D' = [\sum_{i,k} (D^{-1})_{ik} X_i X_k]^{-1}. \quad \text{(F)}$$

An argument of the same type as that leading to (2) shows that at the boundary of the crystal

$$f = -p_{as} \sum_k X_k(\partial v/\partial N_k) = -p_{as}\Omega_0, \quad \text{(G)}$$

where $\partial v/\partial N_k$ is the partial atomic volume of the kth component and Ω_0 is the mean atomic volume.

The form of the matrix D_{ik} of course depends on the mechanism of diffusion, a subject beyond the scope of this paper. We may merely mention that for purely interstitial diffusion the matrix is diagonal, so that for a two-component crystal

$$D' = (X_1^2/D_{11} + X_2^2/D_{22})^{-1},$$

while for a two-component crystal in which there is no diffusion except by place interchange the determinant $|D_{ik}|$ vanishes, making $D' = 0$, as is to be expected for this model.

Streak Photography

IRWIN VIGNESS AND R. C. NOWAK
Mechanics Division, Shock and Vibration Branch, Naval Research Laboratory, Washington, D. C.
(Received December 5, 1949)

A description is given of some methods of "streak photography" used for obtaining displacement records as functions of time. Ordinary streak photography consists of photographing a moving object on a moving film camera with an open shutter. The motion of the object should be in a plane parallel to the film and perpendicular to its motion. Large errors in velocity determinations may occur if the motion of the object has components parallel to the film motion. A modified method of streak photography is described in which these errors are reduced to small values. By this method time-displacement curves have been recorded for displacements of many inches and periods of several seconds with accuracies within a few thousandths of an inch and a few hundred thousandths of a second.

INTRODUCTION

THE measurement of transient motions of mechanical elements is of constant necessity in laboratory and field problems associated with mechanical shock and vibration. The conditions of the experiments require methods of measurements that are easy to perform and that do not appreciably load the mechanical parts under study. While high speed moving pictures provide this together with a wealth of other information, the work of transcribing the motion picture records into quantitative displacement curves is too laborious for many conditions. Methods of streak photography are easy to perform and can often be done with ordinary laboratory equipment. Many types of oscillographic recording cameras can be used with little or no modification. Several Naval Laboratories have made extensive use of the methods of streak photography to conveniently obtain accurate displacement curves.[1] However, no descriptions have been made of these methods except as incidental to other experiments. This paper describes the methods of streak photography most generally used.

[1] Vigness, Kammer, and Holt, "Shock and vibration instrumentation and measurements," Second Partial Report, Naval Research Laboratory Report No. 0-2645 (September, 1945).

ORDINARY STREAK PHOTOGRAPHY

One of the simplest methods of recording transient motions of an object is to photograph the object with a moving film camera. The film of the camera is made to move at a known speed and the shutter is held open during the entire exposure. The camera is arranged so that the direction of motion of the object under study is perpendicular to the camera optic axis and to the direction of film motion. Sufficiently good contrast can often be obtained without any special preparation of the object, but usually it is advisable to arrange bright spots with a dark background on the object whose motion is being studied. These bright spots may be dots of white paint, ball bearings, or small luminous sources. Ball bearings are particularly advantageous if very fine lines are desired. A small light source some distance from the ball should be used, the reflection of this light by the ball closely approximates a point. The ball should be small so that the reflected light will continue to come from essentially the same location on the ball. Many spots may be in the field of view, and, consistent with the requirements of depth of focus, they can be spread over any distance from the camera. Of course the displacement scale will depend upon this distance. Illumination

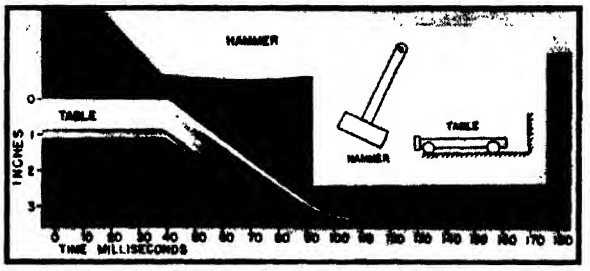

FIG. 1. Ordinary streak photograph showing the horizontal components of a displacement of a hammer and table when the table is struck by the hammer.

can be conveniently obtained for the non-luminous spots by photo-flood lights of the R3 type.

An example shown in Fig. 1 illustrates a hammer striking a steel table. The hammer swung as a pendulum and struck the edge of the steel table which was mounted on rollers and was constrained to move in but one direction. The upper part of the figure shows the motion of the hammer. The impact occurs at the sudden change of slope. The velocity of the hammer and table before and after impact can be determined from the slopes of the corresponding streaks. The boundary streaks of the hammer and table do not come into contact at impact as the camera did not observe the immediate areas of impact.

Special methods of streak photography have been applied for measuring the rate of flame propagation and for determining the velocity of the luminous areas of explosions. A precise and very accurate method of determining the deceleration of a projectile, and hence the force exerted by the projectile, is routinely performed by the Ballistics Branch of the Naval Research Laboratory by an unusual streak photographic technique.[2] In this case the moving film is contained on the inside of a drum that is 4 inches in diameter and that rotates so that film speeds up to 600 feet per second are attained. An intense source of light is flashed on for a half-millisecond during the passage of the projectile and the shadow of one point of the base of the projectile is recorded on the moving film.

The method of streak photography results in a direct plot, in Cartesian coordinates, of the displacement time history of as many locations as can be contained in the field of view. It possesses the advantage over high speed moving pictures of greater accuracy and the elimination of point by point plotting of curves when displacement records are required. High speed moving pictures, of course, possess many advantages in other respects.

Accurate time scales can be obtained by a variety of methods. Perhaps the most obvious is to place a stationary arc in the camera field of view. "Point" arc light sources similar to that supplied by Central Scientific Company can be controlled by an amplified electrical signal that has been generated by a tuning fork. When a camera slit is used, as for the modified method of streak photography described below, it is convenient to reflect the light from a "Strobolux" (General Radio Company) into the slit so that timing lines are formed at regular intervals. Some oscillographic cameras use spark discharges that expose the film adjacent to the spark. Others have an intermittent light source internal to the camera and focused on the film. Rotating drum cameras may have their film speeds determined simply by measuring the rotational speed of the drum. Generally, little difficulty is encountered in obtaining a precise time scale even if the film speed is non-uniform.

MODIFIED STREAK PHOTOGRAPHY

A source of error in the ordinary method of streak photography lies in the possibility of small motions of the object in a direction parallel to the film motion. In order to eliminate this error, to measure large displacements (4 or 5 inches), and to obtain an accuracy within a few thousandths of an inch, a modified method of streak photography was devised. The principles of this method are shown in Fig. 2. In this figure the object consists of a series of bright lines on a dark background. The lines are contained in a plane parallel to the direction of the film motion. The direction of motion of the object, which is rigidly attached to the part whose motion is being studied, should be perpendicular to the camera optic axis and to the direction of film motion. The camera lens will focus an image of these lines on the film. A slit and a cylindrical lens (the lens is optional) placed near the film focuses the line to an approximate point. Motions of the object in a direction parallel to the film motion will not result in any displacement of the image on the film. Small rotations in a plane perpendicular to the camera axis will produce second-order errors, and motions out of this plane will result in the usual scale changes and depth of focus problems. Such an arrangement, used at the Naval Research Laboratory, had an object that consisted of a grid of music wire; the wires of which were about 0.01 of an inch in diameter and were spaced 0.200

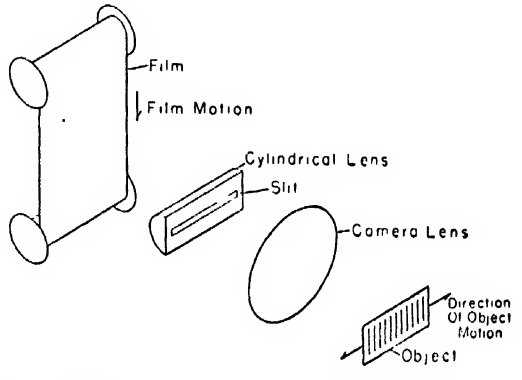

FIG. 2. Principal parts used for the modified method of streak photography. The slit should be near to the film compared with the film-lens distance.

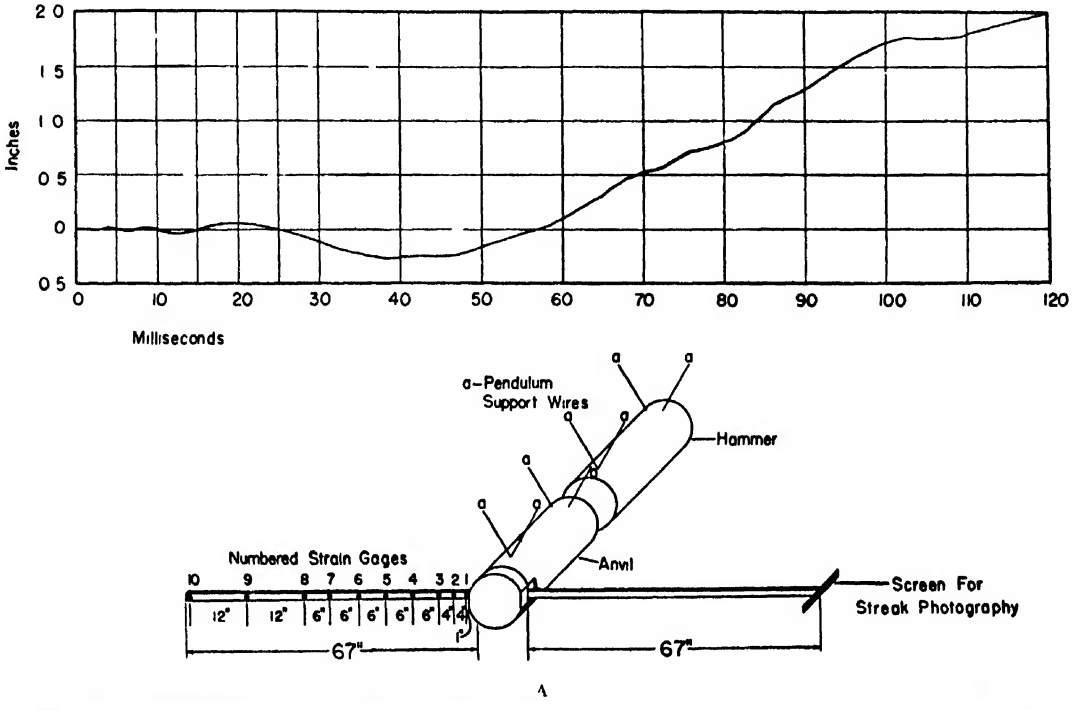
[2] A. Victor Masket, "The measurement of forces resisting armor penetration," J. App. Phys. **20**, 132–140 (February, 1949).

of an inch apart in narrow grooves that were machined in a black Bakelite base. The object was varnished so as to cement the wire in position. The use of a wire for the modified method of streak photography is analogous to the use of a ball for the ordinary method and makes possible a very fine line image. Reasonably good results were also obtained by simply filling sharp machined scratches with white ink in a similar Bakelite base. A convenient camera arrangement consists of a 2-inch focal length lens attached to a moving film oscillograph camera (General Radio GR 651A-E). An extension tube was usually used that held the lens about 9 inches from the film. This arrangement caused the object to be enlarged about 4 times in linear dimensions and the image of 2 object wires could be seen on the 35-mm film when one image was near the edge of the film. This fixed the displacement scale on the film. A cylindrical lens was cemented over a $\frac{1}{16}$-inch wide slit which replaced the



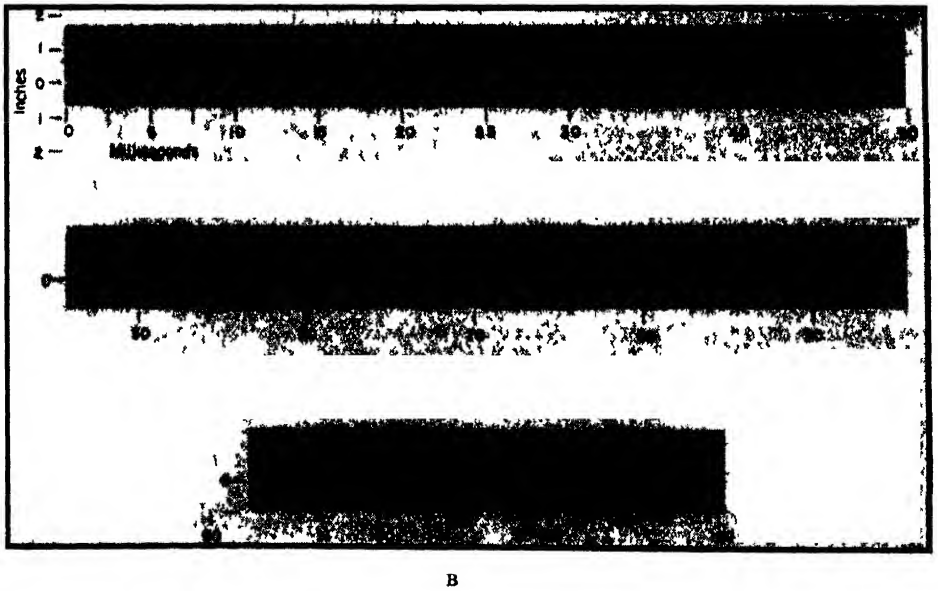


FIG 3. Displacement curves obtained by streak photography. The upper curve was derived from the photographic record shown on part B of the figure.

ordinary film gate. Fair pictures may be had with a $\frac{1}{32}$-inch slit and no cylindrical lens. When wires were used for the grid lines the best results were obtained with a small source of illumination, such as a laboratory arc with a focusing lens. The light must of course be in a plane perpendicular to the grid lines and containing the lens optic axis. Sufficient illumination is easily obtained for writing speeds up to 11 ft./sec.

Figure 3 illustrates this method as used to determine the motion of the free end of a cantilever beam when the built-in end suddenly acquires and maintains a uniform velocity. The experimental arrangement is shown in the center part of this figure. The hammer strikes the anvil

FIG. 4 An instrument shock testing machine with attached grid for streak photography.

and imparts a velocity to the anvil that remains essentially constant for the duration of the experiment. The velocity is in the direction of the anvil axis and the displacement is measured in this direction. A reproduction of the streak photograph is shown on the lower part of Fig. 3. The displacement scale is determined by the vertical separation of lines which represents 0.2 inch on the object. A continuous displacement curve, such as is shown on the upper part of this figure results from

FIG 5 Streak photograph illustrating the motion of the platform of the instrument shock testing machine.

joining together the various curves, shown on the lower section, with proper multiples of the 0.2-inch vertical separation.

Figures 4 and 5 show the application of the modified method of streak photography for the determination of the motions of a shock testing mechanism. As shown on Fig. 4 a small platform falls on a stiff spring and rebounds. The vertical motion of this platform is shown through the impact time in Fig. 5. The object grid in this case consisted of white inked grooves that were machined at 0.2-inch intervals.

SUMMARY AND CONCLUSIONS

Ordinary streak photography which consists of photographing a moving object on a moving film shutterless camera is a convenient and accurate method of obtaining displacement curves as a function of time provided the direction of motion studied is previously known and is unidirectional. When there are components of motion, which result in image displacements parallel to the motion of the recording film, a modified method of streak photography must be used. In this method a small rigid body is attached to the object whose motion is being studied. One or more parallel lines, which are made perpendicular to the principal component of motion and which are contained in the focal plane of the camera, are scribed on this body. The image of these lines on the camera film is cut to an approximate point by introducing a slit near the film or by introducing a slit and cylindrical lens a short distance from the film. By the above method transient displacements of many inches can be measured to an accuracy within a few thousandths of an inch. The time scale can easily be extended to more than a second with an accuracy up to about 10 microseconds.

Surface Tension Effects in Oriented Thin Silver Films*

G. W. JOHNSON†
Department of Physics, State College of Washington, Pullman, Washington
(Received November 7, 1949)

Structural changes of thin oriented films of silver produced by condensation in a vacuum on cleaved surfaces of single crystals of rocksalt were followed as a function of temperature. Marked agglomeration occurred in films of thicknesses less than 1000A. For thicker films in the 1000–2000A range rectangular holes appeared in the films with their edges aligned with the 110 directions of the rocksalt. The effects are attributed to the readjustment of the oriented surface under the influence of surface tension forces.

THE behavior of thin films of silver condensed in a vacuum on various substrates has been the subject of numerous investigations. A large number of these investigations have been concerned with the measurement of the electrical resistivity and its temperature dependence. The general features of all of the resistance measurements have been discussed by Appleyard.[1] There are two principal results common to all of the resistance measurements. The first is that the resistivity of thin films is greater by factors of 10^3 to 10^7 than that of the bulk metal. The second is the irreversible increase of resistance with increase of temperature. Moreover, for films of a given thickness the resistivity is greater the higher the temperature of the substrate at the time of deposition. These observations led to the view that the film as deposited has a granular structure which is a result of the agglomeration of the metal under the surface tension forces. That such agglomeration occurs has been shown directly by the work of Estermann,[2] and by that of Andrade and Martindale.[3] Recent photographs made with the electron microscope clearly reveal the grained structure of thin metallic films.[4] The energetics and proposed mechanisms of aggregation are given by Appleyard and by Lennard-Jones.[5] It was suggested that aggregation occurs if the attractive forces between the condensed metallic atoms is greater than the forces between the metallic atoms and those of the substrate. The tendency to aggregation is opposed by the periodic field of the surface and aggregation can only occur if the rate of surface diffusion at the given temperature is great enough. It is apparent that an increase of temperature will favor the tendency to aggregation since higher temperature results in more rapid diffusion rates.

In the present work the structural changes of oriented thin films of silver all condensed on rocksalt at 200°C were followed as they were heat-treated subsequently at higher temperature. The films were produced by vacuum distillation of silver on freshly cleaved crystals of rocksalt preheated to about 200 C in accordance with well-known techniques.[6] Wilman and Goche[7] in a detailed study of the structure of such films showed them to possess a twinned structure as grown but heat-treatment at 500 C for a few minutes converted them to relatively perfect single crystals.

EXPERIMENTAL METHOD

The method of Lassen and Bruck was used to produce thin oriented films of silver. A single crystal of rocksalt was cleaved and was introduced into the tube which was immediately evacuated. At a pressure of less than 0.01 micron and after preheating the rocksalt crystals to about 200 C, spectroscopically pure silver was vaporized from a tungsten filament and condensed on the rocksalt. The vacuum chamber was designed to permit the introduction of five cleaved crystals with dimensions of about 4×4 mm. The crystals were supported on a glass slide movable at will beneath the vaporizer by means of an external magnet. This arrangement made it possible to vary the exposure to the beam of silver. By using different exposure times the film thickness could be varied for the same heating current and for the same geometry.

The films thus produced were examined under vertical illumination with both bright field and polarized light (crossed nicols) using a Bausch and Lomb metallograph. For the films used in this work it was found in general that polarized lighting was more effective in revealing the structure than was bright field illumination. Accordingly most of the photo-micrographs herein reproduced were made under polarized illumination. The electron diffraction attachment of an RCA electron microscope was used to determine the orientation of the films.

After inspection, the films still supported on the rocksalt substrate were introduced into a vacuum furnace for heat-treatment. The films were heated to various temperatures in the range of 300–500 C for times of from two to twelve hours. After each such

treatment the films were examined optically to note any changes in structure. The nominal film thicknesses were calculated from a chemical determination of the silver, using a colorimetric method, the apparent area of the film, and the bulk density. The nominal thickness is the thickness a film would have if it were uniformly distributed in depth over the surface.

RESULTS

Films were prepared in thicknesses extending from 100A to about 4000A. All were heat-treated in a vacuum (less than 0.01 micron) at temperatures between 200 C, the temperature at which they were grown, and 530 C. Above 500 C the rocksalt vaporized profusely with the result that the films were ultimately detached from the substrate and destroyed. It was found that the behavior of the films depended strongly on their thickness as might have been anticipated. For this reason it is convenient to discuss the results in terms of four different ranges of thickness as indicated in the following. All of the films to be described gave diffraction patterns characteristic of single crystals. All photographs reproduced here were made with the cube edges (100 directions) of the rocksalt parallel to the edges of the photographs.

100–500A.—Typical structures of films of this thickness are shown in Fig. 1. These films are noted to have a granular appearance. At higher magnification they are found to possess a network structure which is characteristic of these films and has been observed and reported by many investigators. Recent papers by Levinstein[4] with indium and antimony, and by Picard and Duffendack[4] with aluminum, gold, and copper for unoriented metallic films deposited on collodion, include photo-micrographs of the network structure obtained with an electron microscope. In their work the aggregation of metal into local regions separated by thinner regions or canals is clearly shown. The thinnest films in this thickness range were non-conducting as was indicated when attempts were made to get electron diffraction patterns. Under such conditions it is impossible to get a diffraction pattern because the beam drifts about capriciously as local regions acquire or lose electric charge. The granular structure may be seen on the film as deposited (Fig. 1a). In this case the individual grains are of the order of 1 micron in diameter and on the photo-micrograph (500×) are about 1 mm in diameter. However, the structure becomes accentuated with heat-treatment for a few hours at 320 C (Fig. 1b). There was little observable change in the films on heat-treatment at higher temperatures until a temperature of 500 C was reached, at which point the aggregation of the film became marked (Fig. 1e).

Occasionally the silver as deposited showed a preference for cleavage lines on the crystal. As the temperature was raised the lines faded out. These effects are illustrated in Figs. 1a and 1b which are photographs of the same area before and after heat-treatment.

500–1000A.—The structures observed in this thickness range and their change with temperature can be seen in Fig. 2. The films as deposited resembled those of the thinner range but their changes with temperature are different. On heating to 320 C for four hours the network structure became plainer, with some indication of agglomeration. After heat-treatment at 400 C the

network structure practically disappeared and the silver had collected into relatively large aggregations. At 475 C in some of the films the silver collected along cleavage lines to form ridges and also in small stubby rods extending normal to the surface. The protuberances of silver, whether along cleavage lines or in isolated regions, seemed to grow to about the same height above the crystal surface. The height of growth was about 0.001 mm and was measured by noting the movement of the microscope objective to bring into focus alternately the tops of the growths and the surface of the film.

1000–1500A.—While films of thickness less than 1000A all underwent some adjustment on heating to 320 C, films of greater thickness did not change in appearance until the temperature was increased at least to 400 C. In this thickness range the thinner films on heating to 420 C for four hours were perforated by approximately rectangular windows with the edges aligned with the (110) directions of the rocksalt. The holes were uniformly distributed and were all about the same size within perhaps a factor of two. On increasing the temperature to 450 C the holes increased in size by some 20 percent which was accompanied by the addition of spurs in some cases resulting in changes in shape. In Figs. 3a and 3b are shown some typical holes and also their growth with temperature. Both 3a and 3b were made under bright field illumination and are of the same area of the film. Figure 3c is the same area under polarized light. In this latter photograph the advantage of polarized light for revealing the granular structure is clearly seen, for while the holes are outlined under both bright field and polarized light, the granular structure is only shown under polarized light. For thicker films in this region the rectangular holes appeared also but their density was not as great and the film in general retained its continuity (Figs. 3d and 3e). Further examples of the holes and their growth are shown in Figs. 4a and 4b. Of interest in these photographs is the growth of serrations or steps from a scratch in the film. In Figs. 4c and 4d are shown holes in the neighborhood of a cleaved edge of rocksalt to show the relative orientation of the holes with respect to the (100) directions of the rocksalt. The preference of the straight edges of the windows for the face diagonal directions is clearly illustrated. The density of the windows decreases as a scratch or a free edge is approached. It is of interest also to note that the windows or parts thereof seem to develop from such free edges. (See scratch in Fig. 4b.)

1500–2000A.—Films of this thickness were quite stable and did not show any marked structural changes until heated to 480 C, whereupon the films were found to be criss-crossed by systems of straight lines spaced about 1 micron apart and directed along the (110) directions of the rocksalt. The lines became more pronounced on further heating at 520 C until finally the films disintegrated. Windows sometimes appeared in the form of crosses or rectangular openings with serrated edges. The serrations appeared to have magnitudes corresponding

to the observed spacing of the lines covering the entire film. These effects are all shown in Fig. 5. On the original photo-micrographs could be seen systems of faint straight lines running along the face diagonals of the rocksalt.

Above 2000A.—Films thicker than 2000A did not undergo any pronounced structural changes with heat-treatment until they disintegrated after heating to 520 C for eight hours. The heaviest film studied was about 4000A in thickness.

GENERAL OBSERVATIONS

All of the films as deposited gave bright specular reflections. The mirror surfaces were maintained until marked agglomeration occurred or until holes formed in the films at which point the films assumed a matte appearance.

On high rates of deposition the silver would occasionally collect in globules along lines of conchoidal fracture on the cleaved surface of the rocksalt. This effect is illustrated in Fig. 6a.

By exposing the films to a moist atmosphere small sodium chloride crystals could be produced on top of the silver. Such crystals were found to grow over a period of a few months while the films were being stored in a calcium chloride desiccator. They can be readily produced by breathing lightly on a film supported on rocksalt. In Figs. 6b and 6c are shown some of these small crystals. In this case the salt crystals are all aligned with edges parallel to the 110 direction of the substrate and also along the 110 direction of the silver, although often they are rotated 45° with respect to this direction. In the lower right-hand corner of Fig. 6b may be noted one crystallite rotated 45° with respect to the others. These two orientations were the only ones observed on any of the films. Since the silver as deposited was oriented with its structure parallel to that of the rocksalt, then the same relative orientation would be expected if sodium chloride were deposited on silver. The salt on silver should then have the same orientation as the underlying substrate. In the photographs the 100 directions of the rocksalt substrate are parallel to the edges of the photograph. If we assume that the cube edges of the sodium chloride crystallites are the 100 directions then the crystallites are rotated 45° with respect to the expected orientation. This orientation is consistent with that reported by Brück and confirmed by Goche and Wilman for films which were not thoroughly rinsed diffraction points were observed and were attributed to sodium chloride retained on the film with the same orientation as was found here.

To determine whether the epitaxy noted in the foregoing for sodium chloride on an oriented silver film was the result of an influence exerted by the substrate through small pores, a film was floated off the rocksalt in water and picked up on a degreased silver plate.[8] After drying, the film was rinsed in a saturated aqueous solution of sodium chloride and quickly dried. Small crystals of sodium chloride were thus produced on the silver film. Examination under the microscope showed the crystallites to be aligned and with the same orientation as was observed for the films on the rocksalt substrate (Fig. 7). This result is of interest in that it gives a ready means of getting a rough check on the degree of orientation of a

film without resorting to electron diffraction. Indeed, it may be more sensitive to the orientation in the first layer since the surface forces are probably of short range.

DISCUSSION

The network or granular structure which was observed for the thinner films is characteristic of such films and is well-understood. The metal as deposited agglomerates into small regions under the influence of surface tension forces which for very thin films may be very great. On increasing the temperature further agglomeration may take place. In the present work this effect is noted in the thinnest films where the network structure is accentuated as the temperature is increased and finally the film breaks into small isolated agglomerated regions.

As the film thickness is increased the adjustment of the surface under the effects of the surface tension forces are not as drastic. For films of intermediate thickness this leads to the formation of holes which are evenly distributed and have sides parallel to the 110 direction of the rocksalt. The origin of the holes is suggested in the following. The silver film has the same orientation as the rocksalt and therefore the lines of closest packing of silver atoms are in directions parallel to the face diagonals of the rocksalt. These directions are therefore directions along which the binding between silver atoms is greatest. As the temperature is raised the film is put under increasing tension as a result of the greater thermal expansion of the rocksalt than that of the silver. At some temperature, depending upon the film thickness, the film fails and since it apparently fails along lines of closest packing the process of failure must be one of shear. The surface tension forces then cause the film to contract further. The difference between the coefficients of expansion can only account for about 1 percent total strain. Since the holes are much larger than this, one concludes that the primary cause of growth of the holes lies with the surface tension forces. The holes continue to grow somewhat with increase of temperature. For the thickest films (1500–2000A) the surface tension forces are not sufficiently great to cause large changes in the surface. The film is strained enough, however, to lead to rupture or local yielding sufficient to be visible under the microscope. The lines broaden on further heating indicating an extension of the rupture process but also indicating the films are sufficiently thick to resist any large scale readjustment to the surface tension forces.

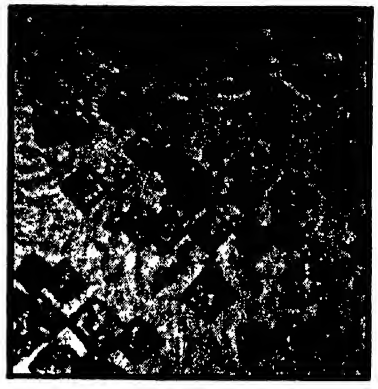

FIG. 7. Sodium Chloride Crystals deposited from an aqueous solution on an oriented silver film supported on a silver plate 400×.

Essig[9] noted in one case the formation of regular holes in a silver film condensed on mica. The windows were bounded by lines intersecting at 60° and 120°. The explanation of the origin of these holes must be similar to that given here for rectangular holes. The silver for the conditions used by Essig must have condensed with the 111 plane parallel to the surface. For this orientation there are three lines of densest packing of atoms in the plane of the surface and they intersect at 120°. Thus when failure occurs if it were by a shearing process it would be expected to take place along lines of closest packing, in which case the windows would have straight sides intersecting at the observed angles. Since the relative orientation of the silver relative to the mica was not determined, it is not known whether the orientations would be consistent with the picture postulated here. However, there appears to be little question about the general description of the result.

Upper and Lower Bounds of Eigenvalues for Composite-Type Regions

E. L. Chu
Microwave Laboratory, Stanford University, California
(Received October 21, 1949)

A survey is made to compare the essential features of different variational methods. Schwinger's method is found to have special merits for boundary value and eigenvalue problems concerning composite-type regions. It can give both an upper bound and a lower bound for the eigenvalue of any mode, one bound being as good as the other. It closely resembles the Courant-Trefftz method and is simpler. In both methods the trial functions are so chosen as to satisfy the differential equation while the boundary or continuity conditions are perturbed. The applicability and power of Schwinger's method, being hitherto demonstrated only for particular examples, are exhibited for a whole class of problems by a general formulation of the method in precise terms. The formulation for the upper-bound case presents no difficulty, and a simple proof is given in this paper. A similar proof for the lower-bound case is possible but has a more restricted field of application. The general formulation places the two different cases on equal footing. A way of avoiding the difficulty of having no exact knowledge of the lower eigenfunctions in higher mode cases is discussed in detail.

I. SURVEY OF METHODS

THE best-known variational method of Rayleigh[1]-Ritz[2] has the great drawback of giving only an upper bound for the true eigenvalue with no information about the accuracy of the bound. One is usually content to indicate the degree of accuracy obtainable by applying the method to problems which can be solved exactly and comparing the approximate value with the true one. This is not quite satisfactory, because the examples chosen may happen to be particularly favorable. Besides, the minimizing process of Ritz is somewhat involved especially for high orders of approximation or for higher modes. There have been recommended, notably by Galerkin,[3] some modifications of the Ritz method, in which the minimizing process is simplified. Yet, the character of overestimation remains the same.

Weinstein[4] has devised an ingenious method which is capable of giving both an upper and a lower bound for the eigenvalue for any one mode. It is rather unfortunate that the expression to be minimized is somewhat complicated, being the difference between a certain integral and the square of another, and the evaluation of one of these integrals is considerably more difficult than that of the Rayleigh-Ritz expression. To facilitate the evaluation of the integrals, only simple trial functions can be used, thus limiting the accuracy of the process. Though interesting and attractive, this method has not been used much in practice.

The suggestion that a lower bound for the eigenvalue can be obtained by calculating the stationary value of the variational expression under loosened boundary conditions or loosened conditions of continuity was first made by Courant.[5] The value calculated must be stationary with respect to small arbitrary variations for otherwise it may not be a lower bound. How this can be done was first shown by Trefftz.[6] Unlike the Rayleigh-Ritz method, the trial functions used by Trefftz satisfy the differential equation but are subject to less restrictive boundary and continuity conditions. The Courant-Trefftz method may be considered as the counterpart of the Rayleigh-Ritz method, because the requirements on the trial functions for these two methods are just opposite to each other. In view of the elegance and the wide applicability of the Courant-Trefftz method, it seems desirable to give here a brief account of its application.

Consider the Sturm-Liouville differential equation for two independent variables x and y:

$$L[u]+\lambda\rho u=(pu_x)_x+(pu_y)_y-qu+\lambda\rho u=0, \quad (p>0,\ \rho>0), \quad (1)$$

for a region R with boundary Γ.[7] The boundary condition is given as $u=f(s)$. According to Trefftz, the problem is to be modified by replacing the given boundary condition $u=f(s)$ with a set of weaker ones:

$$\int_\Gamma \{w-f(s)\}g_i(s)ds=0, \quad i=1, 2, \cdots, m,$$

where $g_i(s)$ are arbitrary functions chosen in such a way that the differential equation $L[w]+\mu\rho w=0$ can be solved exactly. As in the Rayleigh-Ritz method, the function w that corresponds to the lowest eigenvalue μ will minimize the expression

$$D[w]=\int_R\int p(w_x^2+w_y^2)dxdy+\int_R\int qw^2dxdy, \quad (2)$$

but under a set of modified boundary conditions. The

[7] In Eq. (1), p, q, and ρ are functions of x and y while λ is a constant. $p>0$ and $\rho>0$ in R. $L[u]=(pu_x)_x+(pu_y)_y-qu$ is simply a definition.

normalization relation

$$\int_R\int \rho w^2 dxdy = 1$$

is understood.

Since the modified conditions are weaker than the given condition, that is, the set of compatible functions for w contains the set of functions for u, so the minimum value of $D[w]$ can never be greater than that of $D[u]$. Thus $\mu \leqq \lambda$, μ, and λ are the minimum values of $D[w]$ and $D[u]$, respectively.

The modified problem is the same as that of finding a function w for which the following functional $I[w]$ is stationary:

$$I[w] = D[w] - \mu\int_R\int \rho w^2 dxdy - 2\sum_1^m c_i \int_\Gamma \{w - f(s)\} g_i(s) ds, \quad (3)$$

where c_i's are Lagrangian multipliers. This can be shown by putting the first variation of $I(w)$ equal to zero, to obtain

$$\int_R\int \{L[w] + \mu\rho w\}\delta w dxdy - \int_\Gamma \left\{p\frac{\partial w}{\partial n} - \sum_1^m c_i g_i(s)\right\}\delta w ds = 0.$$

The volume integral vanishes if w satisfies the equation $L[w] + \mu\rho w = 0$. The surface integral will also vanish for any arbitrary δw if

$$p\frac{\partial w}{\partial n} = \sum_1^m c_i g_i(s)$$

on Γ. These requirements on w can be fulfilled if w is taken as

$$w = \sum_1^m c_i w_i(x, y)$$

and $g_i(s)$ as

$$g_i(s) = p(\partial w_i(x, y)/\partial n),$$

where the w_i's are any m particular solutions of the differential equation $L[w] + \mu\rho w = 0$.

The $m+1$ constants, μ and the c_i's, are to be determined from $m+1$ simultaneous equations, m of which are the above boundary conditions while the other one is the normalizing relation. As shown above, μ is a lower bound for λ.

The lower bound may be improved by imposing more stringent boundary conditions. In fact, as m approaches infinity, w may be made to approach the true eigenfunction. Thus μ will approach λ. In some cases it is desirable not to relax the boundary conditions but the conditions of continuity. Such cases have also been considered by Trefftz.

In passing, we may remark that the Trefftz method can also be used for calculating upper bounds. What we have to do is simply to make the boundary conditions more stringent than given in the original problem. However, there would be no advantage to do so even where the trial functions can be easily chosen, because the algebraic process of the Trefftz method is still more involved than that of Ritz.

One method other than Ritz's for calculating upper bounds needs special mentioning. This was described by Grammel[8] and may be considered as the counterpart of Ritz's method or rather that of Galerkin's method, from the viewpoint that this method is more intimately connected with the integral equation rather than with the differential equation.

To be specific, if the differential and integral equations for the same problem are given as $L[u] + \lambda\rho u = 0$ and

$$u(x, y) = \lambda\int_R\int G(x, y; x', y'; 0) \times u(x', y')\rho(x', y')dx'dy' \quad (4)$$

respectively, where $G(x, y; x', y'; 0)$ is the appropriate Green's function of the equation $L[u] = 0$, then the Grammel method deals with the equation

$$\int_R\int \left[w(x, y) - \lambda\int_R\int G(x, y; x', y'; 0)w(x', y') \times \rho(x', y')dx'dy'\right]\rho(x, y)\delta w dxdy = 0 \quad (5)$$

while Galerkin's method deals with

$$\int_R\int \{L[w] + \lambda\rho w\}\delta w dxdy = 0. \quad (6)$$

In both methods we take

$$w(x, y) = \sum_1^m c_i\phi_i(x, y) \quad (7)$$

as the trial function. The functions ϕ_i are any suitable coordinate functions satisfying the appropriate boundary conditions of the problem. We restrict ourselves only to such variations as

$$\delta w = \sum_1^m \phi_i(x, y)\delta c_i.$$

The variational problem is then reduced to the solution

[8] R. Grammel, Proc. 5th Intern. Congress for App. Mech. 691–693 (1938); also Biezeno-Grammel, reference 3.

of m simultaneous equations. They are

$$\sum_1^m c_i \int_R\int\Big[\phi_i(x,y)-\lambda\int_R\int G(x,y;x',y';0)\times\phi_i(x',y')\rho(x',y')dx'dy'\Big]\times\phi_k(x,y)\rho(x,y)dxdy=0,\quad k=1,2,\cdots,m \quad (8)$$

in Grammel's method and

$$\sum_1^m c_i\int\int\{L[\phi_i]+\lambda\rho\phi_i\}\phi_k dxdy=0,\quad k=1,2,\cdots,m \quad (9)$$

in Galerkin's.

The former set of equations appear to be more formidable but actually they are more tractable and easier for calculation than the latter set. This is due to the fact that the choice of ϕ_i's in Grammel's method is always easier than in Galerkin's, because, there, no differentiations on ϕ_i's are involved. If the same expression, i.e., the same linear combination of the same ϕ_i's is used as the trial function for both cases, Grammel has shown that the upper bound calculated by his method is always lower than that calculated by Galerkin's or Ritz's method, the latter two giving exactly the same value.

In some cases we do not even need to know the explicit expression of the Green's function for carrying out the Grammel process. It is usually possible to transform the double integral into a single one

$$\int_R\int\phi_k(x,y)\rho(x,y)dxdy\times\int_R\int G(x,y;x',y';0)\phi_i(x',y')\rho(x',y')dx'dy'=\int_R\int\frac{M(\phi_i,\rho)\cdot M(\phi_k,\rho)}{\alpha(x,y)}dxdy,$$

where M and α can in some cases be easily recognized as known physical quantities.[9] Thus, the set of simultaneous equations may be reduced to

$$\sum_1^m c_i\Big[\int_R\int\phi_i\phi_k\rho dxdy-\lambda\int_R\int\frac{M(\phi_i,\rho)\cdot M(\phi_k,\rho)}{\alpha}dxdy\Big]=0,\quad k=1,2,\cdots,m.$$

[9] For example, M may represent the bending moment in dynamics, then α will be the modulus of rigidity. See R. Grammel and Biezeno-Grammel, references 3 and 8.

In all the methods discussed so far, we need to set up a set of simultaneous equations and to solve them. The process is usually lengthy and difficult. Besides, the accuracy for higher modes is much worse than for the fundamental, because the values for different modes all come out of the same set of equations. No use has been made of the fact that a given eigenfunction is orthogonal to all the lower ones.

If we know approximately the first $n-1$ eigenfunctions, the knowledge can be put into immediate use for calculating the lower bound for the next higher eigenvalue by the help of the so-called maximum-minimum-property of the eigenvalues.[10] We first consider the problem with the original boundary condition $u=f(s)$ but the loosened orthogonality relations

$$\int_R\int w\cdot v_i\rho dxdy=0,\quad i=1,2,\cdots,n-1,$$

where w is the trial function and v_i's are the first $n-1$ approximate eigenfunctions. The would-be eigenvalue for this perturbed problem will be less than the true value on account of its maximum-minimum-property. Then if we also loosen the boundary condition in a similar way as in Trefftz's method, the calculated value will be still lower than the would-be eigenvalue. The more we know about the v_i's, the better will be the calculated lower bound. However, the process is not quite so simple as briefly described above and cannot be applied for calculating upper bounds.

From the above discussion, it is to be expected that some modification of the Courant-Trefftz method formulated on the basis of the integral equation will have the merit of being both simple and flexible. In fact, such has already been furnished by Schwinger.[11] His method for calculating both upper and lower bounds proves to be very successful. It embodies Courant's idea of perturbing boundary conditions and looks like Grammel's method in using an integral equation.

Schwinger has only worked on boundary value problems, while his method can be used for the calculation of eigenvalues as well. We have done some calculations by his method on the resonant frequency of a disk-loaded cavity and have described in a previous paper[12] our results and how we proceeded with our calculations. We have explained how this method can give an upper bound in one type of calculation and a lower bound in another, one being almost as good as the other.

Despite the stringent condition that the trial functions are to satisfy the differential equation, the method can be applied to quite a large number of important physical problems. It is particularly useful for those

[10] For a proof of the property, see Courant u. Hilbert, *Methoden der Mathematischen Physik* (Verlag. Julius Springer, Berlin, 1931), Vol. I, p. 351–353.

[11] J. Schwinger, "Discontinuities in wave guides" (lecture notes prepared by D. S. Saxon).

[12] E. L. Chu and W. W. Hansen, J. App. Phys. 20, 280–285 (1949).

problems concerning composite-type regions. A region is called composite, if it can be divided by simple surfaces into two or more regions, in each of which the problem can be exactly solved once we impose simple enough conditions on those dividing surfaces. The disk-loaded cavity, which we have considered, is one example.

To facilitate further discussions, it is desirable to give a brief summary of the method in simple concise terms. We take $G(x, y; x', y'; \lambda)$ as the Green's function of the differential equation $L[u]+\lambda\rho u=0$, such that either

$$G=0 \text{ on } \Gamma \tag{10a}$$

or

$$\partial G/\partial n=0 \text{ on } \Gamma. \tag{10b}$$

The integral equation to be solved will be either

$$\frac{\partial u}{\partial n}(s)=-\sigma u(s)=-\int_\Gamma pu\frac{\partial}{\partial n}\frac{\partial G(\lambda)}{\partial n'}ds' \tag{11a}$$

or

$$u(s)=-\frac{1}{\sigma}\frac{\partial u}{\partial n}(s)=\int_\Gamma pG(\lambda)\frac{\partial u}{\partial n'}ds' \tag{11b}$$

as the case may be. $\sigma=-(1/u)(\partial u/\partial n)$ is known as given boundary condition and is usually a piecewise continuous function of s. These equations are not exactly soluble, so we perturb the problem and solve $L[w]+\mu\rho w=0$ with boundary values related by

$$\frac{\partial w}{\partial n}(s)=-\xi w(s)=-\int_\Gamma pw\frac{\partial}{\partial n}\frac{\partial G(\mu)}{\partial n'}ds' \tag{12a}$$

or

$$w(s)=-\frac{1}{\xi}\frac{\partial w}{\partial n}(s)=\int_\Gamma pG(\mu)\frac{\partial w}{\partial n'}ds', \tag{12b}$$

where ξ may be left undefined or chosen properly. If we demand

$$\int pw\frac{\partial w}{\partial n}ds=\int_\Gamma p\frac{\partial u}{\partial n}\cdot\frac{w^2}{u}ds$$

or

$$\int pw\frac{\partial w}{\partial n}ds=\int_\Gamma p\frac{u}{\partial u/\partial n}\cdot\left(\frac{\partial w}{\partial n}\right)^2ds,$$

we obtain

$$\int_\Gamma p\frac{\partial u}{\partial n}\frac{w^2}{u}ds=-\int_\Gamma pwds\int_\Gamma pw\frac{\partial}{\partial n}\frac{\partial G(\mu)}{\partial n'}ds' \tag{13a}$$

or

$$\int_\Gamma p\frac{u}{\partial u/\partial n}\left(\frac{\partial w}{\partial n}\right)^2ds=\int_\Gamma p\frac{\partial w}{\partial n}ds\int pG(\mu)\frac{\partial w}{\partial n'}ds'. \tag{13b}$$

By assuming certain functions for $w(s)$ or $(\partial w/\partial n)(s)$, we can calculate μ from (13a) or (13b) respectively. In both types of calculation we may approach the limiting case $w=u$ and $\mu=\lambda$ as far as may be desired.

The value calculated is only an approximation to the true eigenvalue. The accuracy depends on how we perturb the boundary condition, that is, how we choose w. If we have a good approximate knowledge about u to start with, we may be able to get a very accurate value by a single trial without dealing with the simultaneous equations or solving a determinantal one.

Whether the calculated value is an upper or a lower bound depends on whether we have strengthened or weakened the supplementary conditions of the problem. Except for very simple cases, the distinction between a stringent and a weak condition is not quite obvious. Even where we are sure we have weakened the supplementary conditions, the existence of a lower bound depends on a further condition that the calculated value should be stationary with respect to any small variation in all the admissible trial functions. In the simple process described above we have not gone through such variational considerations.

Schwinger has discussed such questions on boundary value problems. He has shown that his variational expressions possess the property of being definite. Yet, further justifications are necessary in order to formulate some general rules for the calculation of eigenvalues. It is the purpose of this paper to concern ourselves with such justifications.

II. THE FUNDAMENTAL MODE

Let λ_1 and u_1 be the lowest eigenvalue and the corresponding eigenfunction for the Sturm-Liouville differential Eq. (1). u_1 will have no zeros in the region R. It is to be found by minimizing the expression

$$J[u]=D[u]+\int_\Gamma p\sigma u^2ds, \tag{14}$$

where $D[u]$ is as given in Eq. (2), under the boundary condition that $u=0$ at least on that part of Γ where u_1 is zero, and also under the normalizing condition

$$\int_R\int\rho u^2dxdy=1.$$

u should be continuous and have piecewise continuous first derivatives in R, but is otherwise arbitrary. σ is any given piecewise continuous function of coordinates on Γ, such that

$$(\partial u_1/\partial n)+\sigma u_1=0 \text{ on } \Gamma. \tag{15}$$

The expression to be minimized may be written as

$$J[u]=D[u]-\int_\Gamma p\frac{u^2}{u_1}\frac{\partial u_1}{\partial n}ds. \tag{16}$$

This is sensible because $u=0$ wherever $u_1=0$ on Γ. The expression (16) may be transformed by Green's theorem, to obtain

$$D[u]-\int_\Gamma p\frac{u^2}{u_1}\frac{\partial u_1}{\partial n}ds$$
$$=D[u]-D\left[u_1,\frac{u^2}{u_1}\right]-\int_R\int\frac{u^2}{u_1}L[u_1]dxdy,$$

where

$$D[u, v]=\int_R\int p(u_xv_x+u_yv_y)dxdy+\int_R\int quvdxdy.$$

Thus

$$D[u]-\int_\Gamma p\frac{u^2}{u_1}\frac{\partial u_1}{\partial n}ds=\int_R\int \frac{p}{u_1^2}(u_1\nabla u-u\nabla u_1)^2dxdy - \int_R\int \frac{u^2}{u_1}L[u_1]dxdy.$$

Since

$$L[u_1]+\lambda_1\rho u_1=0,$$

we get

$$D[u]-\int_\Gamma p\frac{u^2}{u_1}\frac{\partial u_1}{\partial n}ds = \int_R\int \frac{p}{u_1^2}(u_1\nabla u-u\nabla u_1)^2dxdy + \lambda_1\int_R\int \rho u^2dxdy. \quad (17)$$

In carrying out the above transformation, it is tacitly assumed that u has first derivatives everywhere in R. If not, we may consider R as being composed of several regions in each of which u is everywhere differentiable. Equation (17) brings out the variational principle explicitly in view. It states that λ_1 is the minimum value of $J[u]$ for any admissible u that is properly normalized, because

$$\int_R\int \frac{p}{u_1^2}(u_1\nabla u-u\nabla u_1)^2dxdy\geqq 0.$$

Now we restrict ourselves to use only those trial functions which satisfy the differential equation $L[u]+\lambda\rho u=0$. From (17) and

$$D[u]=-\int_R\int uL[u]dxdy+\int_\Gamma pu\frac{\partial u}{\partial n}ds = \lambda\int_R\int \rho u^2dxdy+\int_\Gamma pu\frac{\partial u}{\partial n}ds,$$

we obtain

$$\int_\Gamma pu\frac{\partial u}{\partial n}ds-\int_\Gamma p\frac{u^2}{u_1}\frac{\partial u_1}{\partial n}ds = \int_R\int \frac{p}{u_1^2}(u_1\nabla u-u\nabla u_1)^2dxdy - (\lambda-\lambda_1)\int_R\int \rho u^2dxdy. \quad (18)$$

If we demand

$$\int_\Gamma pu\frac{\partial u}{\partial n}ds-\int_\Gamma p\frac{u^2}{u_1}\frac{\partial u_1}{\partial n}ds\leqq 0,$$

then

$$\lambda\geqq\lambda_1.$$

Thus we formulate a simple rule for calculating an upper bound for λ_1 as follows:

Choose a function $u(s)$ such that $u(s)=0$ on Γ wherever $\sigma=\infty$. Derive $\partial u/\partial n$ from $u(s)$ such that $u(x, y)$ satisfies $L[u]+\lambda\rho u=0$. Solve the equation

$$\int_\Gamma pu\frac{\partial u}{\partial n}ds=-\int_\Gamma p\sigma u^2ds \quad (19)$$

for λ. The value obtained is always an upper bound.

The method of solution is as follows:

Since

$$u(x, y)=-\int_\Gamma pu\frac{\partial G}{\partial n'}ds',$$

the derived expression for $\partial u/\partial n$ is

$$\frac{\partial u}{\partial n}=-\int_\Gamma pu\frac{\partial}{\partial n}\frac{\partial G}{\partial n'}ds',$$

where $G(x, y; x', y'; \lambda)$ is the Green's function of the equation $L[u]+\lambda\rho u=0$, such that $G=0$ on Γ.[13] Thus

$$\int_\Gamma pu\frac{\partial u}{\partial n}ds=-\int_\Gamma puds\int_\Gamma pu\frac{\partial}{\partial n}\frac{\partial G}{\partial n'}ds' = \int_\Gamma\int_\Gamma p(s)u(s)K(s, s'; \lambda)p(s')u(s')dsds', \quad (20)$$

with

$$K(s, s'; \lambda)=-\left[\frac{\partial}{\partial n}\frac{\partial}{\partial n'}G(x, y; x', y'; \lambda)\right]_{\substack{x, y \text{ on } \Gamma \\ x', y' \text{ on } \Gamma.}}$$

and (19) becomes

$$\int_\Gamma\int_\Gamma p(s)u(s)K(s, s'; \lambda)p(s')u(s')dsds'=-\int_\Gamma p\sigma u^2ds.$$

In some cases it is easier to find $K(s, s'; \lambda)$ than it is to find G and then differentiate it. From this equation λ can be determined when $u(s)$ is chosen. λ depends, of course, on $u(s)$ but the above rule implies that this equation can never be satisfied with $\lambda<\lambda_1$ for any admissible $u(s)$.

The function $u(s)$ should be a good approximation to

[13] It is expedient to have $G=0$ only on that part of Γ, say Γ', where the boundary condition is perturbed and $\partial G/\partial n+\sigma G=0$ on the rest of Γ. Then G is appropriate on $\Gamma-\Gamma'$ and $u(x, y)=-\int_{\Gamma'} pu(\partial G/\partial n')ds'$.

$u_1(s)$ and should be so chosen that the integration of $\int_\Gamma pu(\partial u/\partial n)ds$ will be easy. With a good choice of $u(s)$, which is usually practicable, the derived function $u(x, y)$ will be a very good approximation to $u_1(x, y)$, so the calculated value of λ can be very accurate. The Green's function G or the kernel K is usually expressed in the form of an infinite series; we need to sum it before we can solve the Eq. (19). The algebraic process of summing a series, though sometimes difficult, is much simpler than the solution of a high order determinant.

To explain how to obtain a lower bound for the eigenvalue, we interchange u with u_1 and λ with λ_1 in Eq. (18), and thus obtain an equation which is the mate of (18):

$$\int_\Gamma pu_1\frac{\partial u_1}{\partial n}ds-\int_\Gamma p\frac{u_1^2}{u}\frac{\partial u}{\partial n}ds$$

$$=\int_R\int\frac{p}{u^2}(u\nabla u_1-u_1\nabla u)^2dxdy$$

$$-(\lambda_1-\lambda)\int\int\rho u_1^2dxdy. \quad (21)$$

Here we must have the condition that $u_1=0$ on Γ wherever $u=0$ on Γ'. In other words, u can be zero on Γ only where u_1 is known to be zero. Furthermore, u can have no zeros inside R. The latter restriction implies that u must be the solution for the fundamental mode of the modified problem.

If we demand

$$\int_\Gamma pu_1\frac{\partial u_1}{\partial n}ds-\int_\Gamma p\frac{u_1^2}{u}\frac{\partial u}{\partial n}ds\leqq 0, \quad (22)$$

we should have $\lambda\leqq\lambda_1$. But this is not as practicable as the upper-bound case, because u_1 and $u_1(\partial u_1/\partial n)$ are not supposed to be known simultaneously on Γ except where $u_1=0$. The boundary condition is given by $(1/u_1)(\partial u_1/\partial n)$, not by both u_1 and $\partial u_1/\partial n$. Thus we have to demand $(1/u)(\partial u/\partial n)\geqq(1/u_1)(\partial u_1/\partial n)$ everywhere on that part of Γ where $u_1\neq 0$ in order that the condition (22) will be certainly satisfied. If we are going to perturb the boundary condition slightly, the modified problem may not be exactly soluble; if we perturb more, the calculated value may not be accurate enough.

One important case, however, can be dealt with immediately. It occurs most often in practical problems especially those concerning mechanical and electromagnetic oscillations. In this case, the boundary condition is given as $u_1(\partial u_1/\partial n)=0$ everywhere on Γ; so if we choose u such that $\partial u/\partial n=0$ wherever $u_1\neq 0$ (i.e., $\partial u_1/\partial n=0$) on Γ, we will have $\lambda\leqq\lambda_1$.

In general, it is possible to formulate a rule similar to that for the upper-bound case. The rule is as follows:

Choose a function $(\partial u/\partial n)(s)$ *such that* $\partial u/\partial n=0$ *on* Γ *wherever* $\sigma=0$. *Derive* $u(s)$ *from* $\partial u/\partial n$ *such that* $u(x, y)$ *satisfies* $L[u]+\lambda\rho u=0$. *Solve the equation*

$$\int_\Gamma pu\frac{\partial u}{\partial n}ds=-\int_\Gamma\frac{p}{\sigma}\left(\frac{\partial u}{\partial n}\right)^2ds \quad (23)$$

for λ. *The value obtained is always a lower bound.*

It must be understood here that $\partial u/\partial n$ should be reasonably close to $\partial u_1/\partial n$, otherwise we might get a solution for a higher mode.

The solution is obtained in a similar way as in the upper-bound case.

Here $u(x, y)=\int_\Gamma pG(\partial u/\partial n')ds'$, in which $G(x, y; x', y'; \lambda)$ is the Green's function of $L[u]+\lambda\rho u=0$ such that $(\partial G/\partial n)=0$ on Γ.[14] Thus

$$\int_\Gamma pu\frac{\partial u}{\partial n}ds=\int\int_\Gamma p(s)\frac{\partial u}{\partial n}G(s, s'; \lambda)p(s')\frac{\partial u}{\partial n'}dsds'. \quad (24)$$

The above rule implies that the equation

$$\int_\Gamma\int_\Gamma p(s)\frac{\partial u}{\partial n}G(s, s'; \lambda)p(s')\frac{\partial u}{\partial n'}dsds'=-\int_\Gamma\frac{p}{\sigma}\left(\frac{\partial u}{\partial n}\right)^2ds$$

can never be satisfied with $\lambda>\lambda_1$ for any admissible trial function.

The proof of the rule, however, is not so easy as for the upper-bound case. We are not going to be concerned with it here, since it is but a special case of that for the higher modes, for which a general proof is given below.

So far, we have only considered the perturbation of boundary conditions. Similar results will be obtained by perturbation of the conditions of continuity. Discussion of the latter case will also be reserved for the higher modes.

III. HIGHER MODES

1. Upper Bound

We consider the lth mode. Let λ_l and u_l be the lth eigenvalue and the corresponding eigenfunction. u_l has zeros (nodes or nodal lines or nodal surfaces) inside R; they divide R into no more than l sub-regions.[15] It is to be found by minimizing the same expression (14) as for the fundamental mode. The supplementary conditions as to boundary values, the normalizing condition and the continuity requirements are also the same, but there are $l-1$ additional orthogonality conditions. They are:

$$\int\int\rho uu_i dxdy=0, \quad i=1, 2, \cdots, l-1. \quad (25)$$

For the case of a higher mode, the variational expression cannot be transformed into a form as represented by Eq. (17), except when u and u_l have exactly the same zeros inside R. In general, such transformation

[14] See reference 13. If $(\partial G/\partial n)=0$ on Γ' and G is appropriate on $\Gamma-\Gamma'$, then $u(x, y)=\int_{\Gamma'}pG(\partial u/\partial n')ds'$.

[15] Courant u. Hilbert, reference 10, S. 393.

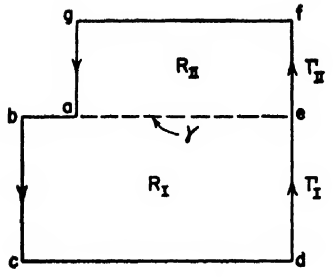

FIG. 1. A composite region R is shown divided into two simple regions R_I and R_{II} by the surface γ. The open boundary *abcde* is denoted by Γ_I and *efga* by Γ_{II}.

cannot be justified. We may, of course, cut out those singularities and then transform the expression, but the result so obtained does not appear to have an explicit extremal property.

It is easier to proceed directly from the variational principle. With u satisfying all the appropriate supplementary conditions mentioned above, the principle assures us that the expression has a minimum value equal to λ_1. The minimum is reached when and only when $u=u_1$. Thus we have, for any admissible u,

$$D[u]+\int_\Gamma p\sigma u^2 ds \geqq \lambda_1 \int_R\int \rho u^2 dxdy. \qquad (26)$$

If u satisfies the differential equation $L[u]+\lambda\rho u=0$, the inequality (26) may be transformed to

$$\int_\Gamma pu\frac{\partial u}{\partial n}ds+\int_\Gamma p\sigma u^2 ds \geqq (\lambda_1-\lambda)\int_R\int \rho u^2 dxdy. \qquad (27)$$

If we demand, as before,

$$\int_\Gamma pu\frac{\partial u}{\partial n}ds+\int_\Gamma p\sigma u^2 ds \geqq 0,$$

then

$$\lambda \geqq \lambda_1.$$

The rule for calculating an upper bound for a higher eigenvalue is just the same as for the lowest except that the trial functions must be orthogonal to all the lower eigenfunctions. If we really need to know the exact form of these latter functions, the method would not be of any practical use. For problems which cannot be solved exactly, we have, at most, only an approximate knowledge about these lower eigenfunctions. If we use approximate functions instead of true ones, the calculated value will be somewhat lower than it would be according to the maximum-minimum-property of eigenvalues. Thus we are not sure whether it is really an upper bound. With the property that u satisfies the differential equation, as it must in this method, this kind of difficulty can easily be removed. We will show how this can be done in a later section.

Now we come to the question of the perturbation of continuity conditions. Let us divide the region R into R_I and R_{II} by γ, as shown in Fig. 1. Let Γ_I and Γ_{II} denote those parts of Γ which belong to R_I and R_{II}, respectively. We choose a function $u_I(s)$ on $\Gamma_I+\gamma$ and $u_{II}(s)$ on $\Gamma_{II}+\gamma$ with $u_I=u_{II}$ on γ, and then derive the trial functions $u_I(x, y)$ and $u_{II}(x, y)$ for the two regions such that they both satisfy the same differential equation.

Thus, u is continuous everywhere in R but the normal component of ∇u is in general discontinuous on γ. u is to satisfy all those restrictions imposed on the trial function for a higher mode for the case of perturbation of boundary conditions, but has no restriction on γ except that it should be continuous there. From the inequality (26), we have instead of (27)

$$\int_{\Gamma_I+\gamma} pu_I\frac{\partial u_I}{\partial n}ds+\int_{\Gamma_{II}+\gamma} pu_{II}\frac{\partial u_{II}}{\partial n}ds + \int_{\Gamma_I+\Gamma_{II}} p\sigma u^2 ds \geqq (\lambda_1-\lambda)\int_R\int \rho u^2 dxdy. \qquad (28)$$

The integrals

$$\int_{\Gamma_I+\gamma} pu_I\frac{\partial u_I}{\partial n}ds \quad \text{and} \quad \int_{\Gamma_{II}+\gamma} pu_{II}(\partial u_{II}/\partial n)ds$$

can be expressed as similar functions of $u_I(s)$ and $u_{II}(s)$ as shown by Eq. (20). We obtain an upper bound for λ_1 by solving the following equation

$$\int_{\Gamma_I+\gamma} pu\frac{\partial u}{\partial n}ds+\int_{\Gamma_{II}+\gamma} pu\frac{\partial u}{\partial n}ds=-\int_\Gamma p\sigma u^2 ds.$$

2. Lower Bound

We perturb the problem by replacing the boundary condition $\partial u_1/\partial n+\sigma u_1=0$ with $\partial w/\partial n+\xi w=0$ such that w does not have to be zero on that part of Γ where $u_1=0$ and $\xi(s)$ is finite wherever $\sigma(s)$ is finite. $\xi(s)$ is a piecewise continuous function and when chosen is to be considered as fixed. The modified problem is to minimize the expression

$$J_1[v]=D[v]+\int_\Gamma p\xi v^2 ds \qquad (29)$$

under the same orthogonality, normalizing and continuity conditions as those imposed on u for minimizing the expression

$$J[u]=D[u]+\int_\Gamma p\sigma u^2 ds$$

of the original problem. Only the boundary conditions are different. Here $v(s)=0$ wherever $\xi(s)$ is infinite, i.e., $w(s)=0$ and $v(s)$ may not be zero where $u_1(s)=0$.

Let us denote the set of trial functions for the original problem by u and that for the modified problem by v. It is obvious that every function of u is contained in v, so u_1 is admissible as a trial function for the expression (29). Let w be that function of the set v which minimizes $J_1[v]$ and μ its minimum value, i.e., $J_1[v]_{\min}=J_1[w]$

$=\mu$. According to the usual variational principle w must satisfy the differential equation $L[w]+\mu\rho w=0$ besides the boundary condition $\partial w/\partial n+\xi w=0$.

Since $J_1[u_l]\geqq J_1[w]$, we obtain easily

$$\int pu_l\frac{\partial u_l}{\partial n}ds+\int_\Gamma p\xi u_l^2ds\geqq\mu\int_R\rho w^2dxdy-\lambda_l\int\rho u_l^2dxdy,$$

i.e.,

$$\int_\Gamma pu_l\frac{\partial u_l}{\partial n}ds-\int_\Gamma p\frac{u_l^2}{w}\frac{\partial w}{\partial n}ds\geqq\mu-\lambda_l. \tag{30}$$

Thus, if

$$\int_\Gamma pu_l\frac{\partial u_l}{\partial n}ds-\int_\Gamma p\frac{u_l^2}{w}\frac{\partial w}{\partial n}ds\leqq 0,\quad \mu\leqq\lambda_l \tag{31a}$$

and conversely if

$$\mu\geqq\lambda_l,\quad \int_\Gamma pu_l\frac{\partial u_l}{\partial n}ds-\int_\Gamma p\frac{u_l^2}{w}\frac{\partial w}{\partial n}ds\geqq 0. \tag{31b}$$

The inequality (30) is the generalization of (21) for higher modes.

As mentioned before in connection with the fundamental mode, the condition (31a) is not quite practical because u_l and $u_l(\partial u_l/\partial n)$ are not known simultaneously on Γ except for certain special cases. In fact, (31a) is not a necessary condition for $\mu\leqq\lambda_l$ and there may exist other conditions which can better serve the purpose. To find one of more general usefulness, it is natural to think of replacing u_l in (31a) by w. One way of doing this is to demand instead of (31a)

$$\int_\Gamma p\xi w^2ds-\int_\Gamma p\sigma w^2ds=0,$$

but this necessitates that $w(s)=0$ wherever σ is infinite and is only soluble for $\mu\geqq\lambda_l$.

Alternatively we may demand the following condition

$$\int_\Gamma p\xi w^2ds-\int_\Gamma\frac{p}{\sigma}\left(\frac{\partial w}{\partial n}\right)^2ds=0,$$

i.e.,

$$\int\frac{p}{\xi}\left(\frac{\partial w}{\partial n}\right)^2ds-\int_\Gamma\frac{p}{\sigma}\left(\frac{\partial w}{\partial n}\right)^2ds=0 \tag{32a}$$

with $\partial w/\partial n=0$ on Γ wherever $\sigma=0$. Since w satisfies the differential equation $L[w]+\mu\rho w=0$, the above condition may be written as

$$-\int_\Gamma p\frac{\partial w}{\partial n}ds\int p\frac{\partial w}{\partial n'}G(s,s';\mu)ds'-\int_\Gamma\frac{p}{\sigma}\left(\frac{\partial w}{\partial n}\right)^2ds=0. \tag{32b}$$

Here $G(x,y;x',y';\mu)$ is the Green's function of $L[w]+\mu\rho w=0$ such that $\partial G/\partial n=0$ on Γ. It will be shown immediately that the condition (32a), i.e., (32b) is indeed sufficient to make $\mu\leqq\lambda_l$ for any admissible trial function used for $\partial w/\partial n$.

To prove this, we first note that if $\xi=\sigma$ except where $\xi=0$ but $\sigma>0$, (31a) is certainly satisfied and (32a) becomes an identity. For any such ξ we have a unique solution with $\mu\leqq\lambda_l$. In other words, with such values of μ we can always find a function $\partial w/\partial n$ which satisfies (32b). However, we need to prove the converse statement, i.e., if $\mu>\lambda_l$ (32b) can never be satisfied provided μ is reasonably close to λ_l.

Next we consider w to be in a small neighborhood of u_l and take $\mu=\lambda_l$, i.e., $L[w]+\lambda_l\rho w=0$. Let us denote $w=u_l+\delta w$, $\xi=\sigma+\epsilon$ and

$$\delta J(u_l)=\int_\Gamma p\xi u_l^2ds-\int p\sigma u_l^2ds,$$

δw and ϵ being functions of small magnitudes. Then from (31b) we have

$$\delta J(u_l)=\int_\Gamma p\epsilon u_l^2ds\geqq 0.$$

As is evident from the extremal property of $\delta J(u_l)$, it should be possible to express $\delta J(u_l)$ in terms of second-order small quantities. This can be easily shown as follows:

$$\delta J(u_l)=\int_\Gamma pu_l\frac{\partial u_l}{\partial n}ds-\int_\Gamma p\frac{u_l^2}{w}\frac{\partial w}{\partial n}ds$$

$$=\int_\Gamma p\delta w\frac{\partial\delta w}{\partial n}ds-\int_\Gamma p\frac{(\delta w)^2}{w}\frac{\partial w}{\partial n}ds.$$

Then we consider the corresponding variation for the expression (32a)

$$\delta J(w)=\int_\Gamma\frac{p}{\xi}\left(\frac{\partial w}{\partial n}\right)^2ds-\int_\Gamma\frac{p}{\sigma}\left(\frac{\partial w}{\partial n}\right)^2ds$$

$$=-\int p\delta w\frac{\partial\delta w}{\partial n}ds-\int_\Gamma\frac{p}{\sigma}\left(\frac{\partial\delta w}{\partial n}\right)^2ds,$$

or

$$\delta J(w)=-\int_\Gamma p\frac{\epsilon}{\sigma(\sigma+\epsilon)}\left(\frac{\partial w}{\partial n}\right)^2ds$$

$$=-\int_\Gamma p\epsilon u_l^2\frac{1+[(\partial\delta w/\partial n)/(\partial u_l/\partial n)]^2}{1+\epsilon/\sigma}ds.$$

As long as small variations are considered, $[(\partial\delta w/\partial n)/(\partial u_l/\partial n)]^2\ll 1$ and $\epsilon/\sigma\ll 1$ except in the small neighborhoods of those zeros of $u_l(s)$ where $\partial u_l/\partial n$ is also zero. Let us denote such neighborhoods by η, then

$$\delta J(w)=\delta J_{\Gamma-\eta}+\delta J_\eta$$

where

$$\delta J_\eta = -\int_\eta p\delta w \frac{\partial \delta w}{\partial n} ds - \int_\eta \frac{p}{\sigma}\left(\frac{\partial \delta w}{\partial n}\right)^2 ds$$

and $\delta J_{\Gamma-\eta}$ is a similar expression. As $\partial\delta w/\partial n \to 0$, $\eta \to 0$, $|\delta J_\eta|$ is small in comparison with $|\delta J_{\Gamma-\eta}|$ and $\delta J(w) \to \delta J_{\Gamma-\eta} \to -\int_\Gamma p\epsilon u_l^2 ds$. Since $\int_\Gamma p\epsilon u_l^2 ds \geqq 0$, we must have $\delta J(w) \leqq 0$ at least for small enough variations.

Thus far it has been assumed that ξ is finite wherever σ is finite. We will now remove this restriction.

Let w' be a function which satisfies $L[w'] + \lambda_l \rho w' = 0$ and the given orthogonality conditions. w' is to be in a small neighborhood of u_l; $\partial w'/\partial n = \partial u_l/\partial n + \partial \delta w'/\partial n$, $w' = u_l + \delta w'$. $\partial w'/\partial n = 0$ on Γ wherever $\sigma = 0$. $\xi' = -(1/w')(\partial w'/\partial n)$ may be infinite where σ is finite. By small variations w' may be changed into a function, say w, which satisfies all the conditions imposed on w' and the restriction that $\xi = -(1/w)(\partial w/\partial n)$ is finite where σ is finite. We denote

$$\partial w'/\partial n = \partial w/\partial n + \partial \delta w''/\partial n \qquad (\partial \delta w''/\partial n = \partial \delta w'/\partial n - \partial \delta w/\partial n),$$

$$w' = w + \delta w'' \qquad (\delta w'' = \delta w' - \delta w).$$

As long as $\partial \delta w''/\partial n$ is small, the corresponding zeros of $w(s)$ and $w'(s)$ are near together. Since w may be any suitable function, $\partial \delta w''/\partial n$ may be chosen to be zero on Γ except in those small neighborhoods of the zeros of $w(s)$ and $w'(s)$, say η, where σ and ξ are finite and $(\partial \delta w''/\partial n)$ is to be of suitable form in order that w may satisfy all prescribed conditions.

By simple calculation $\delta J(w')$ is found to be

$$\delta J(w') = \int_\Gamma \frac{p}{\xi}\left(\frac{\partial w'}{\partial n}\right)^2 ds - \int_\Gamma \frac{p}{\sigma}\left(\frac{\partial w'}{\partial n}\right)^2 ds = \delta J(w) + \delta J_\eta',$$

where

$$\delta J_\eta' = -\int_\eta p\delta w'' \frac{\partial \delta w''}{\partial n} ds - \int_\eta \frac{p}{\sigma}\left(\frac{\partial \delta w''}{\partial n}\right)^2 ds + 2\int_\eta \frac{p}{\sigma} \epsilon w \frac{\partial \delta w''}{\partial n} ds.$$

As $\partial \delta w'/\partial n$ and $\partial \delta w/\partial n$ approach zero both $\partial \delta w''/\partial n$ and η approach zero. If $\partial \delta w''/\partial n$ is sufficiently small, η will be so small that $|\delta J_\eta'| < |\delta J(w)|$. Therefore $\delta J(w') \leqq 0$ at least for small enough variations.

Since $\delta J(w')$ can also be expressed in terms of second-order small quantities as

$$\delta J(w') = -\int_\Gamma pw' \frac{\partial w'}{\partial n} ds - \int_\Gamma \frac{p}{\sigma}\left(\frac{\partial w'}{\partial n}\right)^2 ds = -\int_\Gamma p\delta w' \frac{\partial \delta w'}{\partial n} ds - \int_\Gamma \frac{p}{\sigma}\left(\frac{\partial \delta w'}{\partial n}\right)^2 ds$$

and $\delta w'$ is linearly related to $\partial \delta w'/\partial n$, so if $\delta J(w') \leqq 0$ for small $\delta w'$ the same inequality will be true for any large $\Delta w'$ which is a constant multiple of $\delta w'$. Since $\delta w'$ may be any admissible variation, so $\Delta w'$ may be any admissible function. Writing $w = u_l + \Delta w'$ we obtain

$$-\int_\Gamma pw \frac{\partial w}{\partial n} ds - \int_\Gamma \frac{p}{\sigma}\left(\frac{\partial w}{\partial n}\right)^2 ds \leqq 0. \tag{33}$$

Here w is no longer restricted to a small neighborhood of u_l and $\xi = -(1/w)(\partial w/\partial n)$ may be left undefined provided that $\partial w/\partial n = 0$ wherever $\sigma = 0$, $L[w] + \lambda_l \rho w = 0$ and w satisfies all those orthogonality conditions imposed on the set of functions u or v.

We then calculate

$$\frac{\partial}{\partial \mu}\int_\Gamma \frac{p}{\xi}\left(\frac{\partial w}{\partial n}\right)^2 ds = -\frac{\partial}{\partial \mu}\int_\Gamma pw \frac{\partial w}{\partial n} ds$$

for fixed $\partial w/\partial n$ with $L[w] + \mu \rho \dot{w} = 0$.

$$-2\frac{\partial}{\partial \mu}\int_\Gamma pw \frac{\partial w}{\partial n} ds = -2\int_\Gamma p \frac{\partial w}{\partial \mu}\frac{\partial w}{\partial n} ds$$

$$= -2D\left[w, \frac{\partial w}{\partial \mu}\right] + 2\mu \int_R\int \rho w \frac{\partial w}{\partial \mu} dxdy$$

$$= -\frac{\partial}{\partial \mu}\left\{ D[w] - \mu \int_R\int \rho w^2 dxdy \right\} - \int_R\int \rho w^2 dxdy$$

$$= -\frac{\partial}{\partial \mu}\int_\Gamma pw \frac{\partial w}{\partial n} ds - \int_R\int \rho w^2 dxdy.$$

Thus

$$-\frac{\partial}{\partial \mu}\int_\Gamma pw \frac{\partial w}{\partial n} ds = -\int_R\int \rho w^2 dxdy,$$

so

$$\frac{\partial}{\partial \mu}\int_\Gamma \frac{p}{\xi}\left(\frac{\partial w}{\partial n}\right)^2 ds < 0. \tag{34}$$

This inequality is valid everywhere except at certain singular points at which the expression

$$\int_\Gamma p \frac{\partial w}{\partial n} ds \int_\Gamma p \frac{\partial w}{\partial n'} G(s, s'; \mu) ds'$$

goes to infinity and changes sign abruptly.

For $\mu = \lambda_l$ the expression

$$-\int_\Gamma pw \frac{\partial w}{\partial n} ds - \int_\Gamma \frac{p}{\sigma}\left(\frac{\partial w}{\partial n}\right)^2 ds$$

is always less than or equal to zero and its value for any fixed $(\partial w/\partial n)$ can only be increased by decreasing μ, assuming μ to be varied over a range which does not contain the singular points. Therefore the condition (32)

can only be satisfied with $\mu \leqq \lambda_l$ no matter what function is chosen for $\partial w/\partial n$ as long as it is an admissible one and μ is less than the lowest singular point lying above λ_l.

We have thus proved our rule for the calculation of a lower bound for the lth eigenvalue. The rule is just the same as that stated in connection with the fundamental mode except that we have, now, $l-1$ additional orthogonality conditions. In passing, it may be noted that we have only used the orthogonality conditions at $\mu=\lambda_l$ in the above proof.

Regarding the question about the perturbation of continuity conditions, we consider the same region R as shown in Fig. 1, and consider the same problem, that is to minimize the expression (14) under the usual appropriate conditions. This is equivalent to a problem of finding a function u which minimizes

$$J[u]=D_I[u]+\int_{\Gamma_I} p\sigma u^2 ds - \int_{\gamma_I} pu(\partial u/\partial n)ds + \text{similar terms for } II \quad (35)$$

under the additional restriction that both u and $\partial u/n$ are continuous on the common boundary γ, i.e.,

$$\int_{\gamma_I+\gamma_{II}} pu(\partial u/\partial n)ds \equiv 0.$$

Here the subscripts I and II refer to regions R_I and R_{II} respectively.

We then perturb the problem such that only the normal derivative of the function should be continuous, not necessarily the function itself and the two surface integrals over γ should add up to zero. Let v denote the new set of trial functions; v certainly contains the set u. Therefore, some functions in v will have

$$J[v] \leqq J[u]_{\min} = J[u_l] = \lambda_l.$$

Let w be a sub-set of functions contained in v such that every function of w has a $J[w]$ which is a minimum among all functions of v which have the same normal derivative $\partial w/\partial n$ on γ. u_l is contained in w.

If the set v has functions with $J[v]<\lambda_l$, w must also have functions with $J[w]<\lambda_l$. This is obvious because there exists a function w corresponding to any such function v such that $\partial w/\partial n=\partial v/\partial n$ on γ and $J[w] \leqq J[v]$.

Since $J[u_l]$ is stationary with respect to arbitrary variations in the normal derivative on γ while other $J[w]$ are not, we must have either $J[w] \leqq J[u_l]$ or $J[w] \geqq J[u_l]$. Otherwise the second variation of $J[w]$ should vanish identically for $w=u_l$, but this can easily be shown to be impossible. Moreover, since it is always possible to find a function w which satisfies $J[w] \leqq J[u_l]$, e.g., $\partial w/\partial n=0$ on γ is such a function, therefore we must have

$$J[w] \leqq J[u_l].$$

The case where $J[w]$ is close to a higher eigenvalue is to be excluded.

We denote $J[w]=\mu$. It follows directly from the usual variational treatment that we must have

$$L[w]+\mu\rho w=0 \text{ in } R, \quad \partial w/\partial n+\sigma w=0 \text{ on } \Gamma.$$

Under these conditions

$$w_I = \int_\gamma p \frac{\partial w_I}{\partial n'} G_I(s, s'; \mu)ds',$$

$$w_{II} = \int_\gamma p \frac{\partial w_{II}}{\partial n'} G_{II}(s, s'; \mu)ds',$$

$$\left(\frac{\partial w_I}{\partial n} = -\frac{\partial w_{II}}{\partial n} \text{ on } \gamma\right),$$

where $G_I(x, y; x', y'; \mu)$ and $G_{II}(x, y; x', y'; \mu)$ are Green's functions of the same equation $L[u]+\mu\rho u=0$, such that G satisfies the appropriate boundary conditions on Γ and $\partial G_I/\partial n=\partial G_{II}/\partial n=0$ on γ. Both G_I and G_{II} exist because we have postulated that the problem can be solved exactly for separate regions once we impose boundary conditions on γ.

Hence we may conclude that the condition

$$0=\int_{\gamma_I+\gamma_{II}} pw\frac{\partial w}{\partial n}ds = \int_\gamma p\frac{\partial w_I}{\partial n}ds \int_\gamma p\frac{\partial w_I}{\partial n'}G_I(s, s'; \mu)ds' + \int_\gamma p\frac{\partial w_{II}}{\partial n}ds \int_\gamma p\frac{\partial w_{II}}{\partial n'}G_{II}(s, s'; \mu)ds' \quad (36)$$

can never be satisfied with $\mu>\lambda_l$ for any admissible trial function used for $\partial w/\partial n$ on γ, provided μ is reasonably close to λ_l.

We may further point out that the two processes of perturbation, that of perturbing boundary conditions and of perturbing continuity conditions, may be carried out together for the same problem and the above proofs can easily be extended to such cases.

IV. SERIES EXPANSION AND ORTHOGONALITY CONDITIONS

We will show in this section how we can avoid the difficulty of having no exact knowledge about the lower eigenfunctions. We consider the case of perturbation of continuity conditions, the other case, namely, the perturbation of boundary conditions is somewhat simpler. The variational expression for the upper-bound case has properties closely connected to those of the expression for calculating the lower bound, so we will discuss them together.

We consider the lth mode for the same problem as before. Either $w(s)$ or $\partial w/\partial n$ is to be continuous on γ (Fig. 1) and $\partial w/\partial n+\sigma w(s)=0$ on Γ. In either case, we

may expand $w_I(s)$ and $w_{II}(s)$ into series in terms of different sets of orthogonal functions. This implies that we may expand G_I, G_{II} or $\partial G_I/\partial n$, $\partial G_{II}/\partial n$ in terms of their respective sets of eigenfunctions.

Thus we write

$$\begin{aligned} w_I(s) &= \sum_{j=1}^{\infty} b_{I,j}\phi_{I,j}(s) \text{ on } \gamma \\ w_{II}(s) &= \sum_{j=1}^{\infty} b_{II,j}\phi_{II,j}(s) \text{ on } \gamma, \end{aligned} \tag{37}$$

where b_j's are functions of λ but not of position, and $\phi_j(s)$ are the orthonormal coordinate functions such that

$$\int p\phi_{I,i}\phi_{I,j}ds = \delta_{ij}$$

and

$$\int_{\gamma} p\phi_{II,i}\phi_{II,j}ds = \delta_{ij}. \tag{38}$$

The existence of such functions depends, of course, on the assumption that exact solutions for the modified problem are known for R_I and R_{II} separately. In general, $\phi_{I,i}$ are not orthogonal to $\phi_{II,i}$.

We denote as before the first $(l-1)$ eigenfunctions of the original problem by u_i $(i=1, 2, \cdots, l-1)$. $u_i(s)$ may also be expanded in terms of ϕ_I's or ϕ_{II}'s. Thus

$$\begin{aligned} u_i(s) &= \sum_{j=1}^{\infty} \epsilon_{I,ij}\phi_{I,j}(s) \text{ on } \gamma \\ &= \sum_{j=1}^{\infty} \epsilon_{II,ij}\phi_{II,j}(s) \text{ on } \gamma \\ & i=1, 2, \cdots, l-1. \end{aligned} \tag{39}$$

Instead of (37) $w(s)$ may be expressed in a somewhat different form by using the $(l-1)$ functions $u_i(s)$ to replace any $(l-1)$ coordinate functions ϕ_j. Let $l-1=2v$ or $2v-1$ according as l is odd or even. We replace the first $(l-1)\phi_j$'s by u_i's and write $w(s)$ as

$$\begin{aligned} w_I(s) &= \sum_{i=1}^{l-1} c_i u_i(s) + \sum_{j=v+1}^{\infty} c_{I,j}\phi_{I,j}(s) \\ w_{II}(s) &= \sum_{i=1}^{l-1} c_i u_i(s) + \sum_{j=v \text{ or } v+1}^{\infty} c_{II,j}\phi_{II,j}(s). \end{aligned} \tag{40}$$

Substituting the expression (39) for $u_i(s)$ into (40) and comparing with (37), we obtain

$$\begin{aligned} b_{I,j} &= \sum_{i=1}^{l-1} c_i\epsilon_{I,ij}, \quad j=1, 2, \cdots, v; \\ b_{II,j} &= \sum_{i=1}^{l-1} c_i\epsilon_{II,ij}, \quad j=1, 2, \cdots, v-1 \text{ or } v. \end{aligned} \tag{41}$$

If the determinant $|\epsilon_{ij}| \neq 0$, the above $l-1$ equations will just be enough for the determination of $l-1$ c_i's. In case all b_j's vanish, c_i's can only be zero. If $|\epsilon_{ij}| = 0$, we may write $w(s)$ as

$$\begin{aligned} w_I(s) &= \sum_{i=1}^{l-1} c_i u_i(s) + c_N u_N(s) + \sum_{j=v+1}^{\infty} c_{I,j}\phi_{I,j}(s), \\ w_{II}(s) &= \sum_{i=1}^{l-1} c_i u_i(s) + c_N u_N(s) + \sum_{j=v \text{ or } v+1}^{\infty} c_{II,j}\phi_{II,j}(s), \end{aligned}$$

with N being any integer $\geqq l+1$, such that the rank of the matrix $(\epsilon_{ij}, \epsilon_{N,j})$ is $l-1$. Then we have in place of (41)

$$\begin{aligned} b_{I,j} &= \sum^{l-1} c_i\epsilon_{I,ij} + c_N\epsilon_{I,Nj}, \quad j=1, 2, \cdots, v, \\ b_{II,j} &= \sum_{i=1}^{l-1} c_i\epsilon_{II,ij} + c_N\epsilon_{II,Nj}, \quad j=1, 2, \cdots, v-1 \text{ or } v. \end{aligned}$$

By assigning a certain value, zero or non-zero, to one suitable coefficient c_i we will be able to determine the other c_i's and c_N uniquely. The rest of the discussion will be seen to be essentially the same for the two different cases. Therefore, we may assume without loss of generality that $|\epsilon_{ij}| \neq 0$ and $w(s)$ can be expressed in the form of (40).

Similarly, we can also express $\partial w/\partial n$ in terms of ϕ_j's and $u_i(s)$ as

$$\begin{aligned} \frac{\partial w_I}{\partial n} &= -\sum_{i=1}^{l-1} c_i\chi_{I,i}u_i(s) - \sum_{j=v+1}^{\infty} c_{I,j}\sigma_{I,j}\phi_{I,j}(s), \\ \frac{\partial w_{II}}{\partial n} &= -\sum_{i=1}^{l-1} c_i\chi_{II,i}u_i(s) - \sum_{j=v \text{ or } v+1}^{\infty} c_{II,j}\sigma_{II,j}\phi_{II,j}(s), \end{aligned} \tag{42}$$

where σ_j are functions of λ but not of position, just as are c_i and c_j. Since $u_i(x, y)$ are eigenfunctions, $\partial u_i/\partial n$ must be continuous on γ, so $\chi_{I,i} = -\chi_{II,i}$.

With such expansions for $w(s)$, $\partial w/\partial n$ and $u_i(s)$ at hand, we proceed to find what conditions $w(s)$ must be subject to in order that the orthogonality conditions may be satisfied.

By Green's theorem, we have

$$\begin{aligned} &\int_{\Gamma_{I+\gamma}} p\left(w\frac{\partial u_i}{\partial n} - u_i\frac{\partial w}{\partial n}\right)ds \\ &= \iint_{R_I} \{wL[u_i] - u_iL[w]\}dxdy, \quad (i=1, 2, \cdots, l-1) \end{aligned}$$

and similar equations for R_{II}. Combining the equations for I and II together and putting $L[u_i]+\lambda_i\rho u_i=0$ and $L[w]+\lambda\rho w=0$, we obtain

$$\int_{I+II} p\left(w\frac{\partial u_i}{\partial n} - u_i\frac{\partial w}{\partial n}\right)ds = -(\lambda_i-\lambda)\iint_R \rho w u_i dxdy.$$

The latter equation is further reduced to

$$\int_{\gamma_I+\gamma_{II}} p\left(w\frac{\partial u_i}{\partial n}-u_i\frac{\partial w}{\partial n}\right)ds=-(\lambda_i-\lambda)\int_R\int \rho w u_i dxdy,$$

because w is to satisfy the appropriate conditions, i.e., $\partial w/\partial n+\sigma w=0$ on Γ. So we must have

$$\int_{\gamma_I+\gamma_{II}} p\left(w\frac{\partial u_i}{\partial n}-u_i\frac{\partial w}{\partial n}\right)ds=0$$

in order that w will be orthogonal to u_i. Furthermore, since either w or $\partial w/\partial n$ is continuous on γ, we must have both

$$\int_{\gamma_I+\gamma_{II}} pw\frac{\partial u_i}{\partial n}ds=0 \quad \text{and} \quad \int_{\gamma_I+\gamma_{II}} pu_i\frac{\partial w}{\partial n}ds=0. \tag{43}$$

Substituting (40) and (42) into (43), we obtain

$$\int_{\gamma_I+\gamma_{II}} pw\frac{\partial u_i}{\partial n}ds=-\int_\gamma p\chi_{I,i}u_i(s)\times\{\sum_{j=\nu+1}^{\infty} c_{I,j}\phi_{I,j}(s)\}ds+\text{similar term for } II=0 \tag{44}$$

and

$$\int_{\gamma_I+\gamma_{II}} pu_i\frac{\partial w}{\partial n}ds=-\int_\gamma pu_i(s)\times\{\sum_{j=\nu+1}^{\infty} c_{I,j}\sigma_{I,j}\phi_{I,j}(s)\}ds+\text{similar term for } II=0. \tag{45}$$

Now we calculate

$$\begin{aligned}J(\lambda)&=\int_{\gamma_I+\gamma_{II}} pw\frac{\partial w}{\partial n}ds\\&=-\sum_{i=1}^{l-1}c_i\int_\gamma pu_i(s)\{\sum_{j=1}^{l-1}c_j\chi_{I,j}u_j(s)\}ds-\sum_{j=\nu+1}^{\infty}(c_{I,j})^2\sigma_{I,j}\\&\quad-\sum_{j=\nu+1}^{\infty}c_{I,j}\sigma_{I,j}\int_\gamma p\{\sum_{i=1}^{l-1}c_iu_i(s)\}\phi_{I,j}(s)ds\\&\quad-\sum_{j=\nu+1}^{\infty}c_{I,j}\int_\gamma p\{\sum_{i=1}^{l-1}c_i\chi_{I,i}u_i(s)\}\phi_{I,j}(s)ds\\&\quad+\text{similar terms for } II.\end{aligned}$$

By virtue of (44) and (45) and $\chi_{I,j}=-\chi_{II,j}$, the above equation is reduced to

$$J(\lambda)=-\sum_{j=\nu+1}^{\infty}(c_{I,j})^2\sigma_{I,j}-\sum_{j=\nu \text{ or } \nu+1}^{\infty}(c_{II,j})^2\sigma_{II,j}. \tag{46}$$

Thus, if w is orthogonal to $u_i(i=1, 2, \cdots, l-1)$, the series expansion for $J(\lambda)$ will contain none of the first $(l-1)$ terms. The converse statement, however, is in general not true.

Let us rewrite (40) as

$$\begin{aligned}w_I(s)&=\sum_1^{l-1}c_iu_i(s)+f_I(s)\\w_{II}(s)&=\sum_1^{l-1}c_iu_i(s)+f_{II}(s)\end{aligned} \tag{40'}$$

and (42) as

$$\begin{aligned}\frac{\partial w_I}{\partial n}&=-\sum_1^{l-1}c_i\chi_{I,i}u_i(s)+\frac{\partial f_I}{\partial n}\\\frac{\partial w_{II}}{\partial n}&=-\sum_1^{l-1}c_i\chi_{II,i}u_i(s)+\frac{\partial f_{II}}{\partial n}.\end{aligned} \tag{42'}$$

If $f(s)$ or $\partial f/\partial n$ happens to be of suitable form, w will be orthogonal to $u_i(i=1, 2, \cdots, l-1)$; otherwise not. The function $w(s)$, which approximates $u_l(s)$, can be exactly right only when $J(\lambda)$ has no first $(l-1)$ terms.[16] Thus if we use $f(s)$ in place of $w(s)$ as the trial function, we will be able to get to the exact form of $J(\lambda)$, i.e.,

$$\int_{\gamma_I+\gamma_{II}} pu_l\frac{\partial u_l}{\partial n}ds\equiv 0,$$

by varying $f(s)$. It is to be noted that $f(s)$ does not approximate $u_l(s)$ but the function

$$u_l(s)-\sum^{l-1}c_iu_i(s).$$

Let us rewrite the expression for $J(\lambda)$ also. If we write $J(\lambda)$ for the upper-bound case, where w is matched

[16] For the case of perturbing boundary conditions, the equation $J(\lambda)=-\int_\Gamma p\sigma w^2ds$ or $J(\lambda)=-\int_\Gamma p/\sigma(\partial w/\partial n)^2ds$ will be reduced to

$$-\sum_{j=l}^{\infty}\sigma_jc_j^2=-\int_{\Gamma'}p\sigma(\sum_{j=l}^{\infty}c_j\phi_j)^2ds$$

or

$$-\sum_{j=l}^{\infty}\sigma_jc_j^2=-\int_{\Gamma'}p/\sigma(\sum_{j=l}^{\infty}c_j\sigma_j\phi_j)^2ds,$$

Γ' being that part of Γ where the boundary condition is perturbed and a complete set of appropriate orthogonal functions ϕ_j exist. Thus

$$J(\lambda)+\int_\Gamma p\sigma w^2ds=\int_{\Gamma'}p\sigma f^2ds-\sum_{j=l}^{\infty}\sigma_j\left(\int_{\Gamma'}pf\phi_jds\right)^2$$

or

$$J(\lambda)+\int_\Gamma p/\sigma(\partial w/\partial n)^2ds=\int_{\Gamma'}p/\sigma(\partial f/\partial n)^2ds-\sum_{j=l}^{\infty}1/\sigma_j\left(\int_{\Gamma'}p(\partial f/\partial n)\phi_jds\right)^2$$

will have no first $(l-1)$ terms if w is orthogonal to u_i $(i=1, 2, \cdots, l-1)$. The rest of the discussion will be similar to that for the case of perturbing continuity conditions.

on γ, as

$$J_+(\lambda)=-\sum_1^\infty \sigma_{I,j}(\lambda)\left(\int_\gamma pw\phi_{I,j}ds\right)^2 -\sum_1^\infty \sigma_{II,j}(\lambda)\left(\int_\gamma pw\phi_{II,j}ds\right)^2, \quad (47)$$

the corresponding expression for the lower-bound case, where $\partial w/\partial n$ is matched, will be

$$J_-(\lambda)=-\sum_1^\infty \frac{1}{\sigma_{I,j}(\lambda)}\left(\int_\gamma p\cdot\frac{\partial w}{\partial n}\cdot\phi_{I,j}ds\right)^2 -\sum_1^\infty \frac{1}{\sigma_{II,j}(\lambda)}\left(\int_\gamma p\cdot\frac{\partial w}{\partial n}\cdot\phi_{II,j}ds\right)^2. \quad (48)$$

It is obvious that the corresponding terms of $J_+(\lambda)$ and $J_-(\lambda)$ always have the same sign. For the fundamental mode there is no question about the orthogonality conditions, so only the first term can have a sign different from all the rest. Otherwise we would get at least two values for λ. This could not be possible if w has not zeros inside R. As λ increases, the higher terms will change sign. The second term will have changed sign for the second mode and so the lth term changed for the lth mode. As long as the first $l-1$ terms in $J(\lambda)$ are missing, there can be only one term which has different sign from all the rest. As shown by Schwinger such forms of $J(\lambda)$ are indeed definite for a certain fixed value of λ, being λ_l in the present case. Thus, if we can show that $\partial J_+(\lambda)/\partial\lambda$ has definite sign and the sign is always opposite to that of $\partial J_-(\lambda)/\partial\lambda$, then the value of λ calculated by solving $J_+=0$ or $J_-=0$ will always be greater or lower than the true value.

Though the above result may be anticipated from the proof we had for (34), it is desirable to determine how each term of the series varies with λ. We consider a single coefficient $\sigma_j(\lambda)$ used in (47) and calculate $\partial/\partial\lambda\sigma_j(\lambda)$. Since σ_j satisfies $\partial\phi_j/\partial n+\sigma_j\phi_j=0$ on γ by definition, so

$$\int_\gamma p\phi_j\frac{\partial\phi_j}{\partial n}ds=-\int_\gamma p\sigma_j\phi^2 ds.$$

Since $\phi_j(x, y)$ satisfies the differential equation, we have by Green's theorem

$$\iint_{I\text{ or }II}\{p(\nabla\phi_j)^2+q\phi_j^2\}dxdy +\iint_{I\text{ or }II}\phi_j L[\phi_j]dxdy=\int_{I\text{ or }II}p\phi_j\frac{\partial\phi_j}{\partial n}ds$$

i.e.,

$$D_{I\text{ or }II}[\phi_j,\phi_j]-\lambda\iint_{I\text{ or }II}\rho\phi_j^2dxdy=\int_{I\text{ or }II}p\phi\frac{\partial\phi_j}{j\partial n}ds.$$

Differentiating with respect to λ, we obtain

$$\frac{\partial}{\partial\lambda}D_{I\text{ or }II}[\phi_j,\phi_j]-\iint_{I\text{ or }II}\rho\phi_j^2dxdy -2\lambda\iint_{I\text{ or }II}\rho\phi_j\frac{\partial\phi_j}{\partial\lambda}dxdy=\frac{\partial}{\partial\lambda}\int_{I\text{ or }II}p\phi_j\frac{\partial\phi_j}{\partial n}ds.$$

Since $\phi_j(x, y)$ as $w(x, y)$ satisfies the appropriate boundary conditions on Γ, i.e., $\partial\phi_j/\partial n+\sigma\phi_j=0$ on Γ_I and Γ_{II}, the right-hand side of the above equation becomes

$$\frac{\partial}{\partial\lambda}\int_{I\text{ or }II}p\phi_j\frac{\partial\phi_j}{\partial n}ds =-\frac{\partial}{\partial\lambda}\int_{\Gamma_I\text{ or }\Gamma_{II}}p\sigma\phi_j^2ds-\frac{\partial}{\partial\lambda}\int_\gamma p\sigma_j\phi_j^2ds$$

while the left-hand side is

$$2D_{I\text{ or }II}\left[\phi_j,\frac{\partial\phi_j}{\partial\lambda}\right]-\iint_{I\text{ or }II}\rho\phi_j^2dxdy-2\lambda\iint_{I\text{ or }II}\rho\phi_j\frac{\partial\phi_j}{\partial\lambda}dxdy$$

$$=2\int_{I\text{ or }II}p\frac{\partial\phi_j}{\partial\lambda}\cdot\frac{\partial\phi_j}{\partial n}ds-\iint_{I\text{ or }II}\rho\phi_j^2dxdy$$

$$=-\frac{\partial}{\partial\lambda}\int_{\Gamma_I\text{ or }\Gamma_{II}}p\sigma\phi_j^2ds-\frac{\partial}{\partial\lambda}\int_\gamma p\sigma_j\phi_j^2ds +\frac{\partial\sigma_j}{\partial\lambda}\int_\gamma p\phi_j^2ds-\iint_{I\text{ or }II}\rho\phi_j^2dxdy.$$

In the last step of derivation, we have made use of the fact that σ is the given boundary condition, and so independent of λ, while σ_j depends on λ but not on position.

Therefore by equating the two sides we obtain

$$\frac{\partial\sigma_j}{\partial\lambda}\int_\gamma p\phi_j^2ds=\iint_{I\text{ or }II}\rho\phi_j^2dxdy.$$

Since $p>0$ and $\rho>0$, so

$$\partial\sigma_j/\partial\lambda>0,$$

so also

$$(\partial/\partial\lambda)(1/\sigma_j)<0.$$

Thus we obtain

$$\partial J_+(\lambda)/\partial\lambda<0 \quad (49)$$

while

$$[\partial J_-(\lambda)]/\partial\lambda>0, \quad (50)$$

because every term of J_+ or J_- changes in the same sense.

Now we have proved that, by dropping out the first $l-1$ terms in J_+ or J_- the error in the calculated value of λ will always have one sign. In fact we can be spared the above proof by utilizing the maximum-minimum property of eigenvalues. According to this property the sense of error for the lower-bound calculation cannot be changed by using a trial function which is not exactly orthogonal to the $(l-1)$ u_i's. Since J_- is positive definite, $\partial J_-/\partial\lambda$ must be positive also. By the reciprocal nature of the role played by σ_j in J_+ and J_- we must have $\partial J_+/\partial\lambda<0$. Thus we obtain the same result in a more elegant way.

The original requirements, that $w(x, y)$ should be orthogonal to all the lower eigenfunctions, have been reduced to the requirements that $f(s)$, which approximates

$$u_l(s)-\sum_1^{l-1} c_i u_i(s),$$

should be orthogonal to the first $l-1$ known functions ϕ_j's. This not only simplifies the process but also makes the upper-bound calculation possible without knowing the true eigenfunctions.

Using such a trial function we are assured that the calculated value of λ will always lie above or always lie below λ_l but not always very close. In any case we must use good enough trial functions. The higher terms of the series will be determined by the singular character of the function while the lower ones by the orthogonality requirements. Thus $f(s)$ (and so $w(s)$) can actually be chosen to be sufficiently near to the true function.

We may further improve the accuracy by successive approximations. For example, we take

$$f'(s)=f(s)+\beta\sum_{v+1}^{2v+1 \text{ or } 2v+2}(c_{I,j}\phi_{I,j}(s)),$$

where

$$\sum_{v+1}^{2v+1 \text{ or } 2v+2} c_{I,j}\phi_{I,j}(s)$$

is to be orthogonal to $\phi_{II,i}(i=1, 2, \cdots, v \text{ or } v+1)$, so $c_{I,j}(j=v+1, v+2, \cdots, 2v+1 \text{ or } 2v+2)$ are known to a constant factor. Apply variation on $J(\lambda)$ with respect to β, i.e., put $\delta_\beta J(\lambda)=0$. This determines β and so all the coefficients $\beta c_{I,j}$. The value calculated by using $f'(s)$ will be more accurate than by using $f(s)$. This process can be carried on successively to whatever accuracy we may desire. In most practical cases, however, the trial function may be chosen to be sufficiently accurate, so there is seldom need to go further than a second approximation.

The author wishes to express his deep gratitude to the late Professor W. W. Hansen, from whom he received invaluable advice and friendly encouragement.

Letters to the Editor

Single Crystal X-Ray Techniques for Use with Alloys Requiring Protective Atmospheres*

JOSEPH SINGER AND F. H. ELLINGER
Los Alamos Scientific Laboratory, University of California, Los Alamos, New Mexico
January 27, 1950

PROCEDURES similar to those to be described undoubtedly have been used by others; it was felt, however, that their accessibility in the literature might be desirable.

Our procedures are complicated by the need for handling our alloys in protective atmospheres. An ordinary type of "dry box" equipped with rubber gloves is the preparation chamber through which the inert gas constantly flows. Single crystal fragments of intermetallic compounds have been obtained by shattering ordinary ingots with a hammer. The fragments are viewed in a glass dish against a background of dull black paper. With the aid of suitable tweezers a glass fiber is touched to thin shellac and brought up to a selected fragment. With ingots of small grain size, the fragment selected should be as small as can be seen, preferably with the aid of magnification. If now the mounted fragment were to be dropped into a capillary tube of the type shown in Fig. 1, in which the evacuation and sealing-off is to be done, the specimen would very likely be lost. The following are two ways of controlling the placing of the specimen inside the capillary tube.

One procedure is to place the mounting fiber into a shorter, thin-walled plastic tube which has been formed around a wire smaller than the glass capillary. The metallic fragment is set barely to protrude beyond the plastic and the back end of its mount is fastened to the plastic by clamping. This assemblage can be dropped safely into the glass tube. Figure 1 illustrates this procedure.

A second method consists of using a long fiber, drawn fine only at the end where the specimen is to be attached. Each such fiber is made the right length for a particular capillary tube so that, when the specimen is at a desired position, the back end of the fiber is at the mouth of the tube. With the specimen suitably situated, the tube is held horizontally and shellac brushed on the back end where the fiber touches the wall at the entrance to the tube. When the shellac is dry, the assembly can be held vertically for the evacuation and sealing-off without displacing the specimen. The sealing-off will fasten the fiber within the capillary so that the sample is held rigidly at a desired position.

It is frequently necessary to mount a specimen about a second axis, once a set of single crystal data has been obtained for one

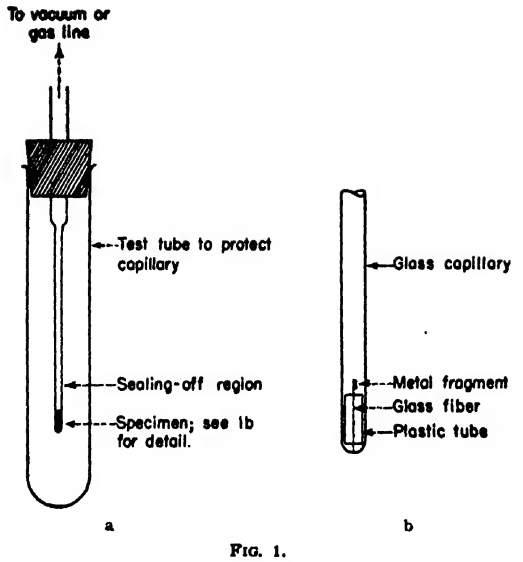

FIG. 1.

axis. With fragments of alloys the usual crystallographic aids for locating an axial direction are not available. However, the position of an axis can be deduced from the previous data. This direction can be set parallel to the x-ray beam. A long, rather heavy glass fiber is set up on a lump of putty-like material and worked over towards the crystal mount until the two pieces of glass touch and the long fiber parallels the selected direction. A small quantity of shellac is deposited around the intersection and is allowed to harden thoroughly. Finally the old mount is carefully detached from the goniometer head, the new fiber shortened, and the crystal aligned on its new axis.

With a little practice one can perform the dry box operations skillfully despite the intervening rubber gloves. The effort is amply repaid with the type of x-ray diffraction data resulting.

Errata: On the Diffraction of an Electromagnetic Wave through a Plane Screen

[J. App. Phys. 20, 760 (1949)]

J. W. MILES
Department of Engineering, University of California, Los Angeles, California

THE scattering cross section for plane, electromagnetic waves normally incident upon a circular aperture in an infinite, plane, perfectly conducting screen given by us in a recent paper[1] was calculated erroneously. This error, in turn, was due to an error

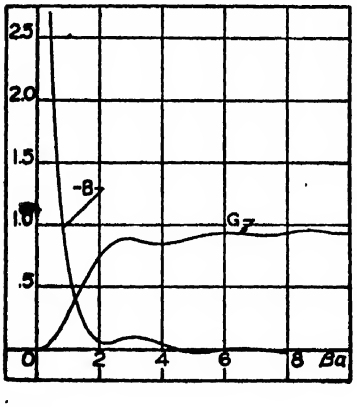

FIG. 9. The conductance and susceptance of a circular aperture for normal incidence of a plane, electromagnetic wave.

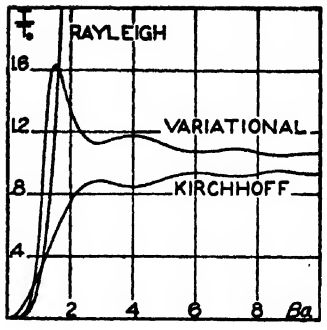

FIG. 10. Scattering cross section (relative to geometric) of a circular aperture for normal incidence of a plane, electromagnetic wave.

in the computation of the aperture susceptance (B). The results have been recalculated, and Figs. 9 and 10 in the original paper should be replaced by those given here.

The error in our calculations was brought to our attention by Professor Harold Levine (Harvard University), who has carried out similar (variational) calculations,[2] using as first and second approximations to the aperture field $[1-(r/a)^2]^{\frac{1}{2}}$ and $A_1[1-(r/a)^2]^{\frac{1}{2}}+A_2[1-(r/a)^2]^{\frac{3}{2}}$, respectively. Our calculation, which uses the static approximation $[1-(r/a)^2]^{\frac{1}{2}}$ for the leading term for small βa and the incident field for the remaining terms, does not predict the first maximum of the scattering cross section as accurately as that of Levine. (We obtain $(T/T_0)_{max}=1.63$ at $\beta a=1.5$; Levine obtains $(T/T_0)_{max}=1.78$ at $\beta a=1.4$.) But it is somewhat more accurate (relative to Levine's first approximation) for large βa, all of which is as should be expected from the nature of the field approximations.

Two other errors in the paper should be pointed out. Equation (86b) should have read

$$B_e(\beta a)=\sum_{m=0}^{\infty}\frac{(-)^m(\beta a)^{2m+1}}{(2m+2)[\Gamma(m+\frac{3}{2})]^2}-(3\pi/8\beta a). \qquad (86b)$$

(This error was typographical and not connected with the calculations.) Moreover, contrary to our statement, Magnus[3] *did* solve the integral equation which he formulated for the Sommerfeld problem,[3] and we should have stated merely that his solution was not as direct as the Wiener-Hopf approach.

Random Noise in Dielectric Materials

R. F. Boyer
The Dow Chemical Company, Midland, Michigan

When thin films of polar plastic materials are subjected to d.c. potentials of 10 to 300 volts per mil they exhibit current fluctuations (with frequencies in the range of 60 to 1000 c.p.s.) which last for minutes and which even persist for a few seconds on removing the voltage. These fluctuations are about 1000 fold above the noise level of the circuit and are about 1 percent of the steady d.c. current. They eventually die out but can usually be restored by reversing the polarity. This noise is greater the more polar the nature of the polymer and the higher its moisture content. The effect seems to arise from water or impurity ions which can jump whenever a hole opens between polymer chains and is thus an activated rate process sufficiently slowed down by the highly viscous nature of the polymeric medium to be readily observable. On an oscillograph screen it is possible to see both the forward and the backward diffusion. This noise is most pronounced in Cellophane, Nylon, and copolymers of vinylidene chloride with acrylonitrile, but also appears with polystyrene stored at 86 percent relative humidity. Films of methylcellulose do not show the effect. Numerically the effect seems to arise from the random motion of groups of several hundred ions as a unit. As an extension of these ideas it is suggested and demonstrated that the moisture vapor diffusion constants for a series of polymers increase with the frequency of the loss factor maximum while the moisture vapor permeability increases with the direct current conductivity.

INTRODUCTION

WHEN a direct current potential of the order of 100 volts/mil is applied to a thin film of dielectric material, as in making a resistivity test, it is always observed that there is an initial high current which drops off rapidly to an approximately steady value. Thus it is customary to measure the current after one minute duration and use this value in computing the specific resistivity. We find however that this "steady" current actually fluctuates in a seemingly random manner. The magnitude of these fluctuations is usually about one percent or less of the average current flow. The duration of this random current is a matter of minutes and in some cases up to an hour or more: depending on the kind of material, moisture content, thickness of sample, and applied voltage.

It is the purpose of this paper to discuss in a general way the main features of this random noise effect; to relate it with the general mechanism of moisture vapor transmission through polymers; and to show how the moisture vapor transmission is numerically related to the d.c. conductivity and the a.c. loss factor of the polymer. Since this random noise effect is apparently a new one, there are many aspects of it which are still obscure to us.

HISTORY

In 1945 R. H. Campbell of the Webster Electric Company informed us that samples of Saran film (vinylidene chloride—10 percent vinyl chloride copolymer) used in condenser A of the high gain circuit of Fig. 1 caused a plopping noise in the loudspeaker whereas polystyrene did not show this effect. Mr. Campbell suspected moisture. We considered it a possible dipole analog of the Barkhausen effect wherein whole regions of dipoles would rotate as a unit. Indeed we tried to look for such effects on a 1000-cycle bridge circuit which used a cathode ray oscillograph as a null indicator, but we were unsuccessful. Two years ago it was decided to repeat Mr. Campbell's observations by using an identical circuit except that the input resistance of our amplifier was 5 meg. We checked his findings. Moreover, we also connected the amplifier output to a Brush recording

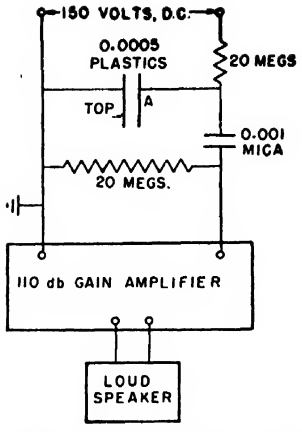

FIG. 1. Circuit used for noise studies. A is the experimental condenser. The amplifier has a 5-megohm input resistance, and cuts off below 30 cycles. In later studies the 0.001 mica blocking condenser was eliminated and the experimental condenser substituted in its place to simplify the circuit.

oscillograph[1] and obtained a permanent record of these plops. They were relatively weak and only a factor of two above the basic noise of the circuit which was estimated to be about a microvolt.

We next tried some other types of vinylidene chloride copolymers, particularly the ones with high acrylonitrile content[2] which would have a high dipole moment. These proved to be quite noisy, with voltage fluctuations of several millivolts. A number of other plastic materials such as Nylon, rubber hydrochloride, paper, Cellophane, plasticized polyvinyl chloride, etc., were then checked. Each of these proved to be more noisy than the original saran sample, although each had a characteristic noise. In fact, it could be said that both the "noise" in the loudspeaker and the pattern drawn by Brush recorders were characteristic of a material. For example, Saran gave an occasional dull plop, Nylon a hissing or frying noise, polyvinyl chloride a scratchy noise. We realize the inadequacy of such verbal descriptions but an examination of typical records may clarify these descriptions. There was, as will be seen later in Fig. 6, a difference in the tracings made by the 60- and 120-cycle pen arms of the Brush recorder. Obviously each "noise" has a frequency distribution spectrum: the Brush oscillograph measures predominantly the low frequency component (say up to 100 cycles); the loudspeaker responds well up to 10.000 cycles, etc. In some instances visual observation of the screen of a fast cathode-ray oscillograph was employed to study the high frequency components in more detail.

Figure 2 shows a time sequence on a sample of coated Cellophane 1.5 mils thick to which 150 volts was applied. Each horizontal line represents one foot of record or one minute of elapsed time while the numbers at the end of the line represent the number of feet of record which has been deleted. The symbols along the chart indicate various operations: B-150 signifies the application of 150 volts d.c. with the bottom electrode negative. The vertical scale is voltage, the maximum peaks representing about 25 mv. At B^+ the polarity on the sample was reversed, leading to considerable noise. Reversal of the voltage as in line 3 leads to a gradual diminution of the noise; the reversal to B^+ in line 6 restores the noise to full intensity with little inclination to die off. Reversal in line 7 again leads to a decaying noise.

The various details of Fig. 2 are characteristic of the behavior of most of the materials, the variation from material to material lying in the direction of intensity of the noise, duration under a given applied voltage, and what we might call the general random behavior of the noise. The main features of Fig. 2, generalized to include most of our experience, are as follows.

1. The noise is usually small at the beginning and its onset may require either a fixed voltage applied for some seconds, or several reversals of the voltage, or increasing the applied voltage to a high value—say 300 volts until the noise starts, and then reducing the voltage.

2. There are usually directional effects in the films. This is quite understandable in a coated Cellophane whereas with a material such as Nylon it might be presumed that manufacturing operations give a different structure to the two surfaces.

3. The noise usually dies out with time but can be restored in general by reversal of the polarity or by increasing the applied voltage. Eventually however, most samples become dead and nothing will restore the

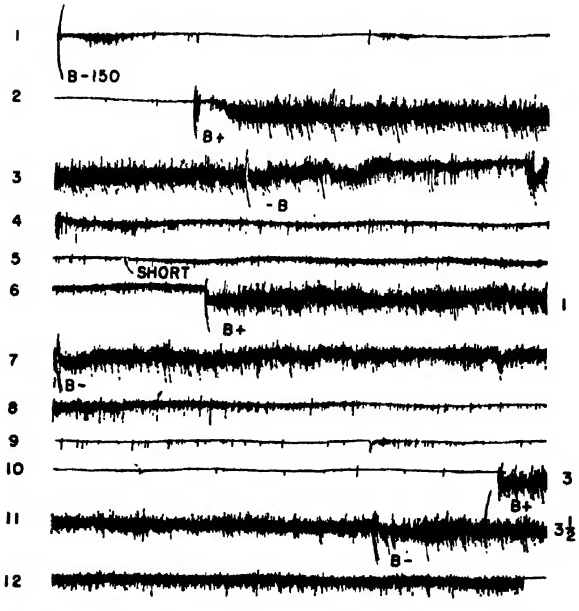

FIG. 2. Noise pattern obtained on a sample of coated Cellophane whose uncoated side was on the bottom electrode. Each horizontal traverse represents one minute of time (one foot of chart paper), the numbers at the right representing feet of record deleted. The ordinates are voltage, the maximum spread being about 25 mv. The symbols B+ and B− refer to the polarity of the bottom electrode.

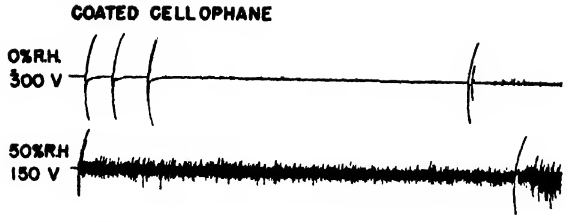

FIG. 3. Effect of relative humidity at which sample was stored on noise pattern of coated Cellophane.

noise. This abrupt termination of the noise is frequently preceded by a particularly loud burst of noise, and one gets the impression of actual dielectric breakdown although we have never noted any visual signs of breakdown.

4. One further effect was noted especially on polyethylene at 86 percent R.H. and 300 volts: the noise level was generally low but at almost regular intervals would increase at least fivefold, persist for a few cycles, and then resume its low level. These bursts would repeat themselves. At low voltages a normal noise pattern similar to that of Fig. 6 (c and d) appears.

In the early work, before these various effects were completely understood, many seeming anomalies were noted, such as apparent failure of the noise to occur with certain types of metal electrodes. We now believe that the single most important variable is the relative humidity at which the sample has been stored. In general the intensity of noise increases with the moisture content and polarity of the sample.

Figure 3 illustrates the effect of relative humidity on coated Cellophane. At zero percent R.H. the sample showed very little activity even at 300 volts and the few displacements which were observed were mostly in one direction with respect to the base line of the recording. At 50 percent relative humidity and with the voltage decreased to 150 volts, the noise has increased tremendously, and the pattern is distributed on both sides of the zero. Figure 4 shows similar behavior for a copolymer of 60 percent vinylidene chloride—40 percent acrylonitrile where the humidity has been carried to 86 percent. At 86 percent R.H. and 250 volts, the loudspeaker was emitting a siren-like noise of gradually increasing pitch and intensity. Figure 5 shows the effect of relative humidity on Nylon; in this case, at 86 percent R.H., the voltage was dropped to 67 volts and still gave a pronounced effect. Here again it is particularly evident that the character of the noise changes markedly on increasing the voltage: low voltages give records symmetrical about the zero line, high voltages gave a more assymmetric recording. This effect will be discussed in the theoretical section.

It should be emphasized that the relative humidity values just given refer to those at which the samples had been stored for 24 hours or more. The measuring electrodes (with associated resistances and capacitors) were housed in a brass case for good electrical shielding. When

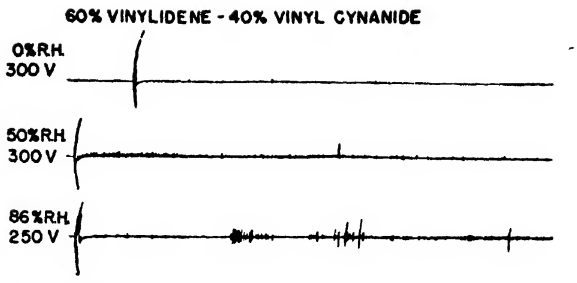

FIG. 4. Effect of relative humidity on current fluctuations in a 60 percent vinylidenechloride—40 percent vinylcyanide copolymer. The fluctuations are unsymmetrical about the axis at high voltage, become symmetrical at higher humidities and lower voltages. The loud speaker emitted a siren-like noise while the bottom line was being recorded.

the film sample was removed from its humidity chamber and placed in the measuring apparatus, where ambient conditions prevailed, the sample either lost or gained moisture. This fact accounts for some but not all of the anomalous behavior which was found. Since the relative humidity of the room was around 20–30 percent for many of these measurements, the very active samples of high moisture content tended to dry out and lose activity. However, Cellophane has an equilibrium moisture content of about five percent even at 20 percent R.H. and hence still has fairly high activity at all times. We noted one case in which the voltage remained on a Cellophane sample overnight; in the morning the sample showed no noise until the voltage was reversed, when it was extremely noisy.

We might conclude this section with a brief description of several additional experiments. Various types of electrodes were tried, such as aluminum, brass, lead and silver, with no appreciable differences as long as a fresh sample of plastic was taken each time from the humidity chamber. Brass was the standard electrode material and was used for all curves given in this report. In general a one-inch diameter electrode was used unless otherwise noted.

A sevenfold range of sample thickness (0.0004 to 0.0028 in.) at a constant potential gradient of 15 volts per mil on a 60 percent vinylidene chloride—40 percent acrylonitrile copolymer at 50 percent R.H. was studied. Each sample was run on one polarity until the noise

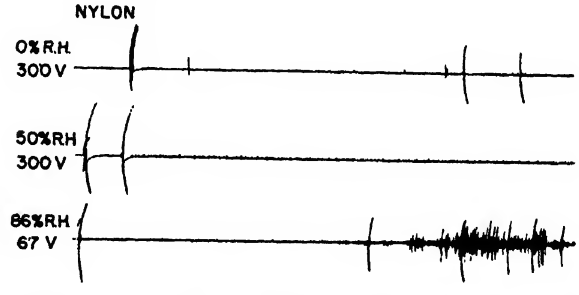

FIG. 5. Effect of relative humidity on Nylon noise pattern. The time scale here as in Figs. 3 and 4 is one minute per horizontal traverse.

stopped. This end point was naturally somewhat arbitrary, but in general the duration of the noise increased linearly with the thickness.

Some of the more noisy materials such as Cellophane were run between two films of polystyrene. They still gave a characteristic noise diminished in intensity. Polystyrene alone did not show this effect unless it had been conditioned first at 86 percent R.H. Films of water soluble methylcellulose were run but did not give any noise apparently because of their extremely high conductivity. If, however, a methocel film was sandwiched between two sheets of polystyrene, it did give a reproducible pattern both on applying and removing the potential, although this pattern does not have the character of a noise but rather of an oscillatory discharge.

We are reserving until a later time studies of the effect of temperature on these noise phenomena. It will be necessary to vary the temperature while keeping the moisture content of the sample approximately constant.

Before concluding this experimental section we wish to call attention to some of the prior literature where analogous effects have been described. Haworth and Bozorth[3] in studying pre-breakdown phenomena in glass observed that the current is "noisy," and occurs in pulses which grow in magnitude as the field intensity increases. Von Hippel[4] has also observed similar effects. Tykociner, Brown, and Paine[5] observed oscillations associated with oil-impregnated paper at high field strengths, and arising from voids in the dielectric. Austen and Hackett[6] ascribe similar effects to the sudden discharge of a local region of the dielectric of lower electric strength than the dielectric in series with it: This discharge may give the appearance of an oscillating current if the circuit constants are of the correct magnitude. Quite recently Glass[7] has studied leakage noise in a number of dielectric materials, both ceramic and organic, at high humidities and high applied voltages. His principle source of noise was surface leakage at the high relative humidity of the samples. Teflon and fluorothene were the only materials free from such effects.

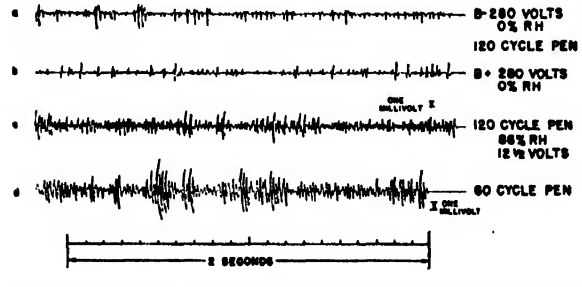

FIG. 6. Fast chart speed record showing detailed noise patterns for Nylon. Lines a and b show unsymmetrical surges at high voltage and low humidity, using the 120-cycle pen. Lines c and d show the symmetrical pattern at low voltage and high moisture content.

Seitz has given a general theory[8] of electron multiplication processes in crystals, which lead to the current avalanches that precede and eventually cause dielectric breakdown. The effects described in the present paper occur at voltages from 15 to 300 volts per mil, whereas the dielectric strengths of the various materials studied range from about 500 to 5000 volts per mil.

Incidentally, some years ago Whitehead and Nethercot[9] studied dielectric breakdown in cellulose acetate, which they called a moist dielectric. They found that this material did not obey Ohm's law but that the conductivity increased linearly with voltage up to 140,000 volts/cm, and even more rapidly at still higher voltages. They spoke of "ion avalanches" as occurring at these higher voltages and actually preceding dielectric breakdown.

More recently Whitehead[10] has presented oscillograph tracings showing the current resulting from applying an alternating potential to polyethylene. There is good evidence on these tracings for what we would call a noise pattern.

THEORETICAL DISCUSSION

The general effects just described in Figs. 2–5 might arise from surface or volume ionic conduction or from rotation of large regions of dipoles. It seems quite possible that several of these effects might be operating together. We are inclined to rule out dipole rotation first on the basis of some of the long-time effects observed, and secondly, because of the marked effect of moisture on polymers such as saran which one would not expect to be markedly plasticized by the absorption of a few hundredths of a percent of water. The cooperative movement of large groups of dipoles would likely be confined to crystalline polymers. Surface conduction, while possibly important at high relative humidities, cannot be of any appreciable importance for samples stored at zero percent R.H., where the noise is still observable at high voltages. We did not use a guard ring on the electrodes. Surface conduction would certainly follow a different mechanism than that of volume conduction, and probably would not place as great dependence on the size of the diffusing ion.

We are thus strongly inclined to view the various phenomena discussed in this paper as arising from the migration of ions through the polymer under the applied electric field. The ions are presumably those of H^+ and OH^- although in the case of saran it is quite possible that Cl^- ions are also present while each of the other polymers may have characteristic impurity ions, both organic and inorganic.

According to Stearn and Eyring,[11,12] the migration of ions in an electric field is susceptible to the usual absolute reaction rate treatment whereby the observed ionic currents are the net resultant of a forward movement of the ions in the direction of the applied field and a backward diffusion because of the concentration gradient of ions thus established. Or

$$\text{Net rate} = (NDc\varphi ze/kT) - NDdc/dx. \qquad (1)$$

N = Avogadro number. D = Diffusion constant of ion. c = Concentration of ion. φ = Potential gradient. z = Valence of ion. e = Electronic charge. dc/dx = Concentration gradient. k = Boltzmann constant. T = Absolute temperature.

Under high potential gradients the second term is almost negligible and the observed current fluctuations are primarily in one direction as may be seen in Fig. 6(a and b) for Nylon film of 0.9 mil thickness at zero percent R.H. and 280 volts applied potential. At higher relative humidities where the fluctuations are much greater and the voltages are greatly reduced, then these fluctuations occur on either side of zero, as can be seen in Fig. 6(c and d) for the same Nylon film.

It might be pointed out that these current fluctuations are frequently of such magnitude as to cause an observable shift in the "steady" current. This can be seen, for example, in line 3 of Fig. 2 where the entire noise pattern shifts its center. Such effects can also be seen on the cathode-ray oscillograph where the base line moves up or down with large fluctuations. It would be desirable, obviously, to record this d.c. component simultaneously with the noise pattern.

We believe these fluctuations arise because of the nature of the medium in which the ionic conduction occurs. One is quite familiar with the mechanism for moisture vapor transmission through polymers as pictured by Barrer and others in terms of absolute reaction rate theory. This theory pictures that as a result of segmental motion of the polymer chains holes occasionally open through which the water molecules can diffuse. This segmental motion presumably has a natural frequency corresponding to that of the peak in the loss factor *vs.* frequency curve for various polymers.

If we apply a similar picture to ionic migration, it will be recognized that on a molecular scale the movement of ions in the direction of the field will be sporadic and that fluctuation phenomena might occur at about the usual frequency for dielectric response. Thus the highly viscous nature of the polymeric medium presumably slows down hole formation to a convenient rate for observation, and makes the measurement of conduction current through such a specimen a convenient tool for the study of this internal molecular process.

If, however, the energy acquired by an ion in the applied field is not too large as compared with kT, then the backward jumps of the ions, as indicated by Eq. (1) will become important. This backward rate must also occur at a rate governed by the frequency of motion of the chain segments. Moreover, it seems likely, especially if H^+ and OH^- ions only are involved, that both types of ions will be subject to the forward and backward jumps, each at its own characteristic rate. Thus the observed noise will be a composite resultant of the random motions

of the ions, which motion depends on the internal mobility of the system, on the size of the ions, on the temperature, and on the applied field.

Some numerical calculations to illustrate orders of magnitude may be helpful at this point. For example, a potential of 250 volts applied to a 1-mil film is 100,000 v/cm which corresponds to an energy of 1.6×10^{-7} erg per cm. Assuming that an ion jumps a distance of 5×10^{-8} cm each time, it acquires an energy of 8×10^{-15} erg. kT is 4×10^{-14} erg and hence at 250 volts the electrical energy is 20 percent of kT. Thus the energies we are using vary from about 1 to 20 percent of kT which accounts already for the characteristic difference in the patterns of Fig. 6(a and c).

Next some estimate of the magnitude of these current fluctuations may be of interest. Thus, in a typical example, Nylon film at 50 percent R.H. and 200 volts gave an extreme fluctuation range of 5 mv. From the nature of the circuit one can calculate that this would correspond to about 10^{-10} electronic charges per burst. Many of the smaller bursts would involve only a tenth of this amount. The steady current, calculated from specific resistivity, is about 10^{12} electronic charges. Additional calculations are given in Table I.

We wish to return now to Fig. 6, which represents studies on nylon at high and low voltages at full chart speed. Lines a and b represent zero percent R.H. and 280 volts with reversal of polarity. In line a the strong surges are seen to be going down with only minor surges in the upward direction; whereas in line b with reversed polarity the strong surges are upward. This conductivity in Nylon at zero percent relative humidity may arise from mobile hydrogen atoms, according to the mechanism suggested by Baker and Yager.[12a] Lines c and d at 86 percent R.H. and 12½ volts illustrate the surges uniformly distributed on either side of the zero line. Line c was recorded with the 120-cycle pen which shows more fine detail than does line d which is on the 60-cycle pen. These two traces are shifted slightly with respect to each other (as can be seen at the right hand side) because of different lengths of the pen arms. It is possible to note the same events on each record and to see that while they do have the same general features yet they actually differ in details.

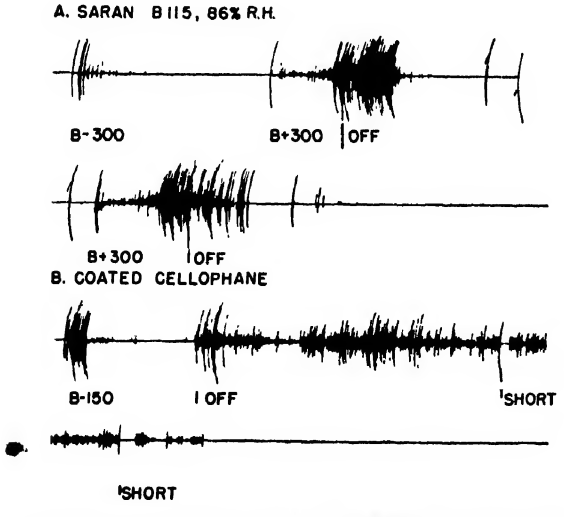

FIG. 7. Typical noise patterns which persist after the voltage is removed from the samples. A is regular saran film which had 300 volts ($B-$) applied, then polarity reverse ($B+$) and voltage off. The same sequence is repeated in the second line. Similar results are shown for coated Cellophane at 86 percent R.H., except that the noise lasts much longer. The two points marked "short" signify that the amplifier input was shorted.

The curves of Fig. 6(c and d) illustrate a principle which is common in fluctuation phenomena, namely, that when the disturbing force is small (low voltage in this case) the fluctuations appear to follow roughly the natural frequency of the system. Thus 6c has about a frequency of 120 cycles, while line 6d corresponds more closely to 60 cycles. Kappler observed this type of behavior with galvanometer mirrors when the ambient pressure was reduced to a low value.[12b] This behavior does not affect the root-mean-square deviation.

Tracings of the kind shown in c and d were obtained both on Nylon and coated Cellophane, using a cross-sectioned recording paper having one millimeter squares supplied with the recorder. These records facilitated statistical studies of the nature of the noise record. For example, by counting the number of intersections of lines parallel to the time axis with the curve, as recommended by Furth[13] and recently applied by Furth and MacDonald,[14] we obtained the distribution data listed in Table I. The 60-cycle pen tracing was used in each case, and the bottom-most point reached by any tracing was taken as zero millimeters for the ordinate scale. It was a coincidence that each of these occupied roughly 25 mm since the actual voltage range was 10-fold greater for the Cellophane. Finally, a similar statistical study was made of the events in line d of Fig. 6, for a period of one second.

It is evident from the distribution data of Table I that the noise peaks are symmetrical about the zero line even up to 200 volts applied potential under conditions when the average current through the film tends to be large. Then the second term of Eq. (1), Ddc/dx, is apparently large and the backward current is appreciable. If, however, as indicated by lines a and b of Fig. 6 the voltage is high and the moisture content low, ideal conditions prevail for observing unsymmetrical surges. In other words, there are presumably so few ions present that the concentration gradient, dc/dx, of ions cannot acquire a large value.

We must now examine in more detail the question of the random nature of these fluctuation currents.[14a] We

have been assuming that the conduction current is composed only of current pulses arising from ion jumps in the dielectric medium, and that these jumps occur at random. If we observe the net current (or a potential drop across a resistance) in the time interval, t, then the root-mean-square current fluctuation, Δi_{rms} is

$$\Delta i_{rms} = (ei_0/t)^{\frac{1}{2}}. \quad (2)$$

Where e is the electronic charge in coulombs, i_0 is the average current, and t is the time interval. t is, for the 60-cycle Brush oscillograph pen, approximately 0.01 sec. Hence, for a typical case i_0 is 10^{-9} amp. or 10^{10} electronic charges per second. For this case one calculates $\Delta i_{rms} = 10^5$ electronic charge units per second. Alternately, one may use the Schottky expression

$$\Delta i_{rms} = (2ei_0\Delta F)^{\frac{1}{2}} \quad (3)$$

where ΔF is the band width and the other symbols have their previous significance. Assuming ΔF as 100 cycles, then the numerical value used above of $i_0 = 10^{-9}$ amp. gives $\Delta i_{rms} = 1.4 \times 10^6$ electronic charges per second, which differs from the preceding value only by the factor $(2)^{\frac{1}{2}}$. The several average and statistical quantities are given in the appropriate columns of Table I. It is seen that Δi_{rms} is from 110 to 450 times the value one would calculate from the average current if normal shot effect conditions applied. Also Δi_{rms} is seen to vary from 0.2 to 5 percent of the steady current. It must be re-emphasized that these values are probably indicative only until we can make simultaneous measurements of the actual steady current.

The fact that these Δi_{rms} values are at least a hundred times larger than one would calculate from the steady current requires a revision of our original premises. The simplest revision is to assume that groups of ions move randomly in the form of "avalanches." Normally the term "avalanche" implies the cumulative building up of a large number of ions by successive collisions. Such a meaning is not intended here. Rather, it seems more likely that if a "hole" opens through the dielectric, it may persist long enough to permit a large number of ions to move through. This may be particularly marked at high moisture contents where small pockets of water exist within the dielectric. It is further possible that the passage of a few ions between a certain pair of chain segments may generate sufficient local heat to keep a path open for additional ions.

Moreover, there is an additional aspect of Eq. (1) which has unique significance for a polymeric dielectric. In any normal electrolysis experiment it does not seem likely that appreciable concentration gradients of ions will exist. However, trapping mechanisms in a high polymer may well give rise to some extremely large concentration gradients. Also, the average current, i_0, which one observes consists of the difference between a forward and backward current,

$$i_0 = i_f - i_b. \quad (4)$$

It is conceivable that the two directional currents, i_f and i_b, could both be large with respect to i_0. The fluctuating current should be based on these individual currents i_f and i_b. Hence the observed fluctuations in current may well seem extremely large in comparison to the average current.

AFTER EFFECTS

There is one final effect which should be mentioned: This noise will frequently persist for a few seconds after the voltage has been removed from the sample. Figure 7 shows some typical records.

According to Maxwell's rule, the relaxation time, τ, for an arbitrary distribution of charge in a solid, is given by $\tau = \epsilon'/\sigma$ where ϵ' is the dielectric constant and σ is the conductivity in m k sec units. Thus a material of dielectric constant 5 and resistivity of 10^{12} ohm-cm should have a relaxation time of 0.4 sec. Some of these observed times are of the order of one minute. Pollissar has discussed conduction in liquids on the basis of a cage model.[15] It seems that in a solid plastic, particularly one that can crystallize, the concept of ions trapped in local cages acquires a high probability. It may well account for some of the long-time constants observed here after the voltage is removed. A highly viscous medium, and especially one in which motion of the ions proceeds in discrete steps, is an ideal one for trapping ions. Two

[c] At 30 percent R.H.

pockets of ions of opposite sign may either move further in the paths toward their respective electrodes, or may mutually discharge each other, giving rise to considerable current surges in the backward direction. It might be noted that the sudden stoppage of an "avalanche" of ions would have the appearance of a surge in the reverse direction.

An inspection of the circuit will indicate that the effective time constant becomes much longer when the potential is removed, based on the discharge of the 0.001 mica condenser to ground through the sample. Thus the time constant can be of the order of several seconds, depending on the actual leakage resistance of the experimental condenser. However, some of these persistent aftereffects last much longer and are the result, we believe, of trapped ions.

RELATIONSHIP OF THIS NOISE TO MOISTURE VAPOR TRANSMISSION

If our picture of this noise is correct: i.e., arising from the activated diffusion of ions where the rate-controlling step is the speed with which chain segments can rotate, then there should be an intimate correlation between these noise effects and moisture vapor transmission. According to Barrer[16–19] the transmission of water through a plastic membrane is given by the expression

$$P = D \cdot S \qquad (5)$$

where D is the diffusion constant in cm²/sec. and S is the solubility of the water molecule in the polymer medium while P is the observed permeability constant in moles per cm² per sec. per unit thickness per unit differential water vapor pressure. Now the diffusion rate should be controlled, among other factors, by the speed with which the segments can open. Hence one would expect a direct relationship between the diffusion constant, D, and the frequency of the maximum in the dielectric response curve, i.e., the frequency at which the loss factor is a maximum. Figure 8 based on the moisture diffusion data of Hauser and McLaren[20] and the dielectric data of von Hippel and associates[21] shows that this is approximately true. Polyethylene itself has no dipoles to give rise to loss so that the observed value of 10^9 cycles presumably arises from impurity groups such as carbonyl. It will be recognized of course that each dielectric material has a differently shaped loss factor *vs.* frequency curve and that the length of the segment engaging in the dielectric response will vary. In some cases also it is mainly a side group rather than a segment of the main valence chain which responds to the applied electric field. Moreover, in Fig. 8 the slope is 0.5, indicating that D increases only as the square root of the segmental frequency.

Nevertheless, we believe the general features of Fig. 8 to be essentially correct and extremely illuminating. It is seen from Table II that Saran and polyethylene represent extreme cases as regards diffusion even though they are relatively close on the final moisture vapor transmission. The outstandingly low moisture vapor transmission of Saran would, in this point of view, be ascribed to the fact that the large chlorine groups have slowed down chain segment rotation to a relatively low frequency. Polyvinyl alcohol is an even more extreme case than saran as far as diffusion at low relative humidities, and here it is presumably both the size of the OH group and hydrogen bonding which slows down dielectric response.

We might mention that results similar to those of Fig. 8 also hold for the diffusion of nitrogen and butane through a series of vulcanized rubbers, using the diffusion data of Barrer and Skirrow[19] and the dielectric data of Scott, McPherson, and Curtis.[22] So far as we know, the seemingly obvious relation between diffusion and dielectric response frequency has not hitherto been noted. However, Levi[23] has already noted that the activation energies and entropies for dielectric relaxation and for moisture vapor transmission follow essentially the same pattern. A further extension of Fig. 8 would be to seek a correlation between the noise frequency spectrum and the dielectric response curve. We have observed qualitatively, on a fast cathode-ray oscillograph, that polyethylene does have higher frequence noise effects than does saran.

Next, if we return to a consideration of Eq. (1), we see from the first term that the electrical conductivity arising from a direct current field is proportional to the product $D \cdot c$ where D is the diffusion constant of the ion

and c is the concentration of ions. But these are precisely the two factors on which moisture vapor permeability depend: except that moisture diffusion refers to the whole electrolyte molecule rather than its constituent ions. However, there is an intimate relation between the diffusion of an electrolyte and the diffusion of its constituent ions. Hence, one is led to predict a relationship between the moisture vapor permeability of polymer films and their direct current conductivities or resistivities. Figure 9, using the data collected in Table II, shows that this relationship holds surprisingly well.

Actually, in the usual electrical resistivity test the sample has been equilibrated in an atmosphere of constant humidity and has a uniform water content throughout its thickness; in a moisture vapor test the water content varies through the film. In addition, different samples were used for the two types of tests. Also, various impurity ions may be present from sample to sample. These various uncertainties may account for the fact that the slope of Fig. 9 is not quite unity.

One may ask now whether or not water vapor diffusion proceeds in part or entirely by an ionic mechanism. For example, a hydrogen ion, having a higher mobility, might diffuse forward and then pull along the slower $-OH$ ion. This is probably the source of the electric currents which Fischer and Muller[24] found to accompany the diffusion of water through plastic films until the steady state was reached. They found that the electrical current passed through a maximum whose height was greater the larger the moisture vapor permeability of the film, and then fell to zero under steady-state moisture transmission. Since the net charge transport would be zero such currents would depend on the difference in velocities of the hydrogen and hydroxyl ions.

SUMMARY

This report is concerned with a description and preliminary interpretation of random fluctuation currents which accompany the application to thin films of moist dielectrics voltage gradients which are higher than those used in normal electrolysis experiments and lower than those leading to dielectric breakdown. These fluctuating currents are believed to arise from the fact that both the forward motion of the ions in the direction of the field and their backward movement because of concentration gradients thus established are regulated by the segmental motion of the polymer chains. It appears now, at least for the low frequency part of the noise spectrum which we analyzed, that groups of ions rather than single ions are acting as the random charge carriers.

This present report must be recognized as a preliminary study of the problem. The following are some of the many experiments which must be performed to elucidate fine details: effect of temperature; simultaneous recording of the average current, especially as it depends on applied voltage; study of the noise frequency spectrum; evaluation of surface *vs.* volume conductivity effects; a study of various ion types other than those of water, such as ammonium, chloride, etc.; and a more detailed study of aftereffects. Finally, a more complete theory needs to be developed. It is interesting to note that Richardson has developed a theory of fluctuations arising from diffusional mechanisms to account for noise developed at electrical contacts.[25]

It is a pleasure to acknowledge the assistance of Herbert Bauss who built the apparatus and aided in making the observations; to F. Towsley for discussions about noise problems in electronic circuits; and to E. B. Baker and L. A. Matheson for helpful discussions about the general significance of these results.

Emulsion Polymerization with Ultrasonic Vibration

A. S. Ostroski and R. B. Stambaugh
*The Goodyear Tire and Rubber Company, Akron, Ohio**

Emulsion-type polymerization reactions have been accelerated by irradiation with ultrasonic energy.

A magnetostriction oscillator at 15 kc gave essentially the same results as a piezoelectric oscillator at 500 kc. The rate of formation of polystyrene was doubled and higher final yields obtained using about 0.03 watt of vibrational power per cc of latex. Experiments were made to separate local heating effects from those due to vibrational energy.

A thermostatted stainless steel cell was developed for irradiating butadiene emulsions under pressures up to 60 p.s.i. About ½ watt of vibrational power per cc of latex doubled the rate of reaction for GR-S, Redox, and Redsol formulas.

The ultrasonic intensity apparently must exceed a critical value before any appreciable accelerative effect is observed. Above the critical intensity, the time to reach a given yield of polymer is approximately inversely proportional to the power used.

I. INTRODUCTION

WHILE the more spectacular phenomena associated with intense ultrasonic radiation have been described by many observers, very little information about practical applications of this energy has been published.[1] Colloidal systems[2] may be affected as to rate of emulsification, particle size and stability, and certain chemical reactions[2,3] are accelerated by the action of ultrasonic waves. The breakdown or de-polymerization of polymers in solution has been studied,[1,4] and the polymerization of acetic acid by treatment with ultrasonic power has been reported.[1] Apparently nothing has been published on the effects of ultrasonic vibration on emulsion polymerization systems such as are used in the production of synthetic rubber and with which the present investigation is concerned.

II. MAGNETOSTRICTION APPARATUS

Both a magnetostriction type of oscillator, operating at 15 kc, and a piezoelectric oscillator, operating at 500 kc, were used as sources of vibrational energy. The magnetostriction oscillator consisted of a laminated nickel bar, 6 in. long and ¾ in. square, excited by a coil made up of 28 turns of ⅛-in. copper tubing through which water was forced for cooling. The coil carried both a d.c. polarizing current and an a.c. current of about 15 to 20 amp. at 400 volts, the latter being supplied by a variable frequency vacuum tube oscillator capable of about 1000 watts output. The bar was supported by a spider inside the insulated coil, and the assembly immersed in the emulsion to be treated. The liquid was maintained at the desired temperature by rapid stirring and the circulation of thermostatically controlled fluid in the jacketed walls of the stainless steel vessel. The chamber was covered and a stream of nitrogen was piped in to prevent contamination by oxygen. A block diagram of this system is shown in Fig. 1, and a photograph of the apparatus is shown in Fig. 2.

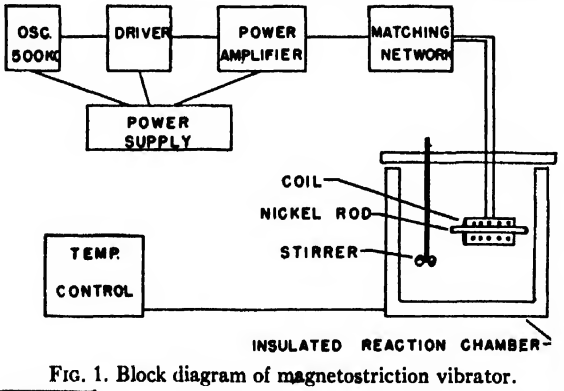

FIG. 1. Block diagram of magnetostriction vibrator.

The reaction was run at atmospheric pressure, and a simple styrene formula was used, containing: 100 parts (by wt.) of styrene monomer; 180 parts, distilled water; 5 parts, soap; 0.6 part, potassium persulfate. Samples were extracted by means of a pipette at intervals during each run so that the course of the reaction could be followed. The polystyrene in each sample was precipitated out in alcohol, dried, and weighed. Figure 3 shows some typical curves obtained with the bath at 50°C with 600- and 1200-cc batches. The percent of the original monomer transformed into polymer (yield) is plotted against the time elapsing after the styrene and soap solution, separately preheated to the bath tempera-

ture, were poured together into the vessel. Controls were run in the same apparatus without current in the coil.

The principle effect of the ultrasonic agitation appears to be the elimination of the induction period, with only a slight increase in the actual rate of the reaction as given by the slope of the curves.

At 40°C, the effect of the irradiation is much more pronounced. As illustrated in Fig. 4, the two curves A and B, obtained with the nickel rod excited, show a much more rapid conversion of the styrene than for curves E and F, when the rod was not energized. Due to magnetic and elastic hysteresis and eddy current losses, a great deal of heat is generated in the rod during a run. This results in a higher temperature in the emulsion immediately around the rod even though rapid stirring is maintained.

In order to show that the acceleration of the reaction was not due solely to this temperature rise, an aluminum rod was substituted for the nickel rod. This was heated by eddy currents to the same temperature as reached by the magnetostriction rod during a run, as measured by thermocouples welded to the surface of the middle section. Runs made with this hot aluminum rod produced curves C and D which show that the rod temperature does have some effect, but not sufficient to explain the rapid reaction of curves A and B which must be attributed to the ultrasonic agitation.

The nickel bar is very inefficient as a source of vibrational energy. The best estimates of actual acoustic power obtained with a kilowatt input to the amplifier were about 50 watts. This fact, combined with the difficulty of designing an enclosed system which could be operated under a relatively high pressure, made it desirable to use a piezoelectric crystal for further measurements.

III. QUARTZ OSCILLATOR

An X-cut quartz crystal was used for a source of energy at 500 kc, powered by a radiofrequency oscillator having a plate input of up to 300 watts. The crystal was 3.81 cm in diameter, having about 8 sq. cm of usable radiating area in contact with the emulsion. An estimated 100 watts of ultrasonic energy was realized with 200 watts plate input to the oscillator which was the usual power level. A few runs were made with 300 watts plate input, but several crystals were shattered in attempts to go above this level.

The crystal was mounted in the special reaction cell pictured in Fig. 5 which could be run at internal pressures of 60 lb./sq. in. This consisted of a stainless steel block through which a 2-in. diameter hole was drilled for the reaction chamber. A number of $\frac{1}{4}$-in. holes were drilled parallel to this chamber for circulation of temperature controlling fluid. The crystal was mounted against a hole cut through the bottom of the reaction

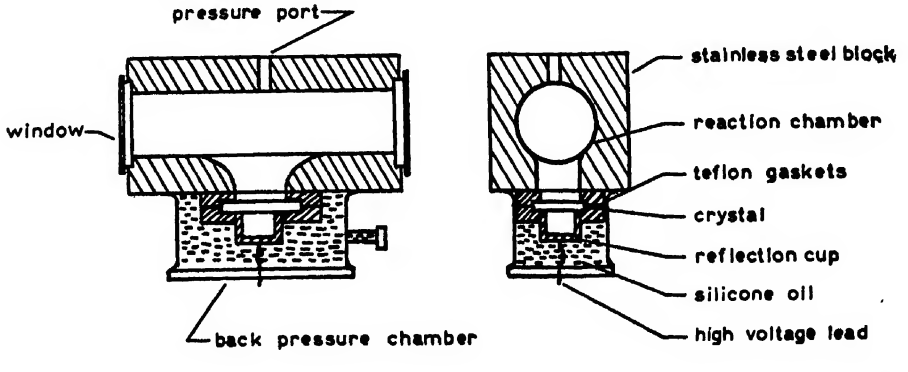

FIG. 5. Stainless steel reaction cell.

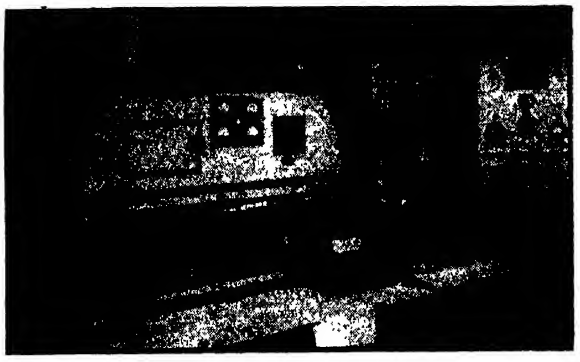

FIG. 6. Photograph of piezoelectric system.

chamber. It was held in place and insulated with Teflon gaskets. The high voltage side of the crystal was surrounded with silicone oil in a steel chamber welded to the block, having a polystyrene lid bolted to a flange on the bottom. The high voltage lead passed through this lid and made a spring contact to the brass, air-filled back-reflection cup which contacted the silvered back face of the crystal.

In the top of the block, a stainless steel pipe and valve was screwed into a threaded hole for filling and emptying the chamber and for insertion of a thermocouple. A pressure gauge was mounted on a side arm off this pipe. Heavy glass windows at each end of the cell provided means for observing the emulsion while it was being irradiated. These could be removed for cleaning the cell.

The photograph of Fig. 6 shows this apparatus with the associated recording and controlling systems for temperature, pressure, and power. The reaction cell in the center foreground is mounted in a cradle with a pneumatic piston beside it which rocked it constantly to prevent layering of the immiscible components of the charges.

When operating with high pressures in the cell, the oil in the chamber on the bottom side of the quartz crystal was automatically maintained at an equal pressure so that there was no tendency for the gaskets holding the crystal to leak. Furthermore, bending and damping of the crystal was minimized.

Since the reaction chamber was limited to charges of 200 cc or less, in order to treat large volumes of styrene at essentially atmospheric pressure, the cell was connected to a thermostatted ten-liter reservoir and a circulating diaphram pump by means of flexible metal hoses. The system was evacuated, the charge sucked in, and nitrogen forced in until the pressure was a few pounds per square inch above atmospheric. Samples of the latex could be removed at any time by means of a pet-cock.

The curves shown in Fig. 7 were obtained using the simple styrene formula given above in four-liter batches at 50°C with 200 watts plate input. As found with the magnetostriction oscillator, the main effect at this temperature was a decrease in the induction period and a somewhat higher final yield, although the actual rate of conversion was very little faster with the ultrasonic power on.

Figure 8 shows some results obtained at 40°C and, again, as found with the magnetostriction oscillator, there is a much more pronounced effect. Each of the three curves drawn in this plot was obtained with a different power concentration which was varied by changing the plate input to the oscillator or by changing the size of the batch.

No accurate method for measuring the actual ultrasonic power was available. Although a number of measurements were made on heating effects and radiation pressures, the figures obtained were unreliable. Probably about 50 percent of the plate input power was available as vibrational energy. However, to avoid the issue, the plate-input power was used as a basis for comparisons.

Figure 9 is a plot of the time required to reach a given yield of polystyrene as a function of the power concentration. These curves show that the reduction in time is approximately proportional to the power used. As the power is increased to very high concentrations, a minimum time to reach a given yield is approached. For

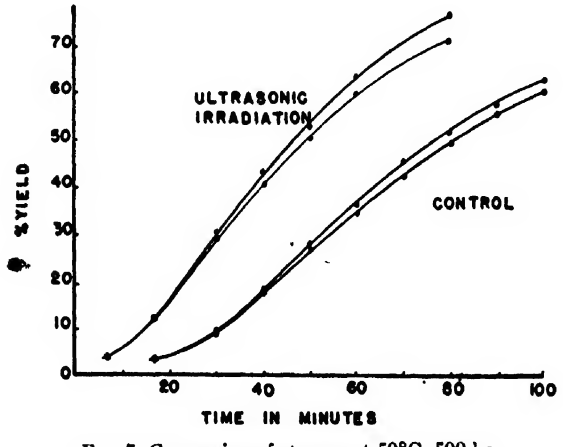

FIG. 7. Conversion of styrene at 50°C, 500 kc.

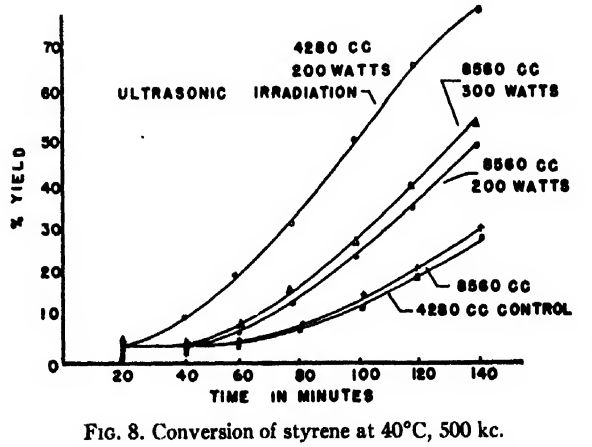

FIG. 8. Conversion of styrene at 40°C, 500 kc.

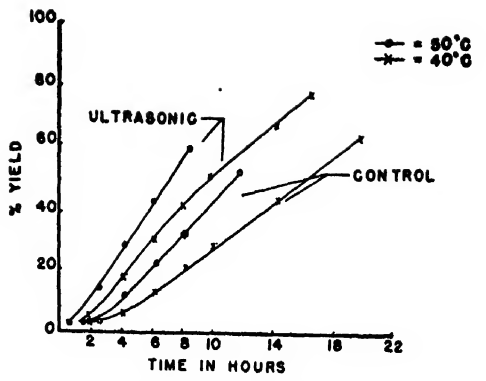

FIG. 10. Conversion of GR-S at 500 kc.

instance, at one watt per cc, 25 min. at 50°C is required to reach 70 percent yield.

As the power concentration is reduced to low levels by increasing the amount of latex in the batch, the curve intercepts the axis at the correct value as obtained from control runs with no power. However, if the batch is held at the same volume and the power concentration reduced by decreasing the plate input, a point is reached when no cavitation is produced. Below this critical intensity, the reaction rate is the same as the control, indicating that cavitation may be a necessary condition for the acceleration of the reaction.

IV. SNYTHETIC RUBBER POLYMERIZATION

For butadiene polymerization reactions, requiring 40 to 60 lb. pressure it was necessary to cut off the reservoir and circulating pump from the system, so that the batch size was limited to the reaction chamber. Figure 10 shows the results obtained for GR-S at 40° and 50°C. This was the standard mutual formula with a small amount of sulfuric acid added: 37.5 g of butadiene; 14.5 g of styrene; 90.0 g of distilled water; 2.5 g of soap; 0.15 g of potassium persulfate; 1.5 cc of 2.1*N* H_2SO_4; 1 to 2 drops of modifier (mercaptan).

The sulfuric acid solution was added to bring the *p*H down to 8.2 which was necessary to prevent foaming and consequent loss of ultrasonic power absorption by the latex. Control runs were made on the identical formula both in the reaction chamber without excitation of the crystal, and in standard glass bottles in a water bath. Samples were taken from the cell at definite intervals by means of a special hypodermic needle inserted through a gasket. The plate input was 200 watts, so that about 1 watt per cc (or about $\frac{1}{2}$ watt of vibrational power per cc) is required to double the yield in a given reaction time at either 40° or 50°C. This is a much larger power requirement than observed for the polymerization of styrene.

Essentially the same results were obtained with both a Redox "cold rubber" recipe at 41°F, as shown in Fig. 11, and a Redsol formula. The GR-S polymer produced with ultrasonic irradiation was apparently the same as the control product. Viscosity and density measurements showed no differences, and the infra-red absorption spectra were the same within the limits of spectrometer reproducibility.

V. DISCUSSION

The exact role of the ultrasonic agitation in accelerating these reactions is not understood. Apparently, cavitation is required, so that the high instantaneous pressures and temperatures produced upon collapse of the cavitation bubbles must be the principal cause of the effects. If higher localized temperatures at the cavitation centers are the cause, the polymer produced should have the characteristics of the control polymer made at higher temperatures. While no differences in the properties have been found as yet, the effects would be small and a more careful analysis of the properties may show these differences. If it were the high pressures (rather than temperatures) produced at the cavitation centers which were responsible for the rapid polymerizations, the properties of irradiated polymers should be compared to those special control polymers made at very high pressures. No such information is available at present.

In the case of the styrene polymerizations, the reduction of the induction period can be explained by the faster and better emulsification produced by the ultra-

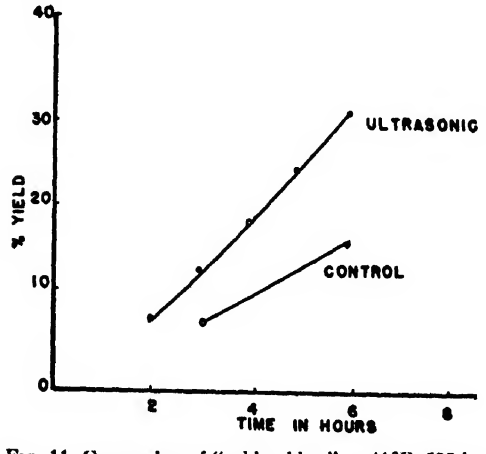

FIG. 11. Conversion of "cold rubber" at 41°F, 500 kc.

sonic agitation, a well-known phenomenon. In addition, several observers[3] have noted the ability of ultrasonic radiation to increase the rate of oxidation and produce peroxides. Since the induction period is usually caused by free oxygen in the system,[5] the rapid removal of this oxygen would permit the polymerization to start much sooner.

The increase in the actual rate of the reaction could be attributed to either increased rate of formation of free radicals by the persulfate reaction, or increased activity of the styrene in the polymer particles. The rate of reaction is usually considered to be established by the number of polymer particles formed initially. This is not greatly affected by irradiation (from particle size measurements) and the reaction cannot be "triggered" by the ultrasonic power. Several runs with both styrene and GR-S were made in which the ultrasonic power was cut off after a definite time. In these cases the reaction rate dropped to that of the control for the rest of the run.

The irradiated runs made with styrene usually proceeded to much higher yields (80 or 90 percent) before the reaction rate dropped off, while most control runs leveled off at 60 to 70 percent. This suggests that an important role of the ultrasonic radiation may be to oxidize inhibiting impurities which prevent the reaction from going to completion.

ACKNOWLEDGMENT

The authors wish to express their thanks to the Goodyear Tire and Rubber Company and to Dr. H. J. Osterhof for permission to publish this work. This investigation was carried out under the sponsorship of the Office of Rubber Reserve, Reconstruction Finance Corporation, in connection with the Government Synthetic Rubber Program.

Transitions in High Polymeric Materials

ROLF BUCHDAHL AND LAWRENCE E. NIELSEN

Monsanto Chemical Company, Plastics Research Laboratory, Springfield, Massachusetts

The evidence for and against the interpretation of the "second-order" transition in polymers in terms of a thermodynamic transition of the second order is reviewed and some new experimental data concerning transition in mixtures of polymers are presented. It is shown that the relaxation theory is insufficient to explain the transition, as observed by mechanical, electrical and thermal measurements. The usual objections which are raised against the assumption of a thermodynamic transition are shown to be invalid. Various molecular processes responsible for a thermodynamic transition are discussed and it is shown that the general mechanism of "hindered" rotation (changes in rotational configuration) is the most likely.

I

EMBRITTLEMENT has long been recognized as one of the characteristic phenomena of all polymeric materials and, from a phenomenological point of view, can best be described by the change of dynamic elastic modulus (E) and mechanical damping with temperature[1–4,*] as shown schematically in Fig. 1. Embrittlement occurs at a temperature, T_b, where the modulus has reached its maximum value. As the temperature is raised, the modulus undergoes a drastic change within a relatively narrow temperature range (the transition or "leathery" region) and then levels off again at higher temperatures where the material usually displays all the typical properties of an elastomer. In the transition the mechanical damping goes through a maximum, as can be seen from Fig. 1. Whether or not a material is classified at room temperature as a "plastic" or as a "rubber" depends only, from this point of view, on the position of the transition region on the temperature scale.

Two important characteristics of a damping temperature curve are the transition temperature defined as the temperature of maximum damping and the width. Within the transition region, as defined by dynamic mechanical measurements, many other physical properties change also in a more or less discontinuous manner. The specific heat undergoes a rather sudden increase as shown in Fig. 2; the thermal expansion coefficient[5] and the refractive index[6] changes, in most cases, in a discontinuous manner; the dielectric constant increases rapidly, and the electrical loss factor goes through a maximum.[7–9] (The dispersion in the electrical case is much more dependent on frequency than in the mechanical case.) Finally, in a few cases, it has been found

that the compressibility[10] and thermal conductivity[11] undergo rapid changes in a narrow temperature region.

On the basis of the experimental evidence available, there can be no doubt that polymers undergo a transition which can be detected by numerous methods; there exists, however, a considerable amount of disagreement concerning the nature and origin of this transition. This problem can be stated quite simply as follows: (1) Is the transition a real one from the thermodynamic point of view? (2) If it is a real one, what is its origin? (3) If it is not real, in the thermodynamic sense, how can it be interpreted in a satisfactory manner? The fact that the transition has been referred to as a "second-order" transition indicates that the interpretation has, at times, been considered in terms of a real thermodynamic transition of the second order.[12] A thermodynamic second-order transition is defined as a transition extending over a small but finite temperature range ΔT with a heat of transition given by the integral $\int \Delta C dT$ where ΔC denotes the excess of specific heat at the transition.[13] However, during recent years the prevalent opinion has been that the transition is an apparent one and can be interpreted as the temperature "point where the rate of attainment of equilibrium is of the same order of magnitude as the time scale of ordinary physical experiments."[14] This conclusion is based on two separate but related experimental findings: The transition as measured by volume expansion shows strong time effects and when equilibrium conditions are approached tends to disappear (at least in the case of polystyrene);[15] the transition region shifts with frequency when measured by the response to an alternating mechanical or electrical force. According to this point of view, the transition is due to the existence of a relaxation spectrum[16] and corresponds to an isoviscous state.[17] Recently, however, several investigators[18-20] have emphasized the fact that the concept of relaxation is not sufficient to give a satisfactory interpretation of these transitions in high polymers and that it is necessary to assume some sort of thermodynamic transition. In the following sections we intend to show in a qualitative manner† (1) why such an assumption is necessary; (2) that the existence of a thermodynamic transition of the second order is in agreement with experimental findings and does not invalidate the existence of dispersion (or rate) effects; and finally we state the molecular process involved in the transition.

II

Before discussing the major limitations of any relaxation or isoviscous theory, it is necessary to consider the results Spencer and Boyer[20a] obtained in their study of the thermal expansion coefficient (α) of polystyrene. They concluded that, at least for polystyrene, the transition is a rate phenomenon and not a thermodynamic singularity. Polystyrene is a typical amorphous material where the mechanical properties are not further complicated by the presence of crystallites, and has only a single transition at about 105°C which is independent of molecular weight above $M_w \sim 150{,}000$;[21] it is important to clarify this point because it has frequently been used as the most powerful argument in favor of the relaxation theory. A careful examination of the published data does not seem to justify a linear relationship without a discontinuity between 20 and 150°C as claimed by the authors, unless the precision of the measurements is much lower than indicated. It seems that the discontinuity persists, irrespective of the time allowed to obtain equilibrium. It should be pointed out that the existence of a discontinuity is not a necessary criteria for the existence of a second-order transition; Fowler and Guggenheim have shown[22] that α above and below the transition temperature (T_t) is given by the

following equations:

$$\alpha - \alpha_0 = -\beta^0(3/2)(w/kT_t^2)(dw/dv)(0 < T_t - T \leq T_t)$$
$$\alpha - \alpha_0 = 0(T > T_t),$$

where α_0 = expansion coefficient of the disordered state and w is the energy of unmixing. It will be noticed that a discontinuity in α at T_t only exists when dw/dv is different from zero or not negligibly small. There might well exist cases where the change in this energy with volume is sufficiently small or actually zero so that a discontinuity will not be found despite the existence of a thermodynamic transition.

One of the major difficulties encountered by the relaxation theory is the temperature dependance of the rate constant τ, near or in the transition region. It is generally assumed that τ varies exponentially with temperature: $\tau = C \cdot e^{W/RT}$, where W has the meaning of an activation energy. Such activation energies have been determined from measurements of electrical[23] or mechanical[1,24] damping, or from stress relaxation curves;[25] the values usually found are between 10 and 50 kcal. and appear to be closely related to the activation energies of viscous flow of high polymers.‡ However, these activation energies are much too low to account for the marked changes in the modulus in the transition region (as observed at low frequencies); in other words, the activation energy becomes itself a function of the temperature as the transition temperature is approached. As a matter of fact, Frenkel[13] has pointed out that the equation given above for τ must be modified by assuming W = const. eu/RT in order to be in agreement with experimental data; and that such an increase of the activation energy is due to a change of the structure which can be specified by an order-disorder parameter, s. It would seem more reasonable to postulate the following relationship for τ = const. $eW/[R(T-T_t)]$ for $T \geqq T_t$. It is therefore quite evident that the relaxation theory by itself cannot give a satisfactory interpretation of the strong temperature dependance of the modulus or damping, which in the case of unplasticized polyvinyl chloride is about 180 kcal., in terms of an activation energy, in the transition region.

Another difficulty arises when one considers the interrelationship between frequency (V) and temperature (T) with respect to the dynamic modulus and damping. On the basis of the relaxation theory there exists a definite interrelationship which can most easily be expressed by the proportionality

$$\ln V_1' \quad T_2$$
$$\ln V_2' \quad T_1'$$

i.e., a lowering of the temperature has the same effect as increasing the frequency, and $E(T)$ and $E(V)$ are closely related functions. Again, in the case of electrical measurements of simple low molecular weight materials in *non*-polar solvents, theory and experiment are in good agreement.[26] The extensive electrical studies by Fuoss[7] on various polymer-plasticizer systems also seem to be in harmony with a relaxation theory when a relaxation spectrum instead of a single relaxation time is assumed. It should be pointed out, however, that this agreement with theory might be somewhat fortuitous in view of the results obtained by Schallamach[27] on the dielectric relaxation of mixtures of dipolar liquids. When one now considers the available data[28,1] on mechanical damping or modulus as a function of frequency and temperature, it becomes immediately apparent that the agreement between theory and experiment is not good: (1) The frequency dependance is such that one has to assume a continuous relaxation spectrum extending over 10 decades or more; an assumption whose physical significance is—to say the least—somewhat doubtful. (2) An upper frequency limit of the modulus has never been experimentally established with certainty. (3) The interdependance between temperature and frequency is not very pronounced and certainly does not hold in the transition region. It will be shown in the next section that the dispersion effects can be interpreted as the consequence of the existence of a thermodynamic transition.

Finally, we wish to consider briefly the difficulties which arise with respect to the dependance of the transition temperature on plasticizer concentration on the basis of a relaxation or isoviscous state theory. ¶The

¶ This problem is intimately related to the general theory of plasticization which we plan to discuss in detail at a later date.

lowering of the transition point is explained in terms of a lowering of the internal viscosity so that upon addition of a plasticizer the isoviscous state (or the equivalent relaxation spectrum) has been shifted toward a lower temperature.[28a, 29] This concept implies that there can be only one transition point upon addition of a plasticizer. However, investigations of the dielectric losses in swollen rubber[30] show that one can obtain, under certain conditions, more than one maximum. Similar results have been found in the case of a mixture of two polymers (polystyrene and 40:60 percent butadiene-styrene copolymer) as can be seen in Fig. 3. Furthermore, a survey of reliable transition temperature data as a function of plasticizer concentration[2, 7, 8, 31] has shown that the transition temperature is a linear function of the volume fraction of plasticizer over a wide concentration range provided certain conditions are fulfilled[32, 2] (see Fig. 4). Recent investigations on the dielectric properties of plasticized compositions[33] have shown that the $T_c - c_v$ relationship when extrapolated to 100 percent plasticizers gives a transition point for the plasticizer which agrees with the experimentally determined transition point. The relationship derived by Boyer and Spencer[28a, ||] on the basis of the theory of isoviscous state is not in agreement with the $T_t - C_v$ relationship which, for the simplest case, is determined only by the transition points of the two components and has to be modified depending on the mutual compatibility of the constituents.

|| In view of the fact that the Flory equation of viscous flow of polymers has recently been found to hold only over a limited molecular weight range, the agreement with experimental data is probably accidental.

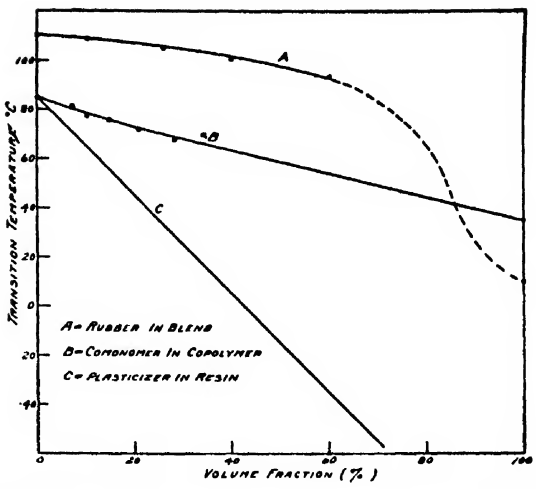

FIG. 4. Transition temperature as a function of volume fraction.

III

It is clear from the preceding discussion that the application of the relaxation concept to the transition phenomenon under consideration is insufficient to explain the salient features of such transitions. The necessity of assuming a real thermodynamic transition becomes, therefore, almost inescapable even when one approaches the problem at first from the relaxation point of view, as has been pointed out by several investigators.[1, 13] On the other hand, an interpretation on the basis of a thermodynamic transition has, in the past, encountered some difficulties because certain experimental findings appeared to be in disagreement with the concept of a true transition. These findings are (a) the apparent disappearance of the discontinuity of the thermal expansion coefficient in the case of polystyrene; (b) the shape of the specific heat curve in the transition region, and (c) the effect of time (or frequency) on the position and magnitude of the transition.

It has already been pointed out that the experimental data on equilibrium volume expansion of polystyrene confirm the existence of a discontinuity; in the one case where similar measurements were made on glass,[34] the discontinuity also persisted. Furthermore, recent measurements[35] of the volume expansion of various polystyrene fractions indicate that in some instances α goes through a maximum at the transition, similar to the specific heat changes observed in second-order transitions of simple low molecular weight compounds or metallic alloys.

At a second-order transition the specific heat changes in a characteristic manner: as the transition point is

[34] A. Winter, J. Am. Ceram. Soc. 26, 189 (1943).
[35] R. W. Raetz, Monsanto Chemical Company (unpublished data).

approached, it increases more and more rapidly; at the transition point, the specific heat falls back, in the case of small and simple compounds, to a value not much above the one it had many degrees below the transition temperature (λ-transition). Published data on the specific heats of polymers, such as the one shown in Fig. 2, are somewhat different; the specific heat increases rather abruptly in the transition region[36] but fails to return to a low value beyond the transition point. It has been argued[13,37,38] that specific heat curves of this type are characteristic of non-equilibrium conditions. This argument, however, overlooks the fact that, as a result of a second-order transition, additional degrees of freedom of the system might become operative, and the appearance of new degree of freedoms are not the cause but the result of the transition. As a consequence of this, the specific heat remains high and the discontinuity disappears, although very precise measurements over a very narrow temperature region within the transition range might or might not reveal a discontinuity; such data are not yet available for polymers. It should be pointed out that even in low molecular weight materials the transition is frequently not too sharp and that the diffuseness of the specific heat-temperature curve usually, but not necessarily, increases as the molecule becomes larger and more complex. Measurements on C_2F_6[39] illustrate this point very nicely and recent studies of hindered rotation on the same material[40] by means of the line width due to nuclear magnetic moments have shown conclusively that the specific heat change is due to a second-order transition.

Finally, there remains the effect of time or frequency on the position and magnitude of a second-order transition. Second-order transitions are usually free of relaxation effects, that is to say, the transition region or the transition temperature remain unaffected when the transition is studied by the application of external forces of different frequencies. In the case of polymers and glasses this is not so. Increasing the frequency shifts the transition temperature to higher values and also makes the transition region broader. This effect is easily understood when one remembers that the transition in polymers leads to a rubber, which on the basis of many extensive theoretical and experimental investigations[41–47] is the relaxing system par excellence; that is to say, its mechanical properties can quite satisfactorily be explained by a set or distribution of relaxation times. It is obvious, therefore, that as the material goes through the transition into the rubbery state, the relaxation effects will immediately become apparent. One should therefore expect that the transition is sharp when measurements are made at low frequency and becomes more diffuse for higher frequencies, because once the system has gone through the transition one deals with a rubber which will respond to forces of a given frequency according to its relaxation spectrum. This interpretation also explains the poor correlation between temperature and frequency in the transition region discussed in the previous section. The frequency dependance of the transition temperature is therefore not in conflict with the assumption of a true second-order transition but is due to the fact that the mechanical properties of one of the "phases" is determined by a widespread of relaxation times.

IV

It now remains to identify the thermodynamic transition with a reasonable molecular process. The absence of simultaneous electrical, mechanical and thermal data on one polymer makes it impossible to come to a definite conclusion on this point at the present time. However, there are a good many indications which point to one molecular process in preference to several others which *a priori* might be possible. These processes are: (1) melting of crystallites; (2) disappearance of long-range order as in the case of metallic alloys,[48] in ferromagnetic substances,[49] and possibly in some polar crystals;[13,50] (3) hindered rotation.[51,**]

The melting of crystallites can be ruled out as the cause of the transition for the following reasons. No latent heat of fusion has ever been found at the transitions under consideration, which means that no sharp discontinuity has been observed in the specific heat and the transition is not of the first order. It should be pointed out, however, that in the case of partly crystalline polymers, one does observe a transition in the mechanical properties;[52] this transition occurs though at considerably higher temperatures than the second-order transition point. Furthermore, in a study of the volume expansion coefficient (α) of amorphous and partly crystalline rubber, it has been shown[53] that the change in α of the latter material at the melting point is only a fraction of the change occurring in α at the second-order transition point, and that the change in α of the amorphous rubber is equal to the sum of the two

separate changes in the partly crystalline material. In other words, the fraction of material which has entered into a crystalline structure does not contribute significantly to the second-order transition at lower temperature. No noticeable change in the x-ray diffraction pattern has been observed in the transition region.

The disappearance of long-range order as a cause of the transition is most unlikely because a transition of that kind presupposes the existence of a "superlattice" for which there exists no experimental evidence in high polymers, at the present time. The rather marked change in the volume expansion coefficient at the transition is another argument against long-range-short-range order transition. Finally, the frequency dependance of the transition—the fact that the transition becomes sharper at lower frequencies and appears to approach a limiting value as $V \to 0$—argues against a transition based primarily on cooperative phenomena.[19]

This leaves the process of hindered rotation[22, 51, 54]—applied here in a very general sense—as the cause of the second-order transition. Experimental evidence available so far and analogies with similar transitions in low molecular weight compounds all favor an interpretation on this basis. First of all, we should recall the volume expansion data on amorphous and partially crystalline rubber, referred to. The non-crystalline phase has its transition at the same temperature and the change in α is of the same type in the amorphous region as it is in the crystalline region. At a given temperature there occurs an "internal" or molecular freezing.[55] This phenomenon has been observed repeatedly in a great many low molecular weight compounds.[54, 56] Such transitions, of which there can be more than one in one compound, are a characteristic property of all solid matter. The close similarity between low and high molecular weight materials is brought out very clearly by the concentration dependance of the transition temperature in polymer-plasticizer compositions.[7, 8, 31, 33, 57] It has already been stated that for several plasticizers transition points have been found experimentally which agree well with extrapolated values from the linear portion of the $T_t - C_v$ curves. It is fortunate that the dielectric and thermal properties of one of these plasticizers, camphor, has been studied extensively[58, 59] where it has been shown that the transitions of this and similar compounds is definitely due to hindered rotation. These studies on camphor furthermore reveal how strongly the transition temperature and the shape of the dielectric constant-temperature curve is affected by slight differences in molecular structure such as *cis-trans*-isomerism. The same has been observed in polymers. Unvulcanized rubber and gutta percha are considered *cis-trans*-isomers exhibiting brittle points at $-58°C$ and $-23°C$, respectively; similarly, the isomers discovered by Schildknecht[60] show characteristic differences in their mechanical properties at room temperature which is indicative of different transition temperatures. It is also of interest to point out that vulcanization leads to an increase in the transition temperature.[5] This has recently been interpreted by Nolle[1] as due to a decrease of the effective chain length between "hindrances." Although vulcanization leads undoubtedly to a large number of crosslinks, it is not the reduced chain lengths which increases the transition temperature, but the increased hindrances which are introduced by sufficiently large amounts of crosslinking.

It appears, therefore, that all available data can be satisfactorily interpreted on the basis of a second-order transition which is due to hindered rotation of complex molecules. The detailed knowledge of the molecular potential which will permit the establishment of a reliable qualitative theory will require more extensive investigation of mechanical, electrical, and thermal properties. The recently developed method of magnetic nuclear resonance[40, 61] should be particularly beneficial.

Mechanical Properties of Oriented Polystyrene Film

LAWRENCE E. NIELSEN AND ROLF BUCHDAHL
Monsanto Chemical Company, Plastics Research Laboratory, Springfield, Massachusetts

Cast films of polystyrene were oriented by stretching at temperatures above the softening temperature of the material and then cooled. A factorially designed experiment was carried out in which the amount of stretching, temperature of stretching, time held in the stretched state before cooling, and effect of several cycles of stretching before cooling were investigated as they affect the birefringence, the stress-strain properties, dynamic modulus and damping, and the softening temperature of polystyrene.

The values of many of the mechanical properties are more closely related to the birefringence than to the amount of hot stretching. In general, the value of the stress-strain properties in the direction of hot stretch, the dynamic modulus, and the birefringence all increase with an increase in the amount of stretching, a decrease in temperature, an increase in rate of cooling after stretching, and a decrease in the number of times the film was stretched before finally cooling. The softening temperature is decreased in direct proportion to the birefringence. Annealed films give higher softening temperatures than films which have been stretched and then allowed to shrink before cooling.

IT is quite well known that often remarkable changes in the physical properties of a high polymeric substance may be brought about by stretching the material while it is at a temperature above its softening point and then cooling it down.[1-3] However, practically no quantitative data have been published showing how the mechanical properties such as the stress-strain characteristics are changed by such a treatment.

This stretching process undoubtedly causes the high polymer molecules to become oriented or arranged in a configuration different from their normal arrangement. On cooling after stretching, the material changes from a soft rubber-like state to a rigid state, thereby "freezing" the molecules in an oriented condition. These lined up molecules, which have different characteristics parallel and perpendicular to their long dimension, give an anisotropic behavior to many physical properties. For instance, the stretched material may show optical anisotropy or birefringence, and the mechanical properties such as ultimate strength may differ greatly parallel and perpendicular to the direction of stretch.

Orientation phenomena are very complex in nature not only because there are many variables such as the amount of stretch and the temperature at which stretching took place but also because of the fact that there are different kinds of orientation. In this investigation only stretching in one direction will be considered. Furthermore, all the data and discussion to follow except on birefringence apply only to the direction of stretch and not to the direction perpendicular to it. It is to be expected that entirely different properties will be found in the direction perpendicular to the stretch.

The problem of quantitatively measuring the degree of orientation arises. On the basis of past work it appears that the birefringence is one of the best methods of measuring the orientation. The amount of hot stretching is not satisfactory because of the tendency of the molecular segments to assume an unoriented condition. Therefore, for a given amount of hot stretching the number of oriented molecular segments found in the cooled sample depends upon the temperature of stretching, how fast the specimen was stretched, and how long it took the specimen to cool down.

All oriented specimens were made up according to the factorial design given in Table I. A factorially designed experiment was chosen because several variables were to be studied and it was desirable to know to what extent these variables interact with one another. In addition it is possible to obtain the largest amount of

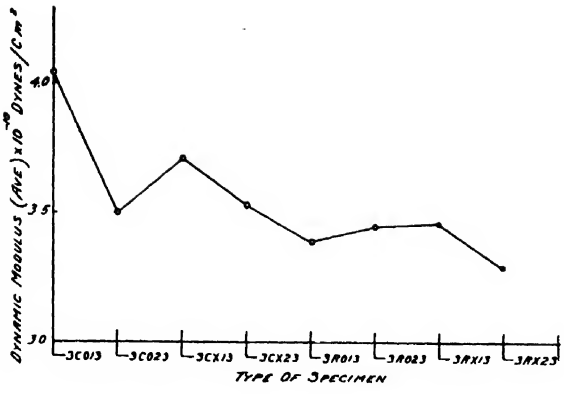

FIG. 1. Dynamic Young's modulus of oriented polystyrene films at 25°C.

information with the smallest amount of work with this type of experiment. All specimens were made from strips of film which before stretching were one inch wide and roughly 0.015-inch thick. These films had been cast from methyl ethyl ketone and were carefully dried and annealed for several days as previously described.[4] Studies were made at three levels of elongation—50 percent 150 percent, and 300 percent hot stretch. Two types of after-treatment were used. In the one case the film was immediately chilled to below the softening temperature after stretching. In the other case the film was held at its final length for 200 seconds before cooling. It has been shown[5] that the birefringence and retractive force of the film are greatly decreased from their initial value after 200 seconds, even though the length has been held constant. Therefore, it was important to be able to separate effects due to elongation from those determined primarily by birefringence or "frozen in" stresses. From our previous work,[5] it had been found that such properties as creep depend upon whether the film had been used previously for such a test. Therefore, for lack of a better term the effect of "working" was investigated. In Table I "O" stands for stretching with no previous working while X means the sample was twice stretched and then allowed to shrink to nearly its original length before the film was stretched again and then cooled. Stretching was carried out at two different temperature levels. At 105°C the film is quite stiff and only slightly rubber-like in nature while at 115°C the polystyrene films are very much like a rubber. In the code numbers to designate the specimens the first numbers 1, 2, and 3 stand for 50 percent, 150 percent, and 300 percent elongation, respectively. Figures 1 and 2 in fourth position of the code numbers indicate 105°C and 115°C, respectively. The number of the sample is given by the last number of the code. For example, a code number 2CO13 would mean the sample had been elongated 150 percent and immediately chilled without working at a temperature of 105°C and that it was the third such specimen prepared. In addition to these 24 types of oriented films some experiments for comparison were made on annealed unoriented films and worked unoriented films. These latter were prepared by stretching and shrinking the film twice before cooling down with no stretching. Actually in most cases the worked films did not completely shrink to their original length; the birefringence, though, was either zero or very small compared to the oriented films.

The following measurements were made on these films: birefringence, tensile stress-strain tests, softening temperature, dynamic Young's modulus, and mechanical damping.

DYNAMIC MECHANICAL TESTS

Since it was suspected that the dynamic Young's modulus and mechanical damping were not radically changed by orientation in the case of polystyrene, only specimens elongated 300 percent were studied. The dynamic properties were determined with an electromagnetic reed vibrator.[4, 6–8] The modulus was calculated from the resonance frequency and the damping from the half-width of the resonance peak. (The half-width of the resonance peak may be expressed as the ratio of the imaginary to real part of Young's modulus by dividing the half-width by $\sqrt{3}$.) The results at 25°C and 30 c.p.s. are summarized in Table II and Fig. 1. Results on annealed and worked films are also included.

Figure 2 compares the damping (half-width of resonance peak) for annealed, worked, and typical oriented (3RX23) films as the temperature is varied.

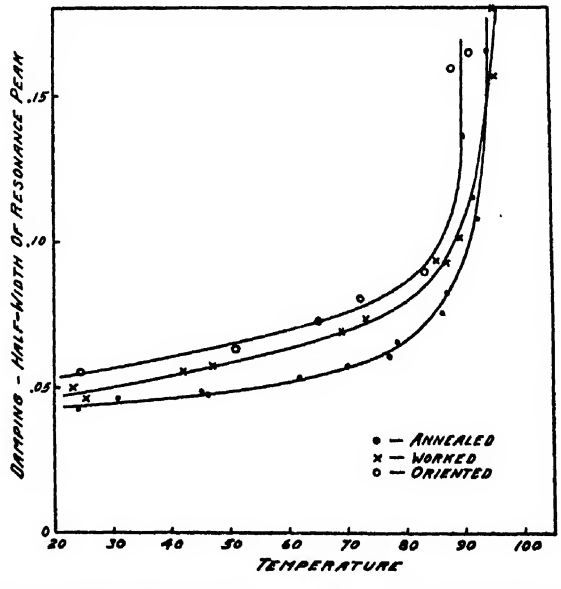

FIG. 2. Mechanical damping as a function of temperature for annealed, worked, and typical oriented polystyrene films.

TABLE II. Dynamic mechanical properties of oriented and unoriented polystyrene films at 25°C.

Type of film	Birefringence A/mil (av.)	Dynamic Young's modulus (dynes/cm²)	Half-width of resonance peak	No. of specimens tested
Annealed	0	$3.24\pm0.10\times10^{10}$	0.046 ± 0.002	5
Worked	~0	$3.18\pm0.14\times10^{10}$	0.049 ± 0.0015	4
3CO13	4500	$4.04\pm0.20\times10^{10}$	0.054 ± 0.002	6
3CO23	2640	$3.50\pm0.09\times10^{10}$	0.049 ± 0.001	3
3CX13	4280	$3.71\pm0.19\times10^{10}$	0.053 ± 0.004	3
3CX23	1970	$3.53\pm0.24\times10^{10}$	0.051 ± 0.002	4
3RO13	2090	$3.39\pm0.08\times10^{10}$	0.051 ± 0.002	3
3RO23	864	$3.45\pm0.13\times10^{10}$	0.056 ± 0.004	3
3RX13	1580	$3.46\pm0.12\times10^{10}$	0.050 ± 0.004	3
3RX23	814	$3.29\pm0.16\times10^{10}$	0.056 ± 0.000	3

On the basis of these results, it is seen that orientation increases the modulus of polystyrene. Comparison with birefringence data indicates the dynamic modulus varies in about the same way as the birefringence. Damping also increases with orientation but only slightly and part of this increase may be attributed to the effect of working which automatically takes place during the process of stretching the film. Both orientation and working lower the transition temperature range where the damping increases very rapidly with temperature.

BIREFRINGENCE AND STRESS-STRAIN DATA

The birefringence and stress-strain data are given in Table III. The notation is the same as used in Table I. Duplicates were made of all the specimens.

The birefringence was measured by a Babinet compensator using polarized light. Figure 3 indicates how the average birefringence changes with the different types of specimens. The birefringence of films stretched at 105°C is always considerably higher than that of films stretched at 115°C, the other conditions being held constant. Chilling the film immediately after stretching gives a higher birefringence than if the film is held in the stretched state for 200 seconds before cooling. Of course, the greater the elongation the greater is the birefringence if the other variables are held constant. Working has very little effect. An analysis of variance[9] was carried out on these data and the effects of the variables temperature, amount of stretching, and after-treatment were found to be significant at the 99.9 percent level of confidence. There seems to be no interaction of the variables in the case of birefringence.

The stress-strain data were obtained on an Instron machine[10] using a crosshead speed of 0.2 inch/minute and a specimen length of 2 inches between the clamps. The tests were conducted at a temperature of 25°C under a relative humidity of 50 percent. Table III also contains data on unoriented annealed and unoriented worked films for comparison; these data are the average

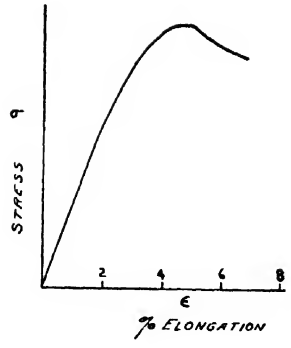

FIG. 4. A typical stress-strain curve for oriented polystyrene films.

specimens gave a yield value. A typical stress-strain curve is given in Fig. 4.

The variation in Young's modulus for the different types of samples is illustrated in Fig. 5. It will be noted that the modulus shows some of the same general trends as the birefringence. The modulus increases with the amount of hot stretching and usually decreases with temperature. However, the analysis of variance indicates the effects of these variables to be at only about a 90 percent level of significance and are largely covered up by a large interaction between elongation and after-treatment. The effect of working and after-treatment on the modulus is not significant. All the oriented films have higher moduli than annealed or unoriented worked films.

The analysis of the data on elongation to break the specimens indicates the elongation increases with the amount of stretching (99 percent level of significance), it decreases with increase in temperature (99 percent level of significance) and it decreases with working (99.9 percent level of confidence). The elongation to break is greater for chilled than relaxed specimens with a level of confidence of 99.9 percent. There are no interactions between the variables for the data on elongation to break. During the tests it was noted that if a yield point was reached, all further elongation took place near this yield point in a small band across the specimen. Much larger elongations would have been observed if all the specimen had elongated as much as that portion near the original point of yielding.

The energy to break a specimen, that is, the area under the stress-strain curve, is relatively free of interactions between the variables also. The more the specimen is stretched while soft the greater is the energy to break (99.9 percent level of significance). Increasing the temperature decreases the area under the stress-strain curve (99 percent level of significance). The values are larger for chilled than relaxed specimens (99.9 percent level of significance). Working decreases the energy to break (99 percent level of significance). The energy to break also shows the same general trends as the birefringence.

The ultimate strength is a complex function of the variables studied, although all the oriented specimens gave higher values than the unoriented ones. The analysis of variance indicated the most significant factor was a very strong interaction between the three variables, amount of stretch, after-treatment, and temperature. Undoubtedly, some of this complexity is brought about by the fact that some of the specimens had yield points and others did not. Most of the specimens which did show yield points gave low values of tensile stress once the yield point was passed, as is shown in Fig. 4. Those films with the greatest amount of hot stretching in general gave yield values while the films with the least amount of stretching broke at the yield point or before. Therefore, the expected increase in ultimate strength with amount of stretching was not picked up.

An analysis of variance was not made on the elongation at yield and the stress at the yield point since some of the films did not show a yield point. Certain general conclusions may be made though. The greater the amount of hot stretching the greater is the possibility of reaching a yield point. Most of the films with 50 percent stretching broke at the yield point or before it was reached. Neither the elongation at yield nor the yield stress depends to any great extent on the temperature of stretching, after-treatment, or working. Although none of the unoriented annealed films gave a yield point, all the unoriented worked films did, surprisingly enough.

In the cases where there are no interactions of the variables as shown by the analysis of variance, it is possible to calculate quite accurately the variation of the properties as the variables are changed. These results are summarized in Table IV.

Since many of the mechanical properties appear to vary in the same manner as the birefringence, correlation coefficients were determined. The results are summarized in Table V. These correlation coefficients were found for the following equations:

$$10^{-5}E = 2.50 + 0.85 \log B$$
$$\epsilon_b = 3.26 + 1.65 \log B$$
$$\sigma_b = 5708 + 3510 \log \log B$$
$$\log(A - 3.00) = 0.13 + 0.32 \log B.$$

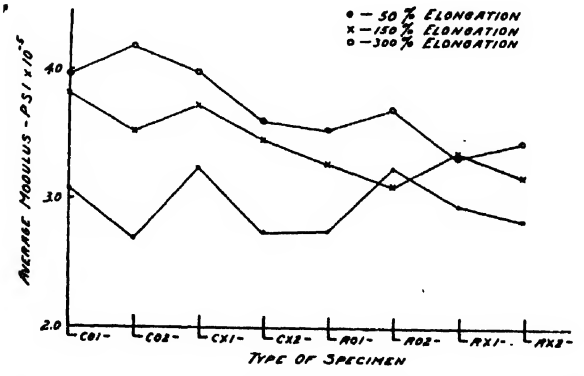

FIG. 5. Young's modulus calculated from the initial slope of the stress-strain curves of oriented polystyrene films. The code designating the types of specimens is given in Table I.

TABLE IV. Relative value of properties on changes of variables.[a]

Property	ϵ_2/ϵ_1	ϵ_3/ϵ_1	T_2/T_1	t_2/t_1	W_2/W_1
Birefringence	2.76	5.74	0.52	0.39	1.0
Elong. @ break	1.09	1.23	0.86	0.83	0.84
Energy to break	1.40	1.72	0.80	0.73	0.77

[a] The reference values are: ϵ_1 = 50 percent hot stretch; T_1 = 105°C; t_1 = chilling after stretching; W_1 = no working. The other variables are: ϵ_2 = 150 percent; ϵ_3 = 300 percent; T_2 = 115°C; t_2 = relaxed before cooling; W_2 = working.

TABLE V. Correlation of birefringence with stress-strain properties.

Variables	Correlation coefficient
Birefringence and Young's modulus	0.813
Birefringence and elongation	0.717
Birefringence and tensile strength	0.802
Birefringence and energy to break	0.864

In these equations B = birefringence in A/mil$\times 10^{-2}$, E = Young's modulus in pounds/square inch, ϵ_b = percent elongation at break, σ_b = tensile strength in pounds/sq. in., and A = the energy to break in arbitrary units.

Table V shows that the stress-strain properties of oriented polystyrene films are very closely related to their birefringence. It is known that birefringence is a fairly good quantitative measure of orientation, and it appears that the mechanical properties are primarily dependent also upon this degree of orientation. The effects of such variables as temperature, after-treatment, and working are, to a first approximation, important only to the extent they change the birefringence. However, the importance of these other variables cannot be completely overlooked in interpreting the stress-strain properties of oriented polystyrene.

SOFTENING TEMPERATURES

One of the most important properties of plastics from the practical standpoint is a softening temperature. This softening temperature may be defined in various ways, but in all cases it gives an indication of the temperature range where the material goes through a transition from a hard, rigid substance to a soft, rubbery one.

If an oriented film is placed in an oven in which the temperature is gradually increasing, the length of film will remain nearly constant until the softening temperature is reached. Over a very narrow temperature range, the film will then rapidly shrink in length as the orientation starts to disappear. Müller[3] has shown that the softening temperature is lowered as the birefringence of the oriented films increases. This has been checked using films whose birefringence has been varied by different amounts of stretch, stretching at different temperatures, and by different after-treatments. Results are given in Table VI and Fig. 6. The softening temperature was arbitrarily defined as that temperature at

TABLE VI. Change in softening temperature with birefringence.

Film No.	Birefringence A/mil.	Softening temperature °C
2RX23	400	95.3
2CO23	1020	93.5
2CX13	2150	91.0
3CO13	5950	83.2

which the specimen had shrunk one percent. The temperature of the oven was increased at the rate of about ½°C per minute.

From these results, it is obvious that the lowering of the softening temperature is primarily dependent upon the birefringence and not upon other possible variables such as elongation or after-treatment.

The softening temperature is also altered by an externally applied force[11] or by working. The effect of stress was verified by gradually heating the specimens to which tensile loads of different sizes were applied by hanging weights from clamps. The length of specimen remains nearly constant till a very sudden increase in length takes place on reaching the softening range. Some of the data are illustrated in Fig. 7, where the softening temperature was again taken as the temperature where the total elongation was 1 percent. The worked films give a softening temperature several degrees lower than annealed films. Since some working automatically takes place in the process of orienting the films by stretching, it is to be expected that the softening temperature extrapolated to zero birefringence (see Fig. 6) would be lower than the softening temperature obtained by extrapolating to zero external force (see Fig. 7). This turns out to be the case, the values being 96.6°C and 98.0°C respectively.

DISCUSSION

On the basis of the data presented here and in the past,[3,6] it has been shown that orientation or the

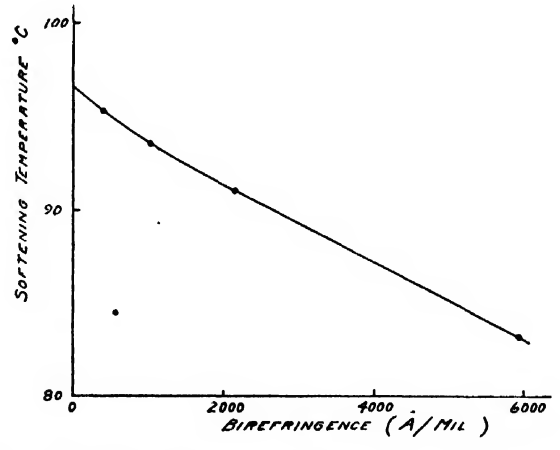

FIG. 6. Variation of softening temperature with the birefringence of oriented films.

[11] R. F. Boyer and R. S. Spencer, J. App. Phys. 16, 594 (1945).

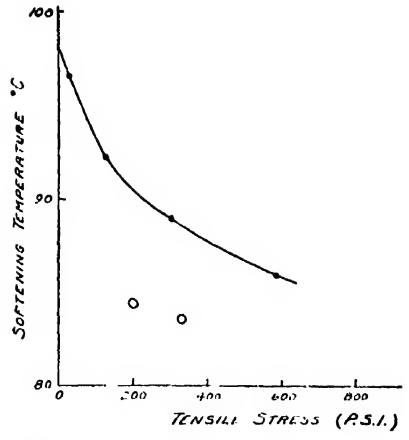

FIG. 7. Variation of softening temperature with tensile load for annealed polystyrene films. The two points enclosed in circles are for unoriented worked films.

lining up of molecular segments is far more accurately measured by birefringence than by the amount of hot stretching in the case of polystyrene. Widely different values of birefringence may be obtained with the same amount of stretching by changing the temperature at which stretching takes place, or by holding the hot film in the stretched state for some time to allow some of the molecular segments to resume their normal relaxed state. Such properties as the softening temperature, and elastic modulus reflect the changes in birefringence which are brought about by these different treatments.

We attribute the decreased birefringence and changes in mechanical properties which accompany an increase in the stretching temperature as due primarily to the molecules being able to assume a relaxed or unoriented condition more rapidly as the temperature increases. Similarly, most of the changes brought about by the after-treatments, such as chilling immediately after stretching or allowing some time to elapse before cooling, may be explained in terms of the degree of orientation "frozen" into the cooled films.

Some of the phenomena which appear to be influenced by "working" may be due to the partial destruction of the network structure of entangled and intertwined molecules found in polystyrene.[5] Other effects such as the lowering of the softening temperature are believed to be due to non-equilibrium conditions existing in worked films. In an annealed film the molecules have had time to assume their most probable shapes and configurations. However, on stretching and shrinking a film, many molecular segments are forced into positions and shapes not most favorable for them; this working would then be expected to decrease the density of the material over that found under equilibrium conditions existing in annealed films. This slight increase in the average distance between molecules of the worked films would be expected to lower the softening temperature somewhat.

We wish to express our appreciation to Mr. C. H. Adams and to the Fabrics Research Laboratory for their help in securing the stress-strain data and to Mr. E. C. Harrington who carried out the statistical analysis of the data.

A Non-Destructive Mechanical Test for Animal Fibers

HARRIS M. BURTE*
The Textile Research Institute and the Department of Chemical Engineering, Princeton University, Princeton, New Jersey

The slope of the force-extension curve in the Hooke's law region can be measured non-destructively, for animal fibers, at three to fifteen minute intervals. The change of this Hookean slope with time is used to follow the course of the heterogeneous reaction between wool and a reagent.

Data are presented on the interaction between concentrated neutral salt solutions and wool fibers. These results indicate that wo processes occur: (a) Relatively rapid hydration or dehydration of the fiber until equilibrium with the activity of water in the salt solution is attained; (b) Relatively slow absorption of salt ions by the fiber. Very concentrated salt solutions dehydrate the fiber so completely that absorption of salt ions is not possible. Swelling experiments and experiments involving other mechanical properties confirm these hypotheses. The interaction between wool fibers and aqueous solutions of large organic molecules follows a similar pattern.

MOST natural high polymers are chemically and morphologically quite complex. A study of the mechanisms and kinetics of their reactions using the classical methods of chemical analysis is frequently a laborious task. Their mechanical properties, however, are easily measured, and usually are strongly affected by chemical treatment. The investigation of chemical reactions by using a mechanical property as the measured parameter has therefore attained some popularity. The present work is concerned with a further extension of these mechano-chemical methods[1] in the field of animal fibers, e.g. hair and wool.

Speakman[1] has developed a non-destructive mechanical test with which he and others have investigated many of the changes resulting from treatment of wool fibers. The basis of the method is the fact that if a wool fiber is rapidly stretched to not more than 30 percent extension in cold water, contracted and allowed to rest 24 hours in cold water before re-extending, the second force-extension curve will closely duplicate the first. Thus, if a chemical reaction were carried out on the fiber just before the second test, the difference between the first and second force-extension curves would be due solely to the effect of the chemical reaction. The initial extension to 30 percent coupled with the rest in water was a non-destructive test. The advantages of such a test are very great; since both measurements are made on a single fiber, the need for cross-sectional area or denier measurements is eliminated and the problem of fiber-to-fiber variance is largely circumvented.

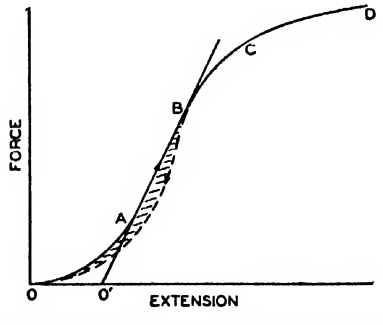

FIG. 1. Typical force-extension curve in the low range of extensions.

One objection to the test described above is the long time necessary between successive measurements. Furthermore, in order to follow the change of mechanical properties with time of treatment, a series of fibers must usually be used with the introduction of errors due to fiber-to-fiber differences. Speakman[1] points out that 30 percent extension is merely a general limit applicable to most animal fibers, and that for special conditions less drastic extensions might be needed. In the present work attention was focused on the Hooke's law region of the force-extension curves. Figure 1 shows a typical force-extension curve for a single wool fiber. In the region O–A the crimp of the fiber is being removed, in the region A–B (Hooke's law region) the force is linear with extension, in the region B–C the curve begins to depart from linearity and at some position, C, the yield point is reached. Extension of the fiber is usually measured from point O', and C generally occurs at from one to two percent extension. The slope of the curve in the linear region A–B will be called the Hookean slope. The fiber is not acting like a true Hooke's law spring in this region, since the contraction curve (dotted line) is always of initially steeper slope than the extension curve and a hysteresis loop (cross hatched) is formed. The Hookean slope is, however, a perfectly definite property that can be measured quite accurately. Dividing it by the cross-sectional area of the fiber will give a quantity analagous to Young's modulus.

Woods[2] has measured the Hookean slope for wool and hair as a function of relative humidity. He states that "under a very wide range of conditions an extension of the fibre by one percent or so involves no change in the fibre properties." The conditions under which the Hookean slope measurement is non-destructive were more closely investigated in the present work.

EXPERIMENTAL TECHNIQUE

Measurements of all mechanical properties were made with the Instron Tensile Tester.[3] Usually, the fiber was

[3] H. Hindman and G. S. Burr, Trans. Am. Soc. Mech. Eng. 71, 789–796 (1949).

extended slightly into the region B–C, and immediately contracted. For sample lengths of one to three inches, the rate of extension used was 0.10 in. per minute. Depending upon the fiber type and conditions of testing, it was possible to make a measurement of the Hookean slope every 3 to 15 min. without any dependence of the Hookean slope on the number of determinations. The shorter time intervals were for water soaked fibers; as the relative humidity of the air surrounding the fiber decreased, the longer time intervals were needed. If the time intervals between measurements were too short, successive values of the Hookean slope would show a slight increase. The fact that both of the above observations are due to imperfect elasticity of the fiber, even when it is extended only one to two percent, is shown in Fig. 2. The time interval between extensions was three to four minutes, the amount of semi-permanent set caused by the first extension was only 0.125 percent, yet it caused an increase in the Hookean slope of 7.3 percent (i.e., from 33.1 to 35.5 g/cm). When a sufficient time interval was allowed, successive measurements were reproducible to about ±1 percent. Furthermore, the test is non-destructive when performed on chemically treated fibers, whereas an extension to 30 percent would often cause a permanent change in fiber properties. Therefore, it is possible to use a *single* fiber to follow the change of Hookean slope as a chemical reaction with the fiber proceeds, and the change in Hookean slope will be due solely to the effect of the reaction. Tobolsky and Andrews[4] have performed similar experiments with rubber, calling the method "intermittent relaxation."

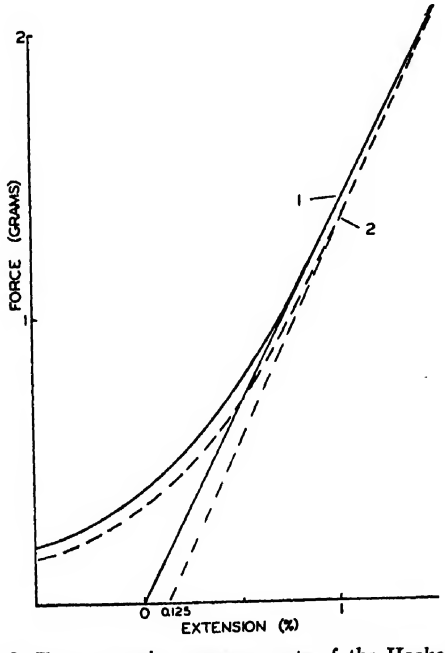

FIG. 2. Two successive measurements of the Hookean slope. (Three to four minute interval between extensions. R.H.=65 percent.) 1—First extension, Hookean slope=33.1 g/cm. 2—Second extension, Hookean slope=35.5 g/cm.

THE INTERACTION BETWEEN WOOL AND CONCENTRATED NEUTRAL SALT SOLUTIONS

As an example of the use of the non-destructive Hookean slope technique, some work on the heterogeneous reaction between single wool fibers and concentrated neutral salt solutions will be described.

Sookne and Harris[5] have shown that the mechanical properties of wool fibers immersed in concentrated solutions of neutral salts are not the same as the properties when in an atmosphere in equilibrium with these solutions. Neither are they the same as the properties of the fiber in pure water. In the present work, fibers at different initial conditions were treated with various concentrated neutral salt solutions. The change of Hookean slope with time of treatment was measured, and was plotted as k/k_0 *vs.* time, where k is the Hookean slope at any time after the reaction has started, and k_0 is the Hookean slope at zero time. The dimensionless quantity (k/k_0) is Woods' "relative Young's modulus."[2]

The fibers studied were from a sample of Columbia ewes wool, 56's grade, which had been cleaned by successive ether extractions and water washings. Single fibers were mounted in suitable containers by means of small hooks and de Khotinsky cement (Fig. 3). The container was attached to the Instron crosshead, the wire hook to the Instron load cell. All values of the Hookean slope were corrected for the small error introduced by the deflection of the load measuring element of the Instron Tester.

The curves of relative modulus (or relative Hookean slope) *vs.* time, for initially wet fibers that were treated with saturated salt solutions, are given in Fig. 4. The following explanation is proposed:

(a) Since the diffusion of water into, and out of, the fiber is probably much more rapid than the diffusion of salt ions, the first process to occur on immersing the fiber in a salt solution will be a dehydration or hydration of the fiber (depending upon its initial state) to a state in equilibrium with the activity of water in the salt solution. For the present purposes, the activity of the water can be indicated by the relative humidity over the solution. Woods[2] and Speakman[6] have shown that

[5] A. M. Sookne and M. Harris, American Dyestuff Reporter 26, 659–666 (1937); 27, 171–173 (1938).

[6] J. B. Speakman, J. Soc. Chem. Ind. 49, 209T (1930).

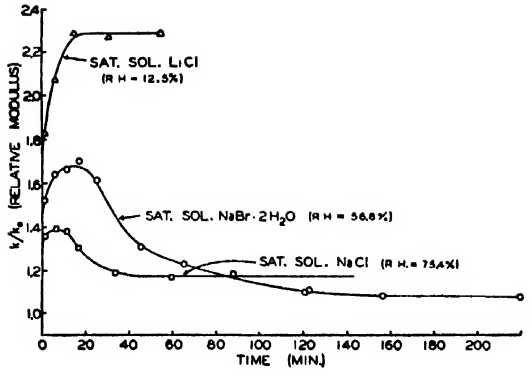

FIG. 4. Relative modulus *vs.* time after adding saturated salt solutions to an initially wet fiber.

dehydration of the fiber will cause the Hookean slope to increase.

(b) Concurrently, a slower process of absorption of the salt ions by the wool fiber occurs. These ions form lyospheres around charged centers in the fiber which are probably the acidic and basic side chains. Lundgren and co-workers[7] have proposed a very similar scheme to account for the effect of salts on synthetic feather keratin fibers. Absorption of the salt ions decreases the Hookean slope by either breaking salt linkages, or increasing the separation of the long polypeptide molecular chains of which the wool is composed. Both mechanisms may be important.

(c) If the activity of water in the salt solution is very low, the consequent rapid dehydration of the fiber may reduce the swelling to such an extent that the slower subsequent diffusion of the salt ions into the wool fiber is greatly hindered. Speakman[8,9] has shown that a wet fiber will absorb molecules that are too large to diffuse into a dry fiber.

Thus, when the fiber was treated with a saturated solution of either sodium chloride or sodium bromide (Fig. 4) the first process was one of dehydration causing the relative modulus to increase. Note that, as expected, the lower the relative humidity over the solution, and thus the greater the dehydration, the greater was the initial increase in relative modulus. The concurrent

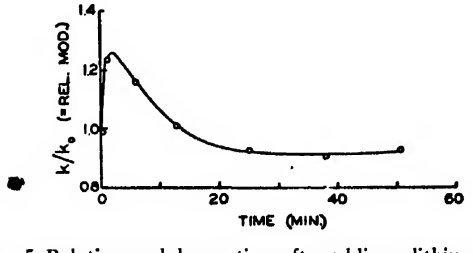

FIG. 5. Relative modulus *vs.* time after adding a lithium chloride solution (one vol. saturated solution, 2 vol. water) to an initially wet fiber.

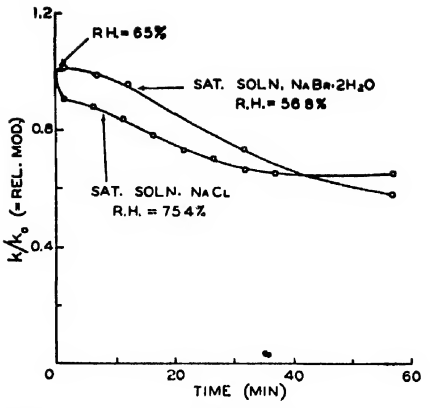

FIG. 6. Relative modulus *vs.* time after adding saturated salt solutions to a fiber initially at 65 percent R.H.

slower absorption of salt ions caused the decrease after the maximum. The bromide causes a greater decrease than the chloride, but the reason for this is not clear. The upper curve, obtained with the saturated lithium chloride solution with a very low partial pressure of water vapor over it, shows no evidence of the absorption of salt although some absorption undoubtedly took place in the early stages of dehydration before the molecular network was sufficiently dehydrated to forbid further diffusion of the salt ions. It might be pointed out that all the curves of Fig. 4 were obtained on the same fiber. It had previously been found that prolonged washing in water would remove all of the absorbed salt, and leave the fiber in its initial state. As might be expected, when a fiber in equilibrium with a saturated sodium bromide or sodium chloride solution was immersed in water, the relative modulus-time curve was found to go through a minimum as first water diffused into the partially dehydrated fiber and then the salt ions diffused out.

For an unsaturated lithium chloride solution, the dehydration of the fiber should not be great enough to prevent absorption of the salt ions, and a maximum in the relative modulus-time curve should be observed. In Fig. 5 this effect is shown for a different fiber from the one illustrated in Fig. 4. Note that, for this concentration of lithium chloride the Hookean slope finally decreased below the initial value in water. This action might be expected, since Alexander[10] has pointed out that lithium salts will cause hydrogen bond breakdown, which would be in addition to the salt effect described above.

When a fiber initially conditioned at 70°F, 65 percent R.H. was brought into contact with a saturated sodium chloride solution the relative modulus-time curve (Fig. 6) decreased rapidly at first as water was absorbed to bring the fiber to equilibrium with the higher activity of water, corresponding to a relative humidity of 75.4 percent, in the salt solution. This decrease was followed

[10] P. Alexander, Research **2**, 246–247 (1949).

by another slower one as salt ions were absorbed. When, however, a different fiber initially at 65 percent R.H. was immersed in a saturated sodium bromide solution (R.H. = 56.8 percent) the relative modulus-time curve went through a slight maximum as the two effects of slight further dehydration of the fiber and absorption of salt ions opposed each other. Eventually, the relative modulus decreased as the ions were absorbed. When this fiber was then removed from the bromide solution and allowed to come to equilibrium with a 65 percent R.H. atmosphere, a slight further decrease of the relative modulus was noted. The latter decrease resulted from the fact that water could be absorbed from the atmosphere (which was at a higher relative humidity than that corresponding to the saturated sodium bromide solution), but the salt ions could not escape. On washing the fiber with water and once more allowing it to stand at 65 percent R.H., the initial value of the Hookean slope was recovered, i.e. the relative modulus became 1. The experiment just described proves that the fiber absorbs salt ions from the solution and that this absorption affects its mechanical properties.

In Fig. 7 are given the relative modulus *vs.* time curves for a series of initially wet fibers which had been treated with a saturated sodium bromide solution. The striking fact is the large fiber-to-fiber variance. It is obvious that, lacking the Hookean slope non-destructive test wherein a *single fiber can be used to follow the entire course of the reaction*, a relatively large number of samples would have had to be tested to clearly indicate the reaction mechanism.

THE INTERACTION BETWEEN WOOL AND GLYCERINE SOLUTIONS

The behavior of the fiber in concentrated salt solutions is in many respects similar to what one would expect in aqueous solutions of large polar organic molecules. Speakman[9] has described such systems (e.g. glycerine-water-wool). If a dry fiber is treated with the anhydrous liquid, the molecular network of wool is too tight for many glycerine molecules to diffuse into the fiber. If, however, an aqueous solution of glycerine is used, the water swells the fiber to an extent permitting absorption of the glycerine molecules. In the first case,

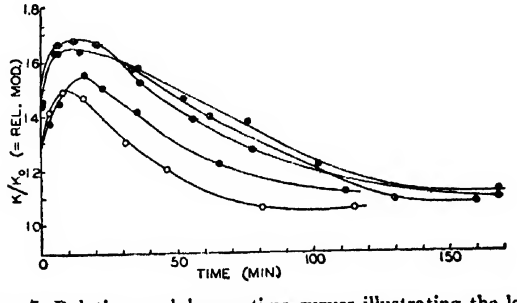

FIG. 7. Relative modulus *vs.* time curves illustrating the large fiber-to-fiber variance (initially wet fibers treated with a saturated sodium bromide solution).

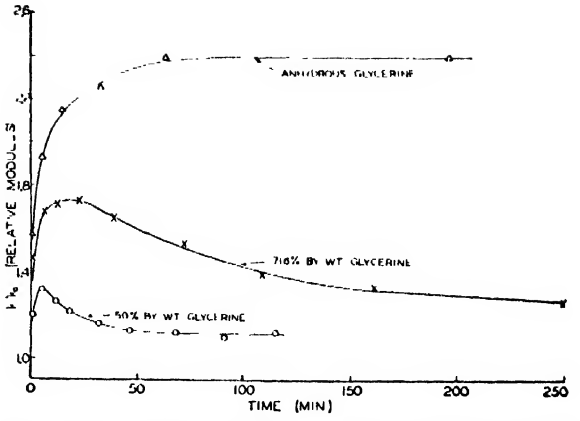

FIG. 8. Relative modulus *vs.* time after adding glycerine solutions to an initially wet fiber.

the behavior should correspond to that for a saturated lithium chloride solution. In the second case, on adding an aqueous glycerine solution to an originally wet fiber, the relative modulus-time curve should go through a maximum. The data of Fig. 8 bear out these hypotheses. The curves for the aqueous solutions are for the same fiber, but that for the anhydrous glycerine is for a different fiber.

USE OF OTHER MECHANO-CHEMICAL METHODS

Extension to 30 Percent

The non-destructive test involving a 30 percent extension was also used for a comparison with the results using the Hookean slope. Figure 9 shows force-extension curves on a human hair fiber extended 30 percent of its original length. A 24-hour rest period in water was allowed to elapse between each extension. Curve *a* is the initial extension in water. Curve *b* is an extension after the fiber had been standing in a saturated sodium chloride solution for 42 min. Curve *c* is a re-extension in water after the salt had been washed out. The reaction occurring in *b* was reversible, and the fiber could in this case be reused. Curve *d* resulted after the fiber had been standing in saturated salt solution for 15.5 min. It is evident that the curve of energy to extend 30 percent *vs.* time must go through a maximum. Also, if the amount of semi-permanent set resulting from extending to 30 percent and then contracting at the same rate were plotted against time, the curve would go through a maximum. Both of these facts are in accord with the explanation developed by using the Hookean slope measurement.

Repeated Cycling Technique

One further mechanical testing technique will be mentioned. When a wet wool fiber is subjected to repeated extensions to a fixed elongation, the force-extension curve is shifted progressively lower on the force axis, (Fig. 10). (The rate of extension used here was about 50

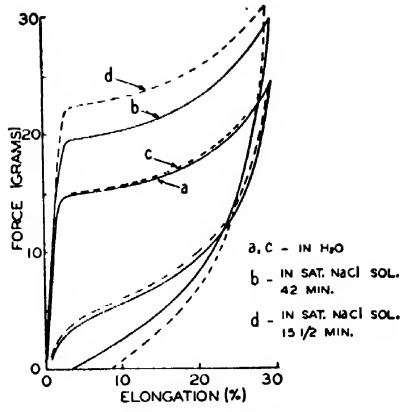

FIG. 9. Force-extension curves to 30 percent extension.

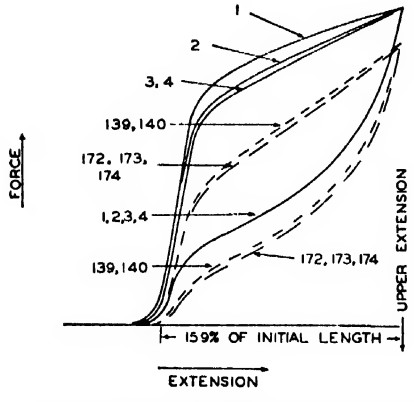

FIG. 10. Successive extension-contraction cycles on a wet wool fiber.

percent per minute.) After a number of cycles, however, the rate of change with number of cycles becomes very slow (compare cycles 140 and 172 of Fig. 10). If, at such a point, some substance which interacts with wool is introduced, the entire change in the force-extension curve should be due substantially to the effect of the extraneous substance on the wool fiber. With the Instron Tester the repeated cycling of the fiber can be made automatic. There are, however, several limitations to this method. (a) The effect of the reaction on a mechanically degraded, rather than the initial undamaged fiber, is being studied. (b) The continued cycling may cause further breakdown due to the repeated stressing of the reacted fiber, whereas it would not do so with the original fiber. This may obscure the main value of the experiment which is to measure the progressive change of mechanical properties of wool with time of reaction. (c) The force-extension curves become somewhat difficult to interpret if practically 100 percent elasticity is not displayed.

In spite of these limitations the method has some value as shown by the results of its application to the interaction between wool and a saturated salt solution (Fig. 11). The repeated cycling technique gave much the same information as the non-destructive extension to 30 percent method in a fraction of the experimental time. The saturated salt solution was sodium chloride and the fiber was subjected to 175 extension-contraction cycles before the solution was added.

Swelling Experiments

In accord with the results of the mechano-chemical experiments, White and Barnard[11] of this laboratory have shown that, when an initially wet hair fiber is immersed in a concentrated salt solution, the swelling *vs.* time curve goes through a minimum. When very concentrated solutions such as saturated lithium bromide are used, the swelling decreases and does not thereafter increase.

WORK IN PROGRESS

If a fiber is initially conditioned to the relative humidity existing over a salt solution before being

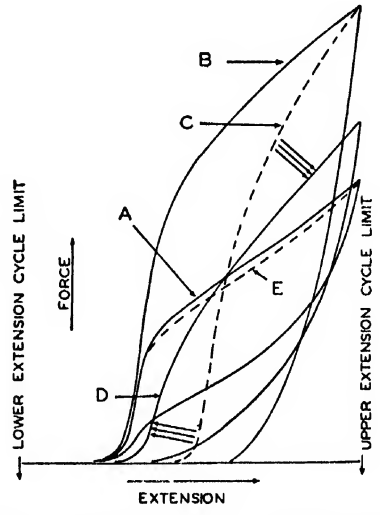

FIG. 11. Repeated cycling technique applied to the interaction between a wool fiber and a saturated sodium chloride solution. A—in water before adding salt solution; B—first cycle after adding sodium chloride solution; C—second cycle in salt solution; D—54 min. after adding salt solution; and E—first cycle after replacing salt solution with water.

[11] H. J. White, Jr. and W. S. Barnard (unpublished communication).

treated with the solution, the initial hydration or dehydration will be eliminated, and the only effect measured should be that of the absorption of the salt ions. Figure 12 shows the relative modulus-time curve for a fiber, initially conditioned in a stream of air which had been bubbled through a saturated sodium chloride solution, and then immersed in a saturated sodium chloride solution. By making use of such curves, the rate of absorption of sodium chloride from its saturated solution is being studied as a function of animal fiber type and diameter.

SUMMARY

(1) An investigation has been made of the conditions under which the slope of the force-extension curve in the Hooke's law region may, for animal fibers, be non-destructively measured.

(2) A *single* fiber can be used to investigate a chemical reaction by measuring the change of Hookean slope with time of reaction.

(3) The usefulness of this technique is illustrated by its application to the heterogeneous reaction between wool and concentrated neutral salt solutions. The heterogeneous reaction between wool and aqueous glycerine solutions was also studied.

(4) Other mechano-chemical methods as well as swelling experiments are described. They give results consistent with those for the Hookean slope technique.

(5) A mechanism consistent with the experimental results is presented.

ACKNOWLEDGMENT

The author wishes to thank Professor J. C. Whitwell under whose direction this work was done and Dr. J. H. Wakelin for their many helpful suggestions. It is also a pleasure to acknowledge the support, in the later stages of this work, of the various organizations sponsoring the "International Wool Project" being carried out in the Textile Research Institute Laboratories. These organizations include The Wool Bureau, Inc., representing both the American Wool Council and the International Wool Secretariat, the U. S. Department of Agriculture, the Office of Naval Research and a group of American wool manufacturers.

Equivalent Effects of Time and Temperature in the Shear Creep and Recovery of Elastomers

F. S. Conant, G. L. Hall, and W. James Lyons

Chemical and Physical Research Laboratories, Firestone Tire and Rubber Company, Akron Ohio

An explicit relationship is set forth for the time-temperature dependence of the *viscoelastic* phenomena in the superelastic polymers. An empirical equation that was found to represent adequately the above-mentioned relationship over the entire multiple-temperature curve is of the form: $\log t_e = [C_\alpha/(T-b)]+C_\beta$. Experimental verification is given for the equivalent influence of time and temperature on the creep and recovery of compounds based on Hevea, GR-S, Neoprene GN, Butaprene, and butyl rubber. A comparison of the empirical equation with that of a theoretical reaction-rate equation of Tobolsky and Eyring indicates a temperature dependence of the energy of activation.

INTRODUCTION

THE dependence of creep phenomena on temperature in high polymers is well known, having been observed and discussed by a number of investigators.[1] The experiments show that, for a given time interval, the viscoelastic strain (or recovery) tends generally to rise to a higher level with an increase in the temperature of the experiment. The present series of experiments have disclosed that for rubber-like materials a consistent elevation of the strain-time curves with an increase in temperature is obtained, if corrections are made for the Gough-Joule effect. While a number of empirical relationships describing the dependence of *viscous* flow on temperature have been proposed and analyzed theoretically, no clear-cut, explicit relationships have been set forth for the temperature-dependence of *viscoelastic* phenomena in the superelastic polymers. The closest approach to such a relationship appears to be one based on a temperature function for viscosity, quoted by Leaderman.[1]

The observed nature of the dependence of viscoelastic behavior on temperature implies that it should be experimentally possible to duplicate the strain S_v attained in time t_1 at temperature T_1 with an equal strain S_v attained in time t_2 at T_2. As has been indicated, a series of creep or recovery experiments on a given material, each conducted over the same time interval, but at different T, will yield a family of creep (or recovery) curves; for increasing values of T the curves will lie higher and higher along the S direction. From these considerations emerges the possibility of selecting a series of temperatures for these experiments such that each curve at its termini in the selected time interval will match the termini of the curves obtained at the next higher and lower temperatures. Each terminus provides

[1] For a review of these studies see H. Leaderman, *Elastic and Creep Properties of Filamentous Materials and Other High Polymers* (Textile Foundation, Washington, 1943), pp. 30–33, 75 ff.

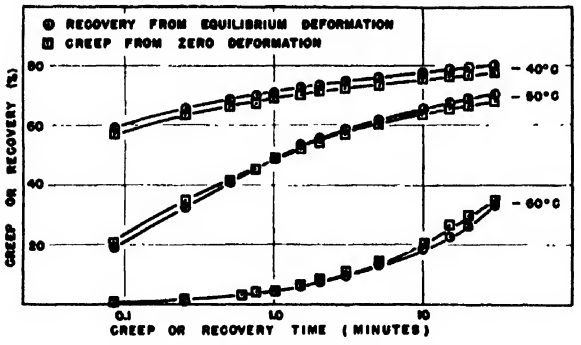

FIG. 1. Equivalence of creep and recovery, Hevea, 35.6 lb /sq. in. load.

the *particular* S_e which, given by one combination t_1 and T_1, can be duplicated by another combination t_2 and T_2. Plotted end-to-end the curves will become segments of one over-all multiple-temperature curve. Tobolsky and Andrews[2] observed such a continuous relationship in analogous stress relaxation tests and proposed an implicit relationship among time, temperature, and stress. Without a knowledge of the time-temperature function, however, it does not appear possible to predict whether the general, synthetic graph will be a smooth curve without discontinuities at the junctions of the segments.

With the aim of testing the foregoing theory, as well as deriving an analytical expression for the relationship between time and temperature, observations in creep and recovery on Hevea, GR-S, Neoprene GN, Butaprene, and Butyl rubber were undertaken.

APPARATUS AND METHODS

The test apparatus used has been described previously.[3] Essentially, it consists of a means of applying a shear stress to a double sandwich-type of specimen, and of observing the deformation of the specimen as test conditions are varied. The test specimens used were also based on the same compounding formulas and cures as given in the above reference.

In the creep tests performed, the unstressed test specimen was first brought to thermal equilibrium at the desired temperature. Twenty minutes conditioning time was allowed after a thermocouple in the center metal web of the specimen indicated that the test temperature had been reached. A shear stress of 35.6 p.s.i. was then applied quickly and the consequent deformation noted at appropriate intervals from 5 sec. to 30 min. after loading. In general, the measurements were made first at the lowest test temperature. After completion of the test the load was removed and the temperature of the test chamber raised. Recovery was usually found to be complete, after conditioning at the next higher test temperature.

In the recovery test the specimen was conditioned overnight (16 hr.) at 35°C under load. At the end of this time, deformation had proceeded to essentially an equilibrium state. The temperature was then gradually lowered to the lowest test temperature, during which time the deformation increased because of the Gough-Joule effect. A curve of equilibrium deformation *vs.* temperature was obtained during the cooling. As soon as thermal equilibrium was reached at the lowest test temperature the load was removed and the recovery noted at appropriate intervals from 5 sec. to 30 min. At the end of this time the load was reapplied and the temperature raised to the next test temperature. The reestablishment of equilibrium deformation was shown by the approach of the deformation to that of the equilibrium curve previously obtained.

In a study of creep or recovery it is often advantageous, if not necessary, to compensate for the Gough-Joule effect, through a normalization of the data. Unless this is done it is found that after a sufficient creep or recovery time the deflection at a low temperature exceeds that at a higher temperature, because of

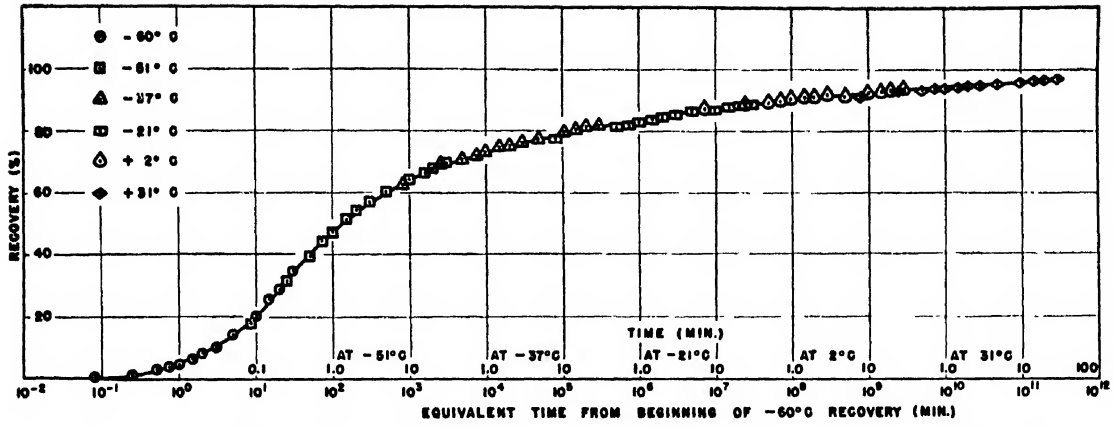

FIG. 3. Recovery from equilibrium deformation, Hevea, 35.6-lb./sq. in. load; adjusted temperature intervals.

this effect. The data presented here were normalized by presenting each creep datum as a percentage of the equilibrium deformation for that temperature and each recovery as a percentage of complete recovery.

Both creep and recovery curves were obtained on all of the stocks in the present series. The normalized data for each showed the two to be equivalent within the experimental error of either Figure 1 shows a typical example of the close correspondence of the two types of data. Only the recovery data will be presented for the other stocks in the series.

JOINING OF RECOVERY CURVES OBTAINED AT DIFFERENT TEMPERATURES

From data such as those shown in Fig. 1, it appears that the creep or recovery curves at different temperatures might be joined end-to-end to form such a continuous, synthetic curve as was projected in the introduction. Such a continuous curve is meaningless, of course, unless the segments are matched so that the logarithmic time scale is continuous. Brief reflection will disclose that it is not necessary actually to procure a continuous locus of experimental points (such as could be obtained only by a fortuitous choice of temperatures) in order to secure a smooth multiple-temperature curve. When a series of parallel curve segments, obtained at reasonably well-scattered temperatures, and overlapping on the time scale, are available, the general continuous curve can be derived by drawing it parallel to these segments. This procedure is illustrated in Fig. 2 which shows 30-min. recovery data for Hevea stock B. The data at some of the temperatures are seen to be displaced from the smooth continuous curve.

The smooth curve of Fig. 2 strongly implies the existence of a continuous functional relationship between normalized creep or recovery time and temperature. Tentatively assuming its correctness, the curve may be used to supply numerical data for a set of simultaneous equations to test various t-functions of T. Following this procedure an empirical equation of the following form has been found to represent adequately the data over the entire viscoelastic region.

$$\log t_c = [C_\alpha/(T-b)] + C_\beta, \qquad (1)$$

where t_c = creep or recovery time, T = absolute temperature, and C_α, b, and C_β are arbitrary constants. The resemblance of Eq. (1) to the Arrhenius formula for the temperature-dependence of rate processes, will be recognized.

While an estimate may be made from data such as those in Fig. 2, of the temperatures at which tests should be made in order that the experimental curve segments should be on the continuous line, it is preferable, by way of testing Eq. (1), to use it to derive the appropriate temperatures. Using the equation and the data in Fig. 2, temperatures of −60°, −51°, −37°, −21°, +2°, and 31°C were selected for test. Figure 3 shows that recovery curves obtained at these selected temperatures do, indeed, form a continuous multiple-temperature curve.

An additional confirmation of the equivalence of time and temperature is provided by the data in Fig. 4. The experimental points show the recovery at −60°C, while the curve shows the joined recovery curves of the same specimen (Hevea stock B). The two are seen to be very nearly equivalent, for the 16-hr. period of test at −60°C.

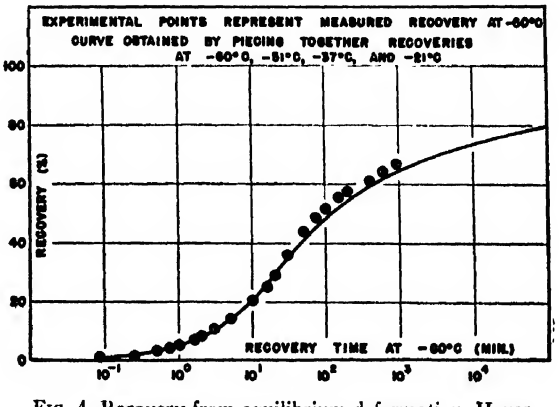

FIG. 4. Recovery from equilibrium deformation, Hevea, 35.6-lb./sq. in. load.

TABLE I. Values of empirical parameters in Eq. (1) for 50 percent recovery from equilibrium shear deformation of various elastomers.

Stock	C_α	C_β	b	Derived test temp. (°C)
Hevea	1780	−17.5	122	−60, −51, −37, −21, 2, 31
GR-S	3121	−19.1	100	−50, −40, −27, −20, −4, 30
Neoprene GN	480	−7.52	193	−40, −32, −20, 0, 40[a]
Butyl rubber	5040	−23.52	33	−60, −46, −38, −30, 0, 40
Butaprene	720	−8.82	183	−30, −18, −10, 0, 30

[a] This is the derived test temperature for the material in the same crystalline state as it was at lower temperatures. In the test made at 30°C some of the crystals had probably melted, resulting in a higher recovery than that calculated. This same singularity appeared in the creep curves for Neoprene GN.

A continuous multiple temperature recovery curve for a GR-S stock is shown in Fig. 5. Test temperatures were selected by an application of Eq. (1) to previous data obtained at even decade temperature intervals. This curve is quite different in shape from that in Fig. 3 for Hevea, reflecting the more sluggish response of GR-S to low temperature stress.

Figures 6–8 show joined together recovery curves at even decade, temperature intervals on motor mounting-type stocks of Neoprene GN, Butyl rubber, and Butaprene. (Formulas are given in reference 3.) Each curve is characteristically sigmoidal. Only the Neoprene GN, however, shows the sharp increase in deformation with time that was evident in the Hevea stock. The Neoprene GN curve also shows a slight upturn at high temperatures, possibly because of the disappearance of a slight degree of crystallization.

An application of the above empirical formula to the data is shown in Table I which gives the constants and derived test temperatures. These calculations were based on the time required for 50 percent recovery at each temperature. The constant C_β is affected by the degree of recovery chosen. The constants C_α and b appear to be properties of the material tested and are independent of the reference point. Values of T and $\log t_e$ were substituted in Eq. (1) at three different temperatures for which the data were on the smooth curve. Solution of the resulting simultaneous equations gave the constants C_α, C_β, and b. The derived test temperatures given in Table I were obtained by an application of Eq. (1) to data obtained at even decade, temperature intervals. If the data shown in Figs. 6–8 had been obtained at the derived test temperatures, then all experimental points should have been on the curves, as they were in Figs. 3 and 5.

The interdependence of time, temperature, stress, and strain in the viscoelastic phenomena is well known. Mullins[4] recognized the need for a test that would use time as a parameter in determining low temperature serviceability. He also stated the need for a simple expression relating time with modulus. Many of the low temperature tests, such as Gehman's torsion test,[5] the Young's modulus test of Conant and Liska[6] and the cold compression set test[7] recognize time only to the extent that they specify a particular loading time in making their measurement. The above-mentioned tests are valuable in that they give the temperature below which, because of change in a particular physical property, the product can no longer be considered serviceable. However, time is not directly included as a parameter in these tests. The T-50 test[8] is arbitrary in that both time and temperature are varied simultaneously. Equation (1) does give a simple relationship between time and temperature, thus enabling time to be used as a parameter in determining low temperature serviceability.

The applicability of the data in Table I in conjunction with Eq. (1) to determine a low temperature serviceability index is readily apparent. For example, one can obtain the temperature at which a stock will recover 50 percent in 1 min. On this basis the stocks tested give the

following indices: Hevea −49.5°C; GR-S −10°C; Neoprene GN −16°C; Butyl rubber −26°C; and Butaprene −6°C. The particular conditions selected for defining the index would, of course, be determined by the use for which the rubber was intended.

THEORETICAL CONSIDERATIONS

In an application of the reaction-rate theory of the mechanical properties of polymers to creep under constant stress, Tobolsky and Eyring[9] arrive at the equation

$$S=\frac{f}{G_1}+\frac{1}{B_2G_1}\ln A_2B_2G_\mu+\frac{1}{B_2G_1}\ln t, \qquad (2)$$

where S= strain in the specimen; f= total stress; G_1 and G_μ are appropriate elastic moduli associated with strains of the primary and secondary network bonds; and t= duration of creep experiment. The quantities A_2 and B_2 are defined by the equations

$$A_2=2n_2\lambda_2(kT/h)\exp(-\Delta F/kT), \qquad (3)$$

and

$$B_2=\lambda_2/2N_2kT, \qquad (4)$$

where k and h are Boltzmann's and Planck's constants, respectively; T is the absolute temperature; F is the free energy of activation for the deformation process; and n_2, λ_2, and N_2 are theoretical quantities related to the unit or elementary process.

If Eq. (2) is written out in full and certain terms are canceled, where possible, we arrive at the equation

$$S=\frac{f}{G_1}+\frac{2NkT}{G_1\lambda_2}\left[\ln\left(\frac{2n_2\lambda_2}{h}\cdot\lambda_2\frac{G_\mu t}{2N_2}\right)-\frac{\Delta F}{kT}\right]. \qquad (5)$$

k and h are well recognized as universal constants. Furthermore, we shall accept the material and structural characteristics, G_1, G_μ, λ_2, and ΔF as being time- and temperature-independent. The parameter N_2, however, Tobolsky and Eyring have deduced, decreases with a rise in temperature, though they do not give an expression for the relationship. We shall assume that the inverse variation of N_2 with absolute temperature is a

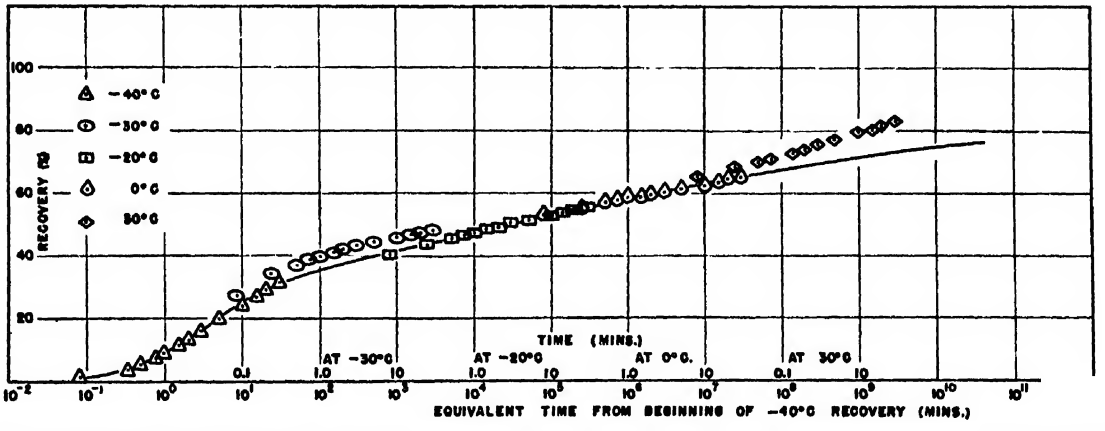

FIG. 6. Recovery from equilibrium deformation, Neoprene GN, 35.6-lb./sq. in. load. Test temperatures taken at multiples of 10°C.

[9] A. Tobolsky and H. Eyring, J. Chem. Phys. 11, 125 (1943).

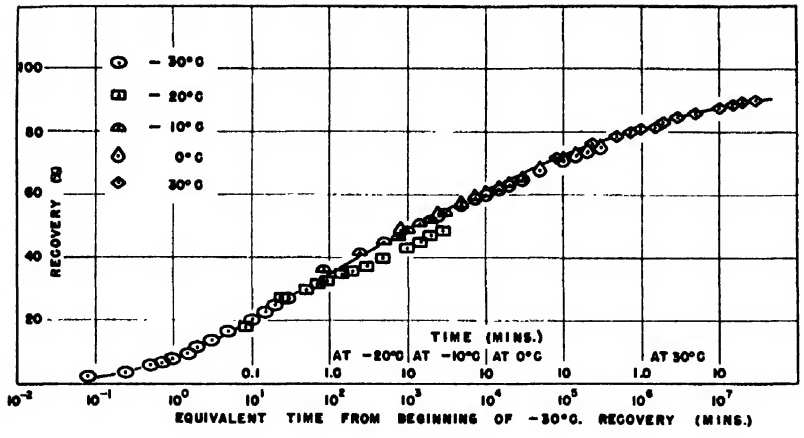

FIG. 8. Recovery from equilibrium deformation, Butaprene, 35.6-lb./sq. in. load. Test temperatures taken at multiples of 10°C.

good approximation, and also, that n_2 effectively varies inversely as the temperature over the range covered by the present experiments. The assignment of this functional dependence to N_2 and n_2 is admittedly quite arbitrary, from the theoretical point of view. However, if the network of secondary bonds can be regarded as behaving like an ideal gas, the assigned dependence on T becomes entirely reasonable, for N_2 represents the number of secondary bonds per unit area, while n_2 is the number of elementary deformation processes per unit length.*

Thus we obtain for the viscoelastic component of the deformation

$$S_v \equiv S - f/G_1 = C_1 \log C_2 t - C_3/T \tag{6}$$

involving the three parameters

$$\begin{aligned} C_1 &= \text{const.} \cdot 2.30(2k/G_1\lambda_2), \\ C_2 &= \text{const.} \cdot \lambda_2^2 G_\mu/h \end{aligned} \tag{7}$$

and

$$C_3 = \text{const.} \cdot 2\Delta F/G_1\lambda_2.$$

By rearranging terms, and selecting a fixed value for S_v, Eq. (6), placing $t = t_c$, may be written with a new set of constants

$$\log t_c = (C_\alpha/T) + C_\beta \tag{8}$$

where

$$C_\alpha = C_3/C_1; \quad C_\beta = (S_v/C_1) - \log C_2.$$

Equation (8) is seen to bear a close resemblance to the empirical Eq. (1), the difference being in the absence of the "correction" term, b on the temperature T, which appears in Eq. (1). The presence of the b in the empirical equation may be interpreted as an indication that the activation energies for the deformation processes involved in these experiments are not independent of temperature, but rather, are functions of temperature, of a form which gives decreasing values with increasing temperature:

$$\Delta F = \text{const. } T/(T-b). \tag{9}$$

Evidence for the temperature-dependence of the activation energy for *flow* in liquids has been recognized by Ewell,[10] though in this case indications were that the activation energy was an increasing function of temperature.

ACKNOWLEDGMENTS

The constructive interest of Dr. George R. Thurman, and his discussions with the authors, have produced valuable suggestions. The encouragement of the officials of the Firestone research organization, and their cooperation in making possible this contribution, is gratefully acknowledged.

* It may be remarked that attempts, before Eq. (1) was adopted for trial, to fit to the experimental data a working equation based on the assumption of the temperature-independence of N_2 and n_2, proved unsatisfactory.

Studies in Plasticization of Polyvinyl Chloride
I. Physical Changes and Their Measurement

M. L. Dannis
B. F. Goodrich Research Center, Brecksville, Ohio

The softening of a hard resin, polyvinyl chloride, by a liquid, dioctyl phthalate, is a set of processes occurring in sequence. Imbibition of the liquid is accompanied by volume reduction in the system. Dilatometer methods evaluate the amount and rate of volume decrease. The rate is temperature dependent, activation energy about 80 kcal. Solution of liquid into the resin follows with no further volume, but large dielectric change. Dielectric changes are measured on material in a cylindrical condenser, using a Schering bridge, and are rate dependent, activation energy about 110 kcal. Data are best described, assuming that segments of the polymer molecule "react" independently of one another.

I. INTRODUCTION

PLASTICIZED polyvinyl chloride (Koroseal) is a material used widely in industrial or consumer goods because of its many excellent physical and chemical properties. Some of these properties such as electrical characteristics have been studied in detail,[1] since they were important to both the manufacturer and the consumer. In all studies published thus far, the material actually investigated was the final product, usually milled and pressed into the required physical form.

This paper concerns itself with a study of the reactions and processes that occur when this final material is made from the original raw materials. These changes are largely physical in nature, but do follow many of the rules of "rate-process" chemistry, permitting some evaluation of thermodynamic barriers in the reacting systems.

"Plasticization" is a term used to describe the softening of a hard resin, usually by means of a viscous liquid. Specifically, polyvinyl chloride, henceforth abbreviated PVC, which is a hard, brittle, horny material, may be softened to a resilient, rubbery material by the addition of appropriate amounts of esters such as di-2-ethylhexyl phthalate (DOP)[2] or *m*-tricresyl phosphate (TCP). The "reactions" accompanying this softening action are not simple and thoroughly understood, but at least three basic steps have been identified.

These steps are listed. (1) "Shrinkage"—believed to be a measure of plasticizer imbibition by the polymer. (2) "Dielectric Conversion"—believed to be a solution of the plasticizer into the resin. (3) "Fusion"—believed to be a simple physical consolidation.

II. SHRINKAGE

The specific volume of plasticized PVC is less than the volume of the components present.[3,4] This difference in volume has been studied as a rate-process phenomenon, using a dilatometer technique, described below.

About three grams of PVC powder or granules, as sold commercially, are weighed into a filter paper capsule. The capsule is inserted into a dilatometer bulb, followed by a glass plug. The plug partially protects the sample from overheating in subsequent glass sealing. The sample bulb is partially constricted just below the plug. Plasticizer fluid is put in the reservoir at the other end of the dilatometer. An oven is slipped over the bulb, vacuum connections made to both ends, and pumping begun. The oven is set at 60°C for one hour, and the liquid is gently boiled for a short time. The bulb is sealed off while the system is still evacuated, then cooled in ice water. The dilatometer is tipped, allowing the cool fluid to immerse the sample, still in ice water. After a few minutes the remaining

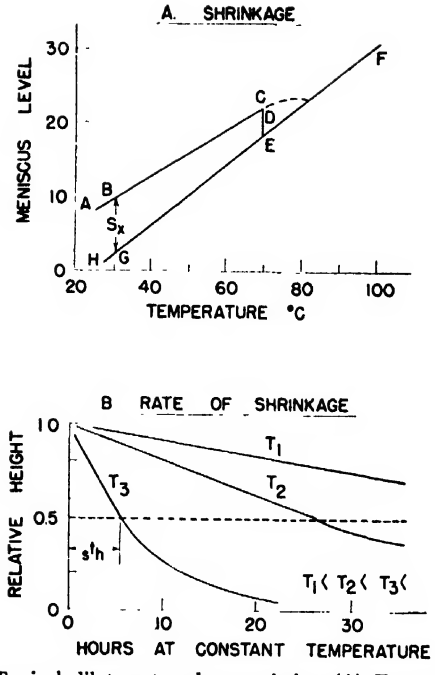

FIG. 2. Typical dilatometer characteristics. (A) Expansion and contraction. (B) Loss of volume at constant temperature.

vacuum connection is broken and the bulb removed from the ice bath. Excess fluid is sucked from the calibrated capillary by a smaller probe capillary. A meter stick is wired to the capillary, and the sample bulb put in a "constant" temperature bath. Typical apparatus is shown in Fig. 1, A, B, C.

The bath is held at a selected temperature long enough to establish thermal equilibration, about 5 minutes, and the meniscus level read. The bath temperature is then raised, thermal equilibration established, and the level read again. No correction is made for the thermal gradient between the bath and the portion of the capillary at room temperature. The bath is ultimately maintained constant at some predetermined value for periods up to 50 hours, and the meniscus level read as a function of time. The temperature of the bath is again raised, at intervals as before, up to a maximum about 100°C. The bath is then cooled in a manner similar to the heating cycle, until the system is at room temperature.

Data from a typical run are shown plotted in Fig. 2. The first portion of the warming, *AC*, up to the constant temperature, shows the characteristics of simple thermal expansion. The second portion, *CE, at constant temperature*, shows that the level decreases, or a net decrease in volume exists. Sufficient time may be allowed for all the possible change in volume to occur, but usually, at slower rates, the volume change is completed at more elevated temperature wherein the rate is faster. Further heating after the volume change is complete, and subsequent cooling and heating traces a reproducible path, *FH*. The cooling relationship is linear, but of different slope than the initial heating relationship. The difference in slope is indicative that the final material has a different coefficient of thermal expansion than the original. No attempt has been made to measure either coefficient.

Two quantities are evaluated from the dilatometer data. (1) S_x, defined as the extent of shrinkage, or loss in volume between initial and final states at 30°C. (2) $s^t h$, defined as the time when half the shrinkage is complete, at the temperature of measurement.

S_x, for a particular PVC with DOP, is 0.053±0.003 cc/cc of PVC. The second quantity, $s^t h$, is more easily visualized if the data are presented as in Fig. 2B. The shrinkage at the particular temperature of test is shown as "relative height," on which a value of unity represents no shrinkage, or the original thermal expansion line, and the value of zero, the final expansion and contraction line. On this presentation, $s^t h$ is the time when relative height is one-half.

The curves, so expressed, are reproducible within a few percent. The shape of the shrinkage curve has not been derived in any satisfactory manner. The slopes or half-times vary considerably with temperature, and may be plotted in the conventional Arrhenius manner, as in Fig. 3, evaluating an activation energy,

$$\Delta E^{**} = 80 \text{ kcal./mole.}$$

III. DIELECTRIC CONVERSION

An electrical method exists for following changes which occur in a plasticizing system. This method involves following the change in over-all dielectric constant of the system, as the change proceeds isothermally. Note that the dielectric constant[1] of plasti-

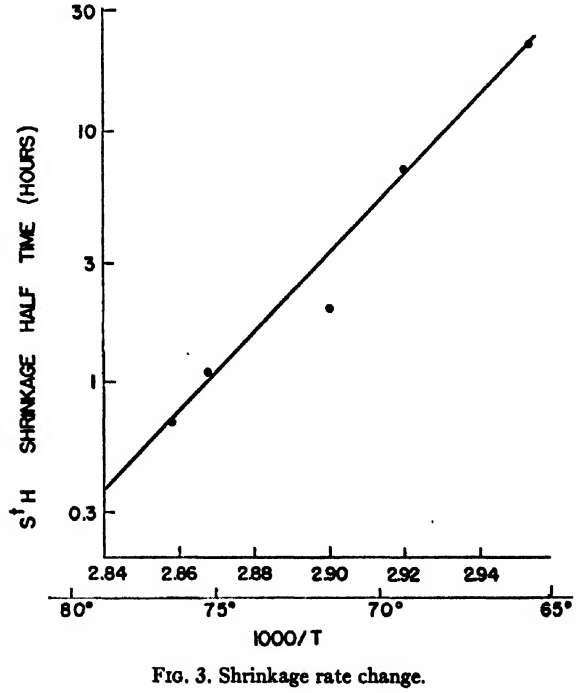

FIG. 3. Shrinkage rate change.

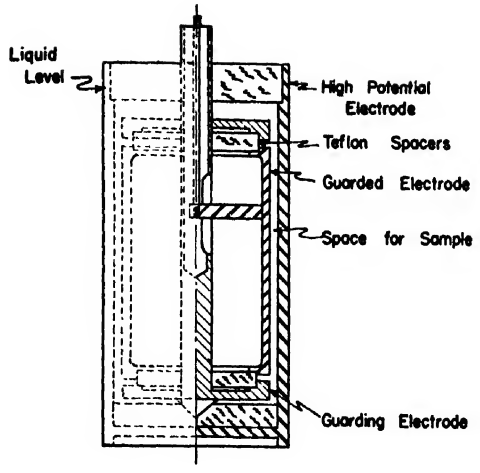

FIG. 4. Guarded cylindrical dielectric cell

cized PVC is greater than the volume fraction summation of its components. Thus, conditions may be established such that this change in dielectric constant may be evaluated in detail. These conditions are established, and measurements made, by procedures generally labeled "dielectric rate studies."

The material studied is a mixture of PVC and plasticizer, proportioned such that the mixture is slightly oily and easily manipulated. Plasticizer ratios are commonly 80–95 PHR, but have been varied from 20 to 150 PHR. The mixture is loaded into a three-electrode, guarded cylindrical cell, shown in Fig. 4.

The cell is placed in an oil bath, controllable to 0.05°C. About ¾ hour is allowed for thermal equilibration, then the (over-all) dielectric constant and loss factor are evaluated, using a Schering bridge at audio-frequencies. In the original state, the measured dielectric constant at any particular frequency is very close to the volume fraction summation of the components, if due allowance is made for entrapped air. This relationship is a limiting case of the Bruggeman formula for small spheres in an inert fluid.[5]

The temperature of the bath is raised about 10°C, thermal equilibration established, and dielectric measurements made again. This procedure is repeated until the temperature reaches some predetermined value. At this constant temperature, measurements are made as a function of time, with intervals ranging from a half-hour to a day each. The measured dielectric constant changes from the value associated with the original mix to a value approaching that expected for plasticized PVC having the same space factor.

The change in dielectric constant is not uniform, but is rapid at first, becoming slower as time progresses. The manner of change is similar to the exponential decay of a source material into a product.

$$\epsilon_t = \epsilon_1(e^{-mt}) + \epsilon_2(1-e^{-mt}), \qquad (1)$$

where ϵ_t = dielectric constant of the mixture at time, t
ϵ_1 = dielectric constant of the mixture originally
ϵ_2 = dielectric constant of the mixture finally.

Equation (1) may be re-expressed.

$$\ln(\epsilon_2-\epsilon_1)/(\epsilon_2-\epsilon_t) = mt. \qquad (2)$$

This is usually plotted

$$\log\Delta\epsilon/\Delta\epsilon_t = m't, \quad \text{as shown in Fig. 5.} \qquad (3)$$

Define a half-life, $_dt_h$, a time such that the fraction doubles, or the logarithm increases by ln2. This half-life is the inverse of the slope of the lines shown, and is a good measure of (relative) dielectric change rate. The half-life is temperature dependent, and a conventional Arrhenius plot, such as Fig. 6, permits an evaluation of the activation energy.

$$\Delta E^{**} = 110 \text{ kcal./mole.}$$

The change in dielectric constant noted during thermal equilibration is only one of several physical changes occurring. The mixture has changed from an oily slurry to a dry, crumbly, non-coherent powder. This powder is believed identical with the material known as "preplasticized PVC."

If this changed material is the same as fully plasticized PVC the change in dielectric constant should be accompanied by appearance of a loss factor peak near room temperature.[1] A "cooling curve" taken on this material showed the required peak. It was noted that the loss factor of the material increased with a decrease in temperature, probably the most characteristic behavior of polar materials near an "absorption" peak.

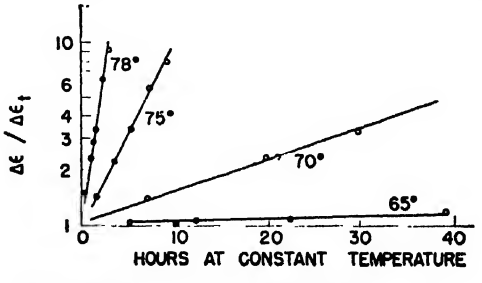

FIG. 5. Dielectric change in PVC-DOP systems.

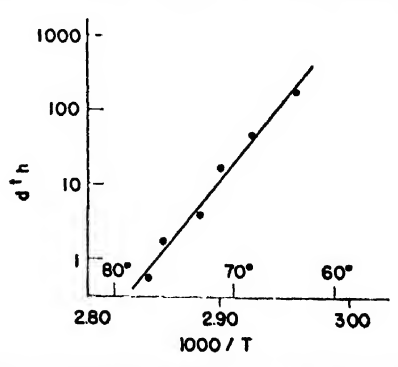

FIG. 6. Rate of change of dielectric properties with temperature.

[5] D. A. G. Bruggeman, Ann. d. Phys 24, 636–64 (1935).

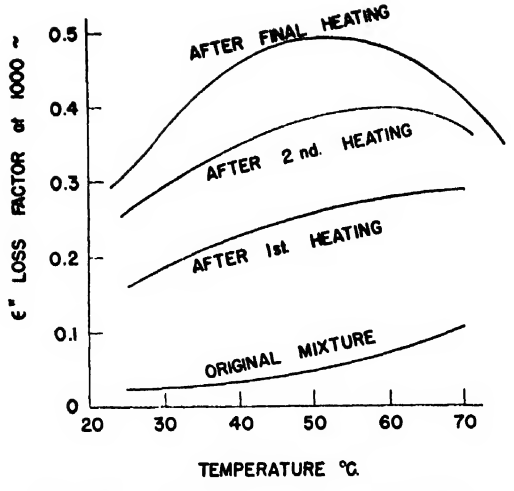

FIG. 7. Change of dipole peak during conversion.

IV. ASSOCIATED EXPERIMENTS

The dielectric data, as expressed by Eq. (2), imply that the final material is formed, as such, without any intermediate "dilution" steps or processes. This implication seemed so radical that other experiments were run to check this hypothesis. If the final material were so formed, it would be expected that the associated dipole peak would "grow" at a given temperature, for several investigators[1,3] have shown that the temperature of the loss factor peak depends upon the amount of plasticizer associated with the PVC. Hence, an experiment was run to try to identify dipole peaks at intermediate stages of this change, i.e., an interrupted conversion run.

The dielectric properties of a mixture in the cell were measured while the cell was warmed. Conversion was allowed to proceed about one $_{d}t_{h}$ only. The mixture was cooled quickly, and a similar warm-up curve obtained. At the same constant temperature, equilibration was established for an additional $_{d}t_{h}$. Quick cooling was followed by the measurement of another warm-up curve. Final heating to complete conversion, and subsequent cooling measurements gave a final curve. The data are presented in Fig. 7. Note that the loss factor peak changes in thermal location, in contrast to concepts of "growing at one temperature."

Another experiment, contributing interesting data, referred to as the "dilution run" was performed as follows. A mixture of PVC and DOP of lower plasticizer content than previously studied was heat-treated to assure complete conversion, but no fusion, i.e., preplasticized PVC was made. This material was then mixed with further DOP and thermal-dielectric curves obtained. The data are presented graphically in Fig. 8.

Note that the dipole peak in the warming portion of the cycle is that for the original plasticized PVC. The dipole peak after additional heat treatment is that for the final mixture. Similarly, note that the dielectric constant of any one mixture increased during the heat treatment. The low absolute values of dielectric constant are due to the low space factor, i.e., the large amount of entrapped air, for which no correction was made. It is concluded that the plasticized PVC of low plasticizer contents "dilutes" further in the same manner as the PVC itself.

V. DISCUSSION

It is important to cite reasons and facts for believing that the shrinkage and dielectric phenomena are two separate "reactions," even though time related. (1) The time sequences are in a fixed order, i.e., shrinkage is essentially complete before dielectric conversion occurs. Note that at 65°C, for example, $_{s}t_{h} \approx 25$ hours, $_{d}t_{h} \approx 200$ hours. (2) The activation energies of shrinkage and dielectric conversion are different. (3) The shrinkage data cannot be expressed by the same relationships that "linearize" the dielectric data.

While "shrinkage" seems to be a distinct step in the plasticization process, the exact meaning of the measurements taken is not clear. It is believed that shrinkage measures the loss in volume of the system as plasticizer enters the PVC particle. However, the data do not fit the relationships derived upon the basis of plasticizer diffusing into a solid spherical polymer particle, simultaneously undergoing a loss in volume.

The large change in dielectric constant noted durin

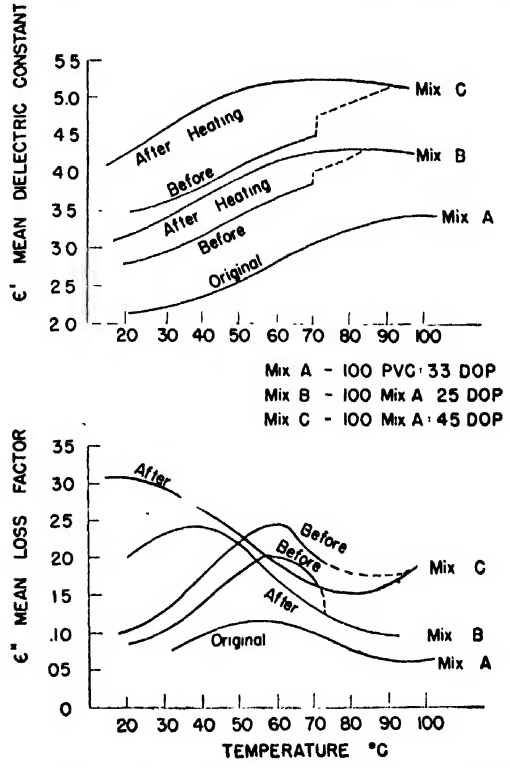

FIG. 8. Dielectric changes in dilution experiments. (A) Changes in measured dielectric constant. (B) Changes in measured loss factor.

plasticization is considered to be closely related to the other changes in physical properties. The assumption is made that these changes in properties are similar to those noted in simple liquids, as they change from solid to liquid phases. Thus, the increased dielectric constant of the plasticized PVC is due to the fact that part of the PVC is in its "liquid" form in which $\epsilon' \approx 11$, contrasted to $\epsilon' \approx 3$ in the "solid" form at room temperature. The "dilution data" suggest that a constant ratio of polymer may be converted from its "solid phase" to its "liquid phase," per unit of plasticizer, but that the plasticizer itself is unchanged in such a reaction. The concomitant effects of diluting the polymer in space allow the plasticizer to exhibit some of its own properties, such as color or viscosity, but such effects are secondary.

The changes in the real and complex part of the dielectric constant can be interpreted as follows. Discrete portions of the PVC chain, henceforth called "segments," have properties either "liquid" or "solid." While an individual segment may appear "liquid" or "solid," the composite behavior of two or more adjacent segments determines the loss factor. The segment is neither the polymerized monomer, nor the whole polymer molecule, but a portion of the chain about 10 vinyl groups or 20 carbon atoms long.

This segment concept of dielectric change leads to relationships identical with Eqs. (1), (2), and (3).

The segment is originally in the state wherein it shows a low dielectric constant. The change to the state wherein it shows the high dielectric constant follows rules of exponential decay, the rate constant depending upon plasticizer and temperature. Then, to a first approximation, the observed dielectric constant of a plasticized PVC system will be as in Eq. (4).

$$\epsilon = V_1\epsilon_1 + V_2\epsilon_2 \tag{4}$$

ϵ = experimentally observed dielectric constant
V_1 = volume fraction of PVC
V_2 = volume fraction of plasticizer
ϵ_1 = dielectric constant of PVC
ϵ_2 = dielectric constant of plasticizer.

In some cases ϵ_1 is apparently neither high nor low and Eq. (5) applies.

$$\epsilon_1 = V_\sigma\epsilon_\sigma + V_\lambda\epsilon_\lambda \tag{5}$$

ϵ_σ = low dielectric constant, about 3.5
ϵ_λ = high dielectric constant, about 11.5
V_σ, V_λ = relative fractions of each kind of PVC.

If an exponential decay process changes ϵ_σ to ϵ_λ, this may be expressed as

$$\epsilon_t = V_1[\epsilon_\sigma e^{-mt} + \epsilon_\lambda(1-e^{-mt})] + V_2\epsilon_2$$
$$\epsilon_t = V_1\epsilon_\sigma e^{-mt} + V_1(1-e^{-mt})\epsilon_\lambda + V_2\epsilon_2. \tag{6}$$

Then, using a procedure to derive a relationship similar to Eq. (2)

$$\ln\frac{V_1(\epsilon_\lambda - \epsilon_\sigma)}{(V_1\epsilon_\lambda + V_2\epsilon_2) - \epsilon_t} = ml. \tag{7}$$

Note that numerator of the fraction expresses the dielectric change in terms of concentration of PVC, and is independent of the kind of plasticizer. Similarly, the denominator expresses the difference between the final value and the instantaneous reading. Also note that the slope, m, or the half-life $_dl_h$, is independent of concentration, or of mix ratio of PVC and plasticizer.

The effect of plasticizer variation in the PVC-plasticizer system is expressed in a subsequent paper.[6]

VI. CONCLUSIONS

The plasticization of PVC by an ester such as DOP is a set of processes occurring in a definite sequence.

Two individual steps or processes have been identified, and labeled "shrinkage" and "dielectric conversion."

"Shrinkage" is a rate-process step not well understood.

"Dielectric conversion" is a rate-process step, which is independent of plasticizer-polymer mix ratio. The change in dielectric constant of a given mixture is related to the PVC content only. The change is assumed due to an unbinding of the PVC elementary segment, in the same manner normally accomplished by temperature alone.

VII. ACKNOWLEDGMENT

The author wishes to express his appreciation of the stimulating discussions with D. L. Loughborough concerning details of this work, and is indebted to the B. F. Goodrich Company for permission to publish the results of this investigation.

[6] M. L. Dannis, "Studies in plasticization of PVC. II. Plasticizer variations in PVC-plasticizer systems," J. App. Phys. **21**, 510 (1950).

Studies in Plasticization of Polyvinyl Chloride. II. Plasticizer Variations in PVC-Plasticizer Systems

M. L. Dannis
B. F. Goodrich Research Center, Brecksville, Ohio

Polyvinyl chloride resin is softened by certain liquids, called plasticizers, through a set of processes with high activation energies, 50–100 kcal. At fixed temperature, "reaction" rates are directly proportional to vapor pressure of the liquid. The dielectric change may be treated similarly to a chemical reaction between a solid and a vapor, and free energy of activation, ΔF^{**}, evaluated. ΔF^{**} is constant for various liquids with one resin. $\Delta E^{**}=\Delta H^{**}+L$ in this system, where ΔE^{**} is Arrhenius activation energy, ΔH^{**} energy barrier, L latent heat of vaporization of the liquid.

THE interaction of PVC and plasticizer (DOP) occurs in a complicated manner through a set of mechanisms apparently independent of concentration. Further information about these "reactions" was obtained in the study of the "reaction behavior" of PVC-plasticizer systems, varying the plasticizer composition as the major variable. The techniques and equipment used have been described previously.[1]

Since the introductory investigation had shown that the rate-curves and activation energy in both shrinkage and dielectric conversion were independent of mixing proportions, the mixes used in subsequent experiments were held constant within any one system, but varied as the plasticizer was changed, as determined by fluidity or compaction requirements.

The PVC used was a commercial polymer, Geon 101. Three different samples of resin were used, labeled *A*, *B*, and *G*. Samples *A* and *B* are believed to be identical. The plasticizers used were either commercial products of high purity, or laboratory prepared esters distilled in vacuum. All the liquids were used as received, with no further attempt at distillation or desiccation.

The systems studied as to shrinkage characteristics are listed subsequently in Table I. The data determining activation are shown in Fig. 1. The equations of the linear relationships shown, and the intercept with the 70°C ordinate, $_st_h$, are presented in Table I.

Note that in the systems with the plasticizers commonly considered the better "fluxing agents," the tendency is to "react" more easily. A fairly good comparison of relative shrinkage rates may be made by computing the shrinkage half-times at a particular temperature, since the slopes or activation energies are about the same magnitude. Note that the activation energies are relatively insensitive to molecular weight of the plasticizer, within the range $200<$M.W.<400. Note that the relative shrinkage rates, as measured by $_st_{70}$, are directly proportional to vapor pressure, as shown in Fig. 2. No other physical parameter of the plasticizer investigated, such as density, viscosity, molar volume, or surface tension gives a reasonable relationship.

The systems studied with respect to dielectric conversion characteristics are listed subsequently in Table II. The data for computing activation energies are shown in Fig. 3. The equations of the relationships shown are listed below in Table II, together with the $_dt_h$ value computed at 70°C, henceforth called $_dt_{70}$.

Note that in the systems with plasticizers commonly considered better "fluxing agents," the tendency is to convert more rapidly at a given temperature or the same speed at a lower temperature. Note that such "borderline" plasticizers as dilauryl phthalate and acetylated castor oil convert only slowly at elevated

temperatures, i.e., above 80°C, or above the second-order transition temperature of the PVC.

Note that ΔE_d^{**}, as a measure of polymer plasticizer interaction tendency, does not correlate with other factors commonly used, namely, "compatibility" in a non-solvent (hexane) dilution test, or the Huggins-Flory "μ" value, as evaluated by Doty and Zable.[2] Note however, that the d_{70} relationship is linear with vapor pressure, over four decades of the variables, as shown in Fig. 4. The vapor pressures used were taken from manufacturers' data, when possible.

THEORETICAL INTERPRETATION

Several facts have been presented about the dielectric conversion rates which classify this behavior as a new phenomenon. (1) The reacting system is two component, a liquid and a (solid) resin. (2) The initial reaction rate in any one system is independent of concentration or of mixing ratio. (3) The instantaneous reaction rate in any one system falls off in a simple exponential manner. (4) The reaction rate, in various systems at comparable conditions is proportional to the vapor pressure of the plasticizer.

The facts cited are consistent with the assumption of a reaction between a solid and a vapor. The concentration of plasticizer in the vapor state would be independent of the mix proportions of resin and plasticizer, but would depend greatly on the temperature. Similarly, the effective concentration of the solid would decay exponentially during the reaction, hence be the rate limiting step.

The dielectric conversion reaction has been expressed as Eq. (1) in the previous paper.[1]

$$\epsilon = \epsilon_1 e^{-mt} + \epsilon_2(1 - e^{-mt}). \tag{1}$$

The rate of change of dielectric constant, per unit change, is obtainable.

$$\frac{d\epsilon/(\epsilon_2 - \epsilon_1)}{dt} = me^{-mt}. \tag{2}$$

Impose the condition that t approaches zero,

$$\frac{d\epsilon/(\epsilon_2 - \epsilon_1)}{dt} = m. \tag{3}$$

So that m is the initial fractional rate of reaction of the system. This quantity has been evaluated experimentally, inasmuch as m is also the slope of the relationships presented previously in Fig. 5, of reference 1. Thus

$$m = \ln 2/3600 d_h. \tag{4}$$

From rate-process theory, as presented by Eyring, Glasstone *et al.*,[3,4] the "rate of reaction" of a system of two components is $C_A C_B k_r$, wherein C_A and C_B are the concentrations of the reactants, and k_r is the "specific reaction rate." k_r is defined

$$k_r = (kT/h)\exp(-\Delta F^{\circ **}/RT) \tag{5}$$

which is equivalent to the probability of finding a single activated complex in one cc of space, with a free energy of formation $\Delta F^{\circ **}$. Since actual experimental conditions do not involve the standard state, ΔF^{**} rather than $\Delta F^{\circ **}$, is the quantity discussed in further operations. Define the rate of reaction $= k_a$.

Then

$$k_a = C_A C_B k_r = m \tag{6}$$

if C_A and C_B are in appropriate units.

Since m has the dimensions of inverse time, C_A and

C_B must be units of mole fractions. Evaluate ΔF^{**}

$$-\Delta F^{**} = RT[\ln(h/kT)+\ln(m/C_A C_B)]$$
$$\Delta F^{**} = -RT[\ln(h/kT)+\ln(\ln 2/3600 C_A C_B\, dl_h)]. \quad (7)$$

Since

$$\Delta F^{**} = \Delta H^{**} - T\Delta S^{**} \quad (8)$$

$$\Delta H^{**} - T\Delta S^{**} = -RT[\ln(h/kT) + \ln(\ln 2/3600 C_A C_B\, dl_h)]. \quad (9)$$

Evaluate (9) at T_1 and T_2, and subtract. Then

$$(-\Delta H^{**}/R)[(1/T_1)-(1/T_2)] = \ln(T_1/T)_2+\ln[(C_A C_B\, dl_h)_1/(C_A C_B\, dl_h)_2]. \quad (10)$$

But for small changes in temperature, $\ln(T_1/T_2)\approx 0$. C_A is the mole fraction of a solid, $(C_A)_2/(C_A)_1 \approx 1$. C_B is the mole fraction of plasticizer vapor.

$$C_B = \left(\frac{P}{760}\times\frac{273}{T}\right) \quad \text{or} \quad (C_B)_2/(C_B)_1 = \frac{(P/T)_2}{(P/T)_1}.$$

But the pressure of a vapor may be given by the Clapeyron equation

$$P_2 = P_1 \exp\{(L/R)[(1/T_1)-(1/T_2)]\}. \quad (11)$$

So

$$\ln[(C_B\, dl_h)_2/(C_B\, dl_h)_1] = \ln(T_1/T_2) - \ln[(dl_h)_2/(dl_h)_1] - (L/R)[(1/T_2)-(1/T_1)].$$

Thus

$$\ln[(dl_h)_2/(dl_h)_1] = (1/R)(-\Delta H^{**}+L)[(1/T_1)-(1/T_2)]. \quad (12)$$

Equation (12) is the method of evaluating ΔE^{**} in the usual Arrhenius plot of experimental activation energy. Thus

$$\Delta H^{**} = \Delta E^{**} - L - RT. \quad (13)$$

Note that Eq. (7) may be expressed as

$$\Delta F^{**} = \text{const} + \log P + \log dl_h. \quad (14)$$

This relationship is shown experimentally by Fig. 4. Figure 4 also implies that ΔF^{**} is a constant from one reacting system to another, or that the mechanism of plasticization is independent of the kind of plasticizer. However, ΔH^{**} and ΔS^{**} do vary from one system to another, depending greatly upon the choice of plasticizer. The values of ΔE^{**}, ΔH^{**}, and ΔS^{**} are presented in Table III. Assuming C_A = unity, $\Delta F^{**} = 16{,}500$ cal./mole at 70°C.

It is interesting to note that ΔS^{**} is the order of magnitude for dipole rotation of the PVC itself.[5]

No ordinary parameter of the molecule, such as molecular weight, molar volume, or viscosity seems to be related to these quantities in a simple manner.

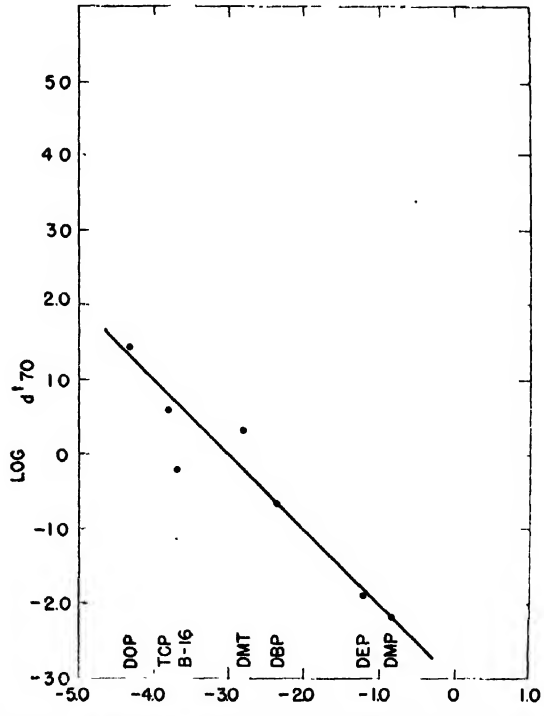
Some data recently obtained, have shown that ΔF^{**} is a variable depending upon the history of the preparation of the PVC.

CONCLUSIONS

The interaction of plasticizer with PVC is markedly dependent upon the vapor pressure of the plasticizer used, and largely independent of all other variables, except temperature.

One part of the interaction process may be described kinetically as the reaction of a solid and a vapor.

The free energy of formation of the activated complex in the critical rate limiting step in plasticization is a



LogP_{70} (P_{70} = vapor pressure of plasticizer) m/m Hg at 70°C

constant, regardless of kind of plasticizer used. This implies that the action of all plasticizers is fundamentally the same.

The Arrhenius activation energy, ΔE^{**}, obtained from a dielectric rate-plot, differs from the heat of activation, ΔH^{**}, by the latent heat of vaporization of the plasticizer used.

The interaction of plasticizer and PVC to form the "activated complex" leading to the plasticized material, does not depend on any simple, obvious property of the plasticizer, nor does it correlate with Huggins-Flory interaction coefficients previously evaluated for some of these systems.

Mechanical Properties of Substances of High Molecular Weight. VIII. Dispersion of Dynamic Rigidity and Viscosity in Concentrated Polyvinyl Acetate Solutions*

JOHN D. FERRY, W. M. SAWYER,† GEORGE V. BROWNING,‡ AND ARTHUR H. GROTH, JR.
Department of Chemistry, University of Wisconsin, Madison, Wisconsin

The dynamic rigidities and viscosities of concentrated solutions of polyvinyl acetate in 1,2,3-trichloropropane have been obtained from transducer and wave propagation measurements. Two polymer samples with number-average molecular weights of 140,000 and 840,000 were studied in the lower audiofrequency range at concentrations from 3 to 40 percent and temperatures from −3 to 41°C. For each sample, when the reduced dynamic rigidity $G'T_0/Tc$ and the reduced dynamic viscosity η'/η were plotted against the reduced frequency, $\omega\eta T_0/Tc$, all the data superposed to give two composite dispersion functions. The distribution of Maxwellian relaxation times can be derived from the dispersion of either G' or η', and the two calculations are in reasonable agreement.

INTRODUCTION

STUDIES of wave propagation in concentrated polyvinyl acetate solutions have provided measurements of the wave rigidity, $\bar{G}$, in several different solvents at various frequencies, temperatures, and concentrations, as reported in the preceding paper of this series.[1] In one solvent, 1,2,3-trichloropropane, the wave damping can be measured with sufficient accuracy to calculate also the dynamic rigidity, G', and dynamic viscosity, η', which can be more directly interpreted. These data are now presented and are supplemented by direct measurements of G' and η' using transducer methods,[2] which are applicable at lower concentrations. When reduced to a standard viscoelastic reference state by a treatment derived elsewhere,[3] the results can be combined to provide dispersion functions for G' and η' which extend over several cycles of logarithmic frequency. The two functions are interrelated through a distribution function of relaxation times.

MATERIALS AND METHODS

The two samples of polyvinyl acetate employed in this work have been described elsewhere.[1,4] The number-average molecular weights of the unfractionated material and of Fraction 1 (a cut comprising 13 percent of the unfractionated) were 140,000 and 840,000, respectively.

Values of the wave rigidity, reported previously in graphical form,[1] were combined where possible with measurements of the damping index, λ/x_0, to give the dynamic rigidity and viscosity by the equations[5]

$$G' = \bar{G}\frac{4\pi^2[(4\pi^2-(\lambda/x_0)^2]}{[4\pi^2+(\lambda/x_0)^2]^2} \tag{1}$$

$$\eta' = \frac{\bar{G}}{\omega}\frac{16\pi^3\lambda/x_0}{[4\pi^2+(\lambda/x_0)^2]^2}. \tag{2}$$

Transducer measurements were made with the Model 2 transducer of Smith, Ferry, and Schremp.[2] The original experimental arrangement was improved by mounting the transducer in a box of sawdust, carefully shielding all leads, and replacing the a.c. operated decade amplifier by a Ballantine[6] Model 220 battery operated amplifier. An isolating transformer was substituted for the amplifier previously employed between the oscillator and impedance bridge. The bridge was calibrated. The mechanical resistance and reactance were calculated by the circle plot method, and the dynamic viscosity and rigidity were obtained from plots of these quantities against depth of immersion of the oscillating rod.[2]

EXPERIMENTAL RESULTS

The results of the wave propagation measurements on the two samples are given in Tables I and II, and those of the transducer measurements in Tables III and IV.

It has been shown[3] that if certain simple postulates regarding stress relaxation in concentrated polymer solutions are valid, dynamic data at various frequencies, temperatures, and concentrations should superpose to form two universal dispersion functions when the reduced dynamic rigidity, $G_r' = G'T_0/Tc$, and the reduced dynamic viscosity, $\eta_r' = \eta'/\eta$, are plotted against the reduced frequency, $\omega_r = \omega\eta T_0/Tc$. Here η is the steady flow viscosity (at small shearing stresses), c the concentration in g polymer per cc solution, T the absolute temperature, and T_0 a standard temperature, taken as 298°K. From the data of Tables I–IV, together with steady flow viscosities measured on these same solutions,[7] and values of c computed by assuming additivity of volumes of polymer and solvent,[1] the quantities G_r', η_r', and ω_r have been calculated and are plotted logarithmically for the two samples in Figs. 1 and 2. In each case the open circles are transducer data and the solid circles are wave propagation data from individual damping measurements. The heavy dashed curves for G_r' are obtained by applying a constant correction to the previously published composite curve for reduced dynamic rigidity,[1] $\tilde{G}_r = \tilde{G}T_0/Tc$; the ratio $G'/\tilde{G}$ is fairly insensitive to the damping index when $\lambda/x_0 < 2\pi$, as shown by Eq. (1), and the variation of λ/x_0 is small enough over the ranges of frequency and concentration employed in the wave measurements so that a fairly good approximation is achieved by setting $G_r' = 0.90\tilde{G}_r$.

The results of the two entirely different experimental methods fit together very well. By the use of reduced variables, the data for unfractionated polymer covering a range of concentrations from 5 to 40 percent and of

temperatures from −3° to 41°C superpose rather closely to give two universal dispersion curves, and the data for Fraction I superpose similarly over a somewhat smaller range of temperatures and concentrations. As the frequency increases by 10^5, the rigidity increases by about 10^2, while the viscosity falls off by about 10^{-4}.

The functions as represented in the figures are reduced to a hypothetical viscoelastic reference state of unit density (concentration) and unit steady flow viscosity (1 poise) at 298°K. Although this state is of course non-existent, it provides a convenient basis for combining data, and approximate dispersion curves for any real state of known temperature, concentration, and steady flow viscosity should be obtainable from Fig. 1 or 2 by adjusting the coordinates. If the postulates[3] that all relaxation mechanisms depend identically on temperature and concentration do not hold strictly, some distortion of the dispersion functions may arise from combining data in this way. However, here as in previous examples[3] the superposition is successful insofar as the data at different concentrations and temperatures overlap, and it is believed that any such distortion is slight.

It is of interest also to plot $\omega_r\eta_r'$ (which is the imaginary part of the reduced complex dynamic rigidity,[5] $G_r''=G''T_0/Tc$) and the mechanical loss factor, $G_r''/G_r'=G''/G'$, against the reduced frequency. These functions are shown in Fig. 3. In both samples G'', like G', increases rapidly with increasing frequency. Their ratio, however, falls off with increasing frequency and appears to approach a constant value of about 0.5.

An attempt to apply the complex plane plot of Cole and Cole[8] showed that the locus of $G'/(G'^2+G''^2)$ and $G''/(G'^2+G''^2)$ is not a circle.

THE RELAXATION DISTRIBUTION FUNCTION

The dispersion curves for G' and η' are not independent; a formulation of the relation between them can provide an additional experimental check. This is most conveniently written in terms of a distribution function of Maxwellian relaxation times, $F(\tau)$, such that each elastic contribution to the rigidity $F(\tau)d\tau$ is relaxed as though by a dashpot $\tau F(\tau)d\tau$.[9] The exact equations for G' and η' in terms of $F(\tau)$ are[10,11]

$$G'(\omega)=\int_0^\infty \frac{F(\tau)\omega^2\tau^2}{1+\omega^2\tau^2}d\tau; \quad \eta'(\omega)=\int_0^\infty \frac{\tau F(\tau)}{1+\omega^2\tau^2}d\tau. \quad (3)$$

[8] K. S. Cole and R. H. Cole, J. Chem. Phys. **9**, 341 (1941); A. W. Nolle, J. Polymer Sci. **5**, 1 (1950).

[9] Although a set of finite mechanisms is more convenient for discussing the effects of temperature and concentration on dispersion (see reference 3), the equivalent continuous distribution is more useful here.

[11] Kuhn, Künzle, and Preissmann, Helv. Chim. Acta **30**, 307 (1947).

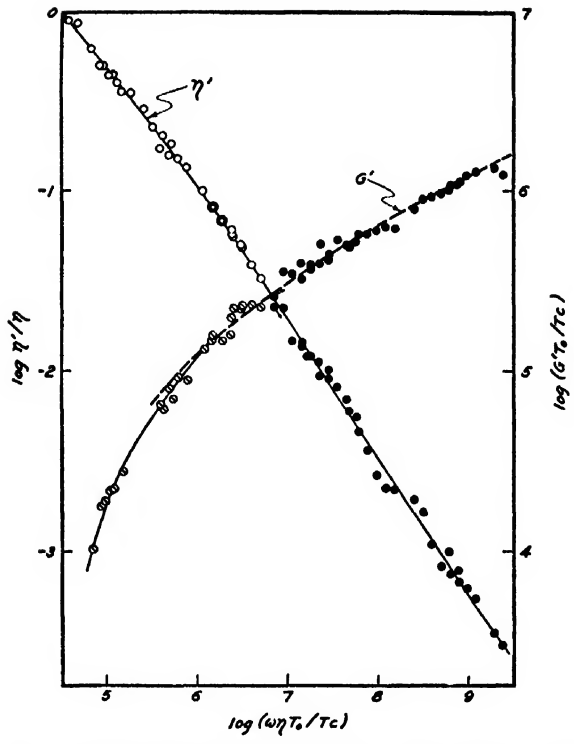

FIG. 1. Reduced dynamic rigidity and viscosity plotted against reduced frequency, for unfractionated sample. ○, η' from transducer measurements; ⊘, G' from transducer measurements; ●, η' and G' from wave propagation measurements with individual damping determinations; · · ·, displaced composite curve for $\tilde{G}_r$, covering concentration range from 16 percent to 40 percent polymer (reference 1, Fig. 3), corresponding to the approximation $G_r' = 0.90\tilde{G}_r$.

For a broad distribution we may use an approximation,

$$G'(\omega) = \int_{1/a\omega}^{\infty} F(\tau)d\tau; \quad \eta'(\omega) = \int_{0}^{1/a\omega} \tau F(\tau)d\tau \qquad (4)$$

such that those Maxwell elements with τ above a certain cut-off time $1/a\omega$ contribute only to the rigidity while those below contribute only to the viscosity. In the use of this approximation by Guth,[12] the numerical factor a was taken as unity; we must make it slightly different from unity to correlate the experimental values of G' and η'.

We define a logarithmic distribution function $\Phi(\ln\tau)d\ln\tau = F(\tau)d\tau$ and differentiate the definite integrals of Eqs. (4) with respect to their limits to obtain $dG'/d\ln\omega = \Phi(-\ln a\omega)$; $d\eta'/d\ln\omega = -(1/a\omega)\Phi(-\ln a\omega)$. For calculations from logarithmic plots such as Figs. 1 and 2, it is convenient to solve for Φ as follows:

$$\Phi(-\ln a\omega) = G'(d\log G'/d\log\omega) = -a\omega\eta'(d\log\eta'/d\log\omega). \qquad (5)$$

In terms of reduced variables, if Φ_r is defined as $\Phi T_0/Tc$, we have

$$\Phi_r(-\ln a\omega_r) = G_r'(d\log G_r'/d\log\omega_r) = -a\omega_r\eta_r'(d\log\eta_r'/d\log\omega_r). \qquad (6)$$

Thus Φ_r may be calculated either from the dispersion of G_r' or the dispersion of η_r'. Excellent agreement between the two methods is obtained for the unfractionated sample if a is taken as 0.77, as shown in Fig. 4, where Φ_r is plotted against $\log\tau_r$ (here $\tau_r = \tau cT/T_0\eta$). The same value of a applied to the data for Fraction I gives agreement at low τ_r but some divergence at high τ_r (Fig. 5). At high τ_r, the values from η' are considered to be more reliable.

The figures also show curves for $\tau_r\Phi_r$. The values of Φ_r and $\tau_r\Phi_r$ approach zero at high and low values of the abscissa, respectively, so that the integrals of Eqs.

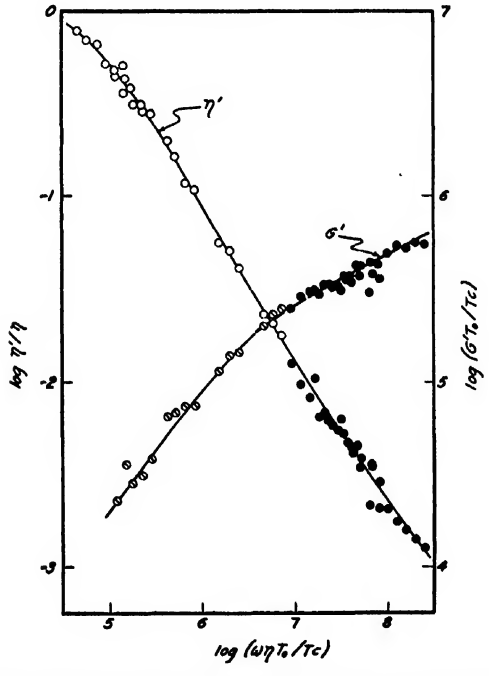

FIG. 2. Reduced dynamic rigidity and viscosity plotted against reduced frequency, for Fraction I. Key to symbols same as in Fig. 1. The displaced composite curve for $\tilde{G}_r$ (reference 1, Fig. 8) includes concentrations of 14 percent and 17 percent polymer.

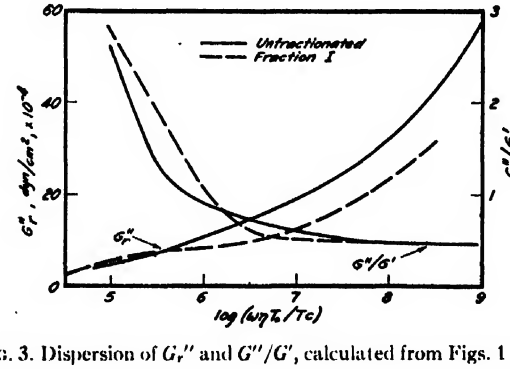

FIG. 3. Dispersion of G_r'' and G''/G', calculated from Figs. 1 and 2.

[12] Ivey, Mrowca, and Guth, J. App. Phys. 20, 486 (1949).

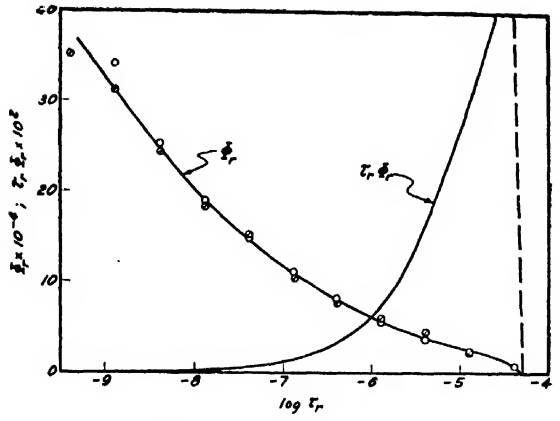

FIG. 4. Distribution functions Φ_r and $\tau_r\Phi_r$ for unfractionated sample, calculated from dispersion of $\eta'(\circ)$ and dispersion of $G'(\varnothing)$.

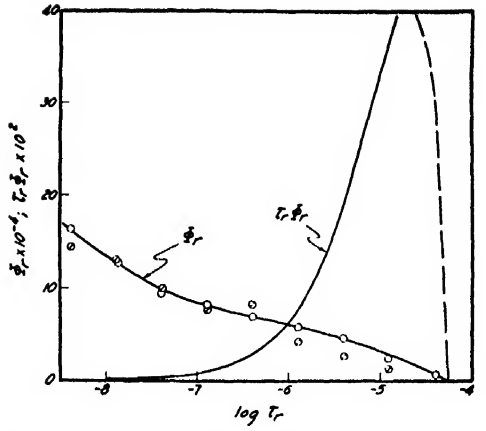

FIG. 5. Distribution functions Φ_r and $\tau_r\Phi_r$ for Fraction I. Key to symbols same as in Fig. 4.

(4) are convergent and may be used to calculate G_r' and η_r' at any desired frequency. Such calculations check the experimental values within graphical errors. The integral of $\tau_r\Phi_r d\ln\tau_r$ from $-\infty$ to ∞ must be unity because of the definitions of the reduced variables, and this is found graphically to be the case. Alternatively, G_r' and η_r' can be calculated from Φ_r by graphical integration of the exact Eqs. (3). These calculations check within about 10 percent, reflecting probably the degree of accuracy of the cut-off approximation. Thus a single empirical function Φ, together with data on the steady flow viscosity η, can provide an approximate description of the dynamic mechanical properties in small deformations over a wide range of frequencies, temperatures, and concentrations.

For the high molecular weight sample (Fig. 5), the function Φ is of the order of 10^6 dyne/cm^2 and, over several decades, has a relatively low slope. It is probable that the existence of such a plateau-like region in the relaxation function of high molecular weight polyisobutylene is responsible for the partial success of the box distribution approximation[11] in fitting stress relaxation data on this polymer.[13] For the low molecular weight polyvinyl acetate (Fig. 4), the slope of Φ is steeper, and it is not expected that the box approximation would be applicable to such a material. It would be of interest to obtain an extension of Φ in the direction of lower τ from high frequency measurements such as those of Mason and Baker.[14] The detailed shape of the function at the high τ end should be obtainable from stress relaxation measurements in concentrated solutions.[15]

Stress Phenomena from the Respective Viewpoints of Solid-State and High Polymer Physics

MAURICE L. HUGGINS
Research Laboratory, Eastman Kodak Company, Rochester, New York

Flow and elastic properties are considered, in a qualitative manner, for the following types of materials: crystalline solids, simple liquids, glasses, and high polymers.

BY "stress phenomena" we mean here certain phenomena associated with the displacements of atoms or molecules relative to their neighbors when acted on by a shearing force or "shear stress." We are interested in the following: (1) The permanence of the displacements: On this basis we distinguish between elasticity, and flow or fracture. (2) The magnitude of the displacements, as related to the magnitude of the stress: Elastic moduli and stress-strain curves, for example, are expressions of this relationship. (3) The rate of displacement, as dependent on the stress: This is usually expressed by the fluidity or its reciprocal, the viscosity.

We are interested in the interpretation of these properties in terms of atomic and molecular structures and interatomic and intermolecular forces. Since the type of structure varies greatly in different classes of materials—crystals, liquids, glasses, high polymers, etc. —it is convenient to consider these classes separately.

In *crystalline solids* the chief effect of an applied stress is to shift all of the atoms or molecules slightly from their equilibrium positions in the crystal structure. Work is done against the interatomic or intermolecular forces; the energy of the system is increased. On removal of the stress, the atoms and molecules return to their equilibrium positions. The substance exhibits *short-range elasticity.*

If *flow* occurs at all, it takes place in jumps, one atom or molecule at a time. The structure after each jump is closely similar to that before the jump; hence the shifts are permanent and this is flow rather than elasticity. The jumps occur readily only where there are irregularities—departures from the perfectly crystalline arrangement—as at grain boundaries or regions where, for accidental reasons, there happens to be either a deficiency or an excess of atoms or molecules (per unit of volume) over the number required for the perfect crystal. Because of the crystalline arrangement, the shifts occur preferentially in certain directions, parallel to the atomic or molecular planes; hence the flow properties of the whole vary with direction.

To break or *fracture* a crystalline solid, the applied stress, greater than a certain "yield value," produces a shift of an atom or molecule to a less stable situation (e.g., one involving greater atomic separations); this shift facilitates a similar shift of a neighbor, such shifts then occurring autocatalytically across the crystal. This process is obviously also directional, the breaks tending to follow the planes of easiest cleavage in the crystal.

In simple *liquids*, irregularities of structure are numerous and irregularly distributed throughout the occupied volume. At some of these irregularities, shifts are constantly (or at least frequently) occurring, as a result of the temperature motions of the molecules. Without the application of an external stress, there is—within the errors of macroscopic observation—as much motion in any one direction as in the opposite direction; hence no over-all motion is observed. Application of a shear stress favors motions having a component in the direction of the stress and hinders those having a component in the opposite direction; *flow* is therefore observed. The rate of flow (hence the fluidity and its reciprocal, the viscosity) depends on the difference between the rate at which energy humps restricting molecular shifts are passed over in the forward and backward directions, and so on the magnitudes of these humps, their number, the temperature, and the applied stress. Unlike the crystalline case, the flow properties are independent of direction. For pure shear stress, there is (in a simple liquid) no "yield value"—an infinitesimal stress is sufficient to produce flow. *Elasticity* (short range) is observed for over-all compression, but not for shear.

Glasses are like liquids in having an irregular structure, but like crystalline solids in having (at ordinary temperatures) few or no atomic or molecular shifts occurring spontaneously—as a result of the temperature motions —or on the application of small shear stresses. Thus they exhibit *short-range elasticity*, and *flow* only with high stresses, long times, or high temperatures. The detailed interpretation of stress phenomena is complicated, for ordinary silicate glasses at least, by the fact that the structures contain charged ions, these being of a variety of chemical types, charges, sizes, and shapes. The existence of a substance in the glassy "state" is a result of the fact that the component atoms can be distributed in space in various ways of about equal stability, but with high energy humps hindering transitions from each such way to others.

High polymers are generally, like glasses, irregular in structure, although they frequently have regions which are more or less crystalline. The crystalline arrangement and many non-crystalline arrangements are usually of nearly equal energy. Moreover, the shifts of atoms needed to change a small non-crystalline region into a

crystalline one often do not require the breaking of any strong bonds—passage over large energy humps. On the other hand, to change a sample of a semicrystalline linear high polymer, in which many of the polymer chains run through two or more crystalline regions as well as amorphous intercrystalline regions, into a single crystal would require either the breaking of many strong bonds or the breaking up of many of the crystalline regions. This would involve passage over large energy humps, so large that the process would not occur at ordinary temperatures; at high temperatures the crystalline arrangement would not be stable relative to an amorphous structure. For these reasons, single crystals of linear high polymers have not been obtained.

Rotation around a single bond in an organic molecule, such as a linear high polymer, ordinarily involves only small changes in energy, of the order of magnitude of the average energy of temperature motion of the atoms. The polymer molecules can therefore change their shapes and their steric relations to their neighbors by motions of a few atoms at a time over relatively small energy humps. Both *flow* and *long-range elasticity* involve such changes. For flow, molecules must permanently shift their positions (e.g., their centers of gravity) relative to their neighbors—more of them shifting in the direction favored by the applied stress than in the opposite direction. In high polymers this shift rarely takes place all at once; it occurs, rather, as a succession of small shifts of portions of the molecule. The stress must be maintained over a time long enough for these successive shifts, and allowing for occasional shifts in the reverse direction—against the stress—in accord with the principles of equilibrium.

A single crosslink to an adjacent molecule can prevent the flow of a given molecule. The molecule can then change its shape, extending itself in the direction favored by the stress, but, on release of the stress, it will tend to revert to its original state, relative to its neighbors. This reversion may not be exactly achieved for a given molecule, but the average over all molecules of this sort will be such that there will be no permanent over-all shift, either in the forward direction or in the opposite direction. This reversible change of molecular shape is responsible for long-range elasticity.

The relative flow of adjacent molecules can be hindered or prevented by any intermolecular interactions of sufficient strength, such as hydrogen bonds or strong polar attractions. The cooperative action of many small forces is also effective. This occurs, for example, in crystalline regions: A portion of a chain molecule cannot be removed from such a region one segment at a time, a very large force being required to pull many segments simultaneously over their small energy humps. Even without crystallinity, a portion of a polymer chain which is extended as much as possible in the direction favored by the stress can move only as a unit. Motion of this unit obviously requires passage over a large energy hump—the summation of a series of small humps; it thus occurs less readily than motion of a smaller portion of the chain by itself.

Another factor to be considered is the extent to which a given shift of a segment in a polymer chain requires the pushing aside of neighboring regions, hence cooperating shifts in other molecules. This depends on the sizes, shapes and rigidities of the chain segments, including attached atoms or groups. Even the orientation, *cis* or *trans*, of the single bonds in a polymer chain adjacent to a chain double bond is important. With the *cis*-orientation (that in natural rubber), smaller segments may be shifted at a time and smaller volumes of the surroundings need to be rearranged, than with the *trans*-orientation (that in gutta percha). This is probably the explanation for the differences in long-range elasticity observed for natural rubber and gutta percha.

It is obviously possible for a material to exhibit both plastic flow and long-range elasticity at the same time. This is the case if, under the action of the applied stress, some of the molecules "flow" relative to their neighbors, while others merely change their shapes reversibly.

The forces restricting the motion of chain segments to give plastic flow and long-range elasticity are similar to those restricting the rotations of chains around the chain axes—the kind of motion which many types of chain molecules take up at their "second-order transition" temperatures, somewhat below the point at which they become fluid. The energy humps restricting both types of motion are similar in magnitude. The second-order transition point can therefore be used, for a given type of polymer at least, as a semiquantitative measure of its ability to undergo deformation of shape, either by plastic flow or by elastic extension, in the evaluation of plasticizers, for instance. For a better understanding of the plastic or elastic behavior of a substance or material, however, it is necessary to know something of the numbers of energy humps of different sizes—or, as some would prefer to express it, the distribution of "activation energies" or the "spectrum" of "relaxation times."

From the foregoing, it is evident that, although the same fundamental principles are involved in the different classes of substances considered, the application of these principles leads to widely different stress phenomena, as macroscopically observed.

Some Theoretical Considerations of Dynamic-Property Data on Textile Specimens

W. James Lyons
Chemical and Physical Research Laboratories, The Firestone Tire and Rubber Company, Akron, Ohio

1. Early stretch-vibrometer data, of quite extensive character, on the frequency dependence of the internal friction μ of a Nylon monofil, has been found to conform to the relation

$$\mu=[\mu_2/(1+\omega^2\tau_2^2)]+\mu_3$$

which was deduced independently by Tobolsky and Eyring from considerations of molecular structure. Among other constants evaluated was the relaxation time for the secondary-bond network τ_2, which was found to have the value 9.3 sec.

2. By more sensitive graphing methods than had been used heretofore, it was confirmed by the Nylon data that the hyperbolic relationship between resonant frequency ω_0 and internal friction μ holds equally as well as the foregoing equation. The two relationships are shown to be nearly equivalent in the present experimental range. On evaluation of graphical parameters, the equation $\mu\omega_0=2.47\times10^9$ ergs/cm³ was obtained.

3. Using the same graphical method with a set of data on 11/4/2 cotton cord the relation $(\mu+0.9)\omega_0=7.05\times10^9$ ergs/cm³ was established.

INTRODUCTION

In the application of a relaxation mechanism of the Kuhn type to dynamic experiments, Tobolsky and Eyring[1] indicate that under suitable conditions of load and frequency (in the range 20 to 200 c.p.s.) the modulus E and internal-friction coefficient μ, dynamically measured, are given by the equations

$$E=E_1+E_2, \tag{1}$$

and

$$\mu=[\mu_2/(1+\omega^2\tau_2^2)]+\mu_3, \tag{2}$$

where E_1 and E_2 are partial moduli governing the elastic deformation of the primary and secondary bonds, respectively; μ_2 and μ_3 represent friction, respectively, in the slippage of the secondary bonds, and in the motion of segments of the linear molecule relative to other parts of the chain; ω is the angular frequency of vibration, and τ_2 is the relaxation time for secondary-bond processes.

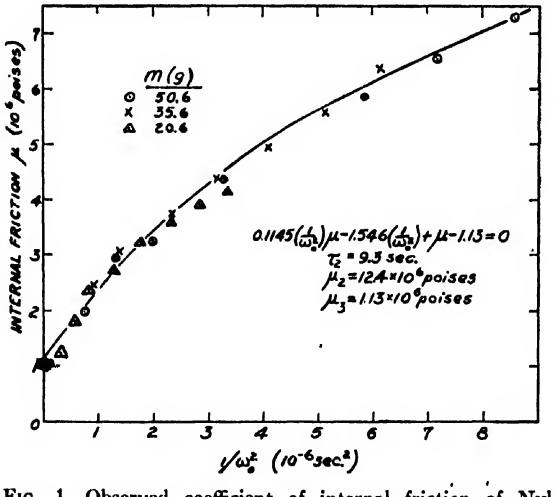

FIG. 1. Observed coefficient of internal friction of Nylon monofil as a function of $1/\omega_0$, at three vibrating masses m. Fitted to the data is a graph of Eq. (2).

The partial moduli E_1 and E_2 being assumed to be material constants in this theory, the dynamic parameter E, according to Eq. (1), should be independent of frequency. In line with its earlier confirmation for rubbers at frequencies above the very lowest,[2,3] this theoretical conclusion has been confirmed on the textile stretch-vibrometer for samples of nine different textile materials,[4,5] up to frequencies between 300 and 400 c.p.s. At frequencies approaching, and in the supersonic range, the frequency-independence of E for textiles probably disappears, as it does for other high polymers.

It has been of further interest to investigate the validity of the internal-friction relation, Eq. (2). For this purpose the extensive data previously obtained on a high tenacity Nylon monofil were selected for treatment.

NYLON MONOFIL DATA

The calculated coefficients μ, obtained on the stretch-vibrometer for eight different lengths of the Nylon monofil, with three vibrating masses (reference 5, Fig. 8), were plotted as functions of $1/\omega_0^2$, $\omega_0(=2\pi f_0)$ being the resonant angular frequency at which the particular measurement was made. The result is shown in Fig. 1.

It can be readily verified that Eq. (2) can be written as an equation in $1/\omega^2$ and μ, as follows:

$$(1/\tau_2^2)\cdot(1/\omega^2)(\mu-\mu_2-\mu_3)+(\mu-\mu_3)=0, \tag{3}$$

where $1/\tau_2^2$, μ_2, and μ_3 are constants. The graph of this equation is a hyperbola having a μ-intercept of μ_3, and asymptotes $\mu=\mu_2+\mu_3$ and $1/\omega^2=-\tau_2^2$. It was recognized that the downward concavity of the pertinent branch of this curve coincided well with the distribution

of the experimental points in Fig. 1. Accordingly the three constants were evaluated to secure a good fit to these points. The resultant theoretical curve, for which $\tau_2=9.3$ sec., $\mu_2=12.4\times10^6$ poises, $\mu_3=1.13\times10^6$ poises, has been drawn in Fig. 1. The values of the constant coefficients in the equation set forth in Fig. 1 are those which are appropriate when $1/\omega_0$ is expressed in 10^{-3} sec.

DISCUSSION

The foregoing analysis has provided a value for the relaxation time τ_2 for secondary-bond processes. The value of 9.3 sec. is consistent with the conditions accepted by Tobolsky and Eyring in deriving Eq. (2), one of the conditions being that τ_2 is of the order of seconds.

If the familiar relation of Maxwellian relaxation theory, $\tau_i=\mu_i/E_i$, is considered as holding in intermolecular-bond processes, it is possible to estimate the value of the partial dynamic modulus E_2, for these processes. Thus

$$E_2=\mu_2/\tau_2 = (12.4\times10^6)/9.3=1.33\times10^6 \text{ dynes/cm}^2. \quad (4)$$

This value is practically negligible in comparison with the value of E which has been found for the Nylon sample: 8.0×10^{10} dynes/cm^2. It would appear then that in the type of longitudinal vibration to which the Nylon sample was subjected in the stretch-vibrometer, secondary bonds contribute very little to the over-all elasticity, and thus,

$$E\approx E_1. \quad (5)$$

The implication here that the primary bonds furnish practically all of the dynamic elasticity is at variance with the interpretation of Tobolsky and Eyring, who consider E_1 to be essentially the static modulus. Thus,

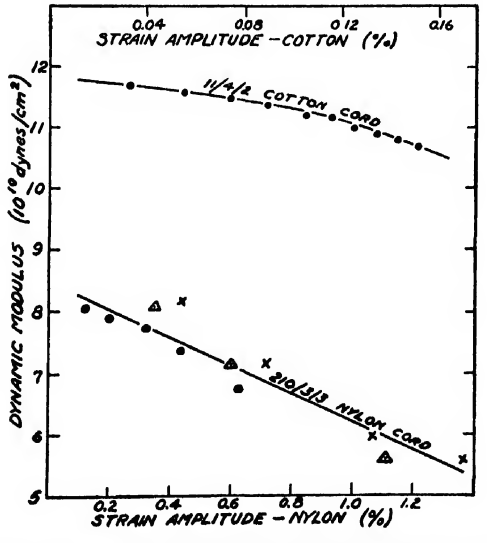

FIG. 2. Influence of strain-amplitude on the dynamic moduli of 11/4/2 cotton and 210/3/3 Nylon cord; three separate experiments on Nylon sample.

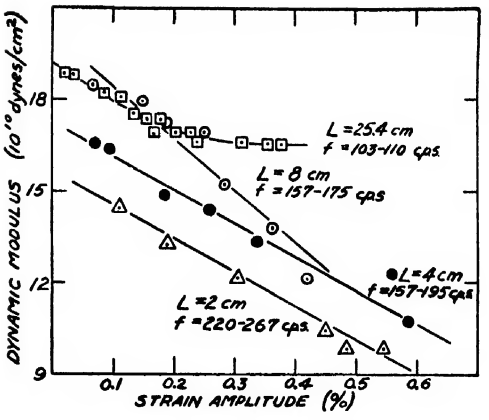

FIG. 3. Influence of strain-amplitude on the dynamic modulus of 1100/2 rayon cord; 2-kg load, at various free lengths of specimen, L.

on this view, E_1 and E_2 would be of the same order of magnitude, with E_1 being actually the smaller of the two, since this, quite generally, is what experiment indicates.

While the Tobolsky and Eyring analysis appears to be reasonable as applied to the rubber-like polymers, it is expected that in an oriented, linear fiber-forming polymer, such as the Nylon, being vibrated at a relatively small strain-amplitude, the basic dynamic, elastic processes could very well be restricted to the primary bonds. This behavior implies that the load is carried principally by the main valence chains, which view, for an oriented textile polymer such as high tenacity Nylon, is indeed tenable. In fact, Mark,[6] speaking of textile polymers, cellulose in particular, says "If any kind of van der Waals' forces were assumed to be responsible for the modulus of elasticity . . . the high values actually observed by various authors (would not be expected)." Secondary bonds, as represented by van der Waals' forces, are estimated to be smaller than primary valence forces by several orders of magnitude, in line with the relation found between E_1 and E_2 in the present analysis.

As the strains are carried to higher amplitudes it may be expected that more and more secondary bonds become involved, and the load is partially shifted over to them. This would result in an increase in the effective secondary-bond modulus E_2, and a decrease in the effective primary modulus E_1, but if replacement here is bond-for-bond, or even in the ratio of 100 for 1, the effect would be a decline in the over-all modulus E. This effect we have found in strain-amplitude studies on cotton, rayon and Nylon cords, as shown in Figs. 2 and 3.

Considered as an equation in μ and $1/\omega_0$, instead of $1/\omega_0^2$, Eq. (3) is a cubic. The graph of this cubic equation is plotted as a solid line in Fig. 4. By equating $d^2\mu/d(1/\omega_0)^2$ to zero the inflection point of the cubic is

[6] H. Mark, *Cellulose and Cellulose Derivatives* (Interscience Publishers, Inc., New York, 1943), edited by E. Ott, p. 995.

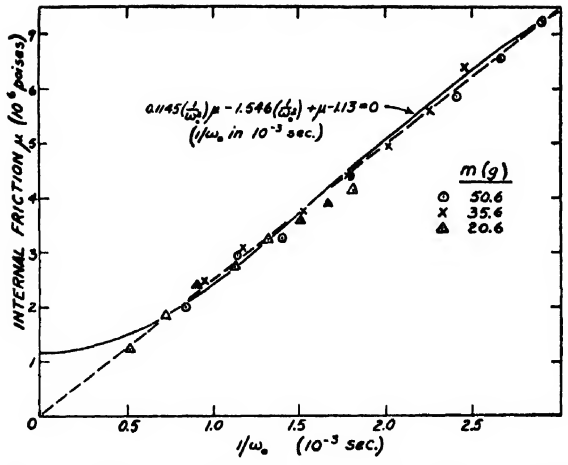

FIG. 4. Observed coefficient of internal friction of Nylon monofil as a function of $1/\omega_0$. Fitted to the data is the graph of Eq. (2) (solid line), as well as that of $\mu\omega_0 = \text{constant}$.

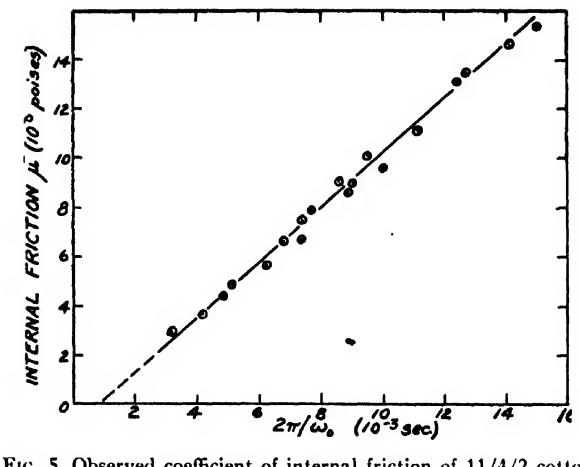

FIG. 5. Observed coefficient of internal friction of 11/4/2 cotton tirecord as a function of $2\pi/\omega_0$.

found to be at $1/\omega_0 = 1.7\times10^{-3}$ sec. The region of the inflection point of a cubic curve can be approximated by a straight line, and since the inflection point falls at about the middle of the array of experimental points in this study, the data themselves, as Fig. 4 shows, can be as well represented by a straight line as by the cubic. The equation of such a straight line is the hyperbolic relation

$$(\mu+\alpha)\omega_0 = \text{constant}, \tag{6}$$

with which, it has been demonstrated,[4,5] our data on a large number of textile samples are in apparent agreement. While Eq. (2) or (3) is not mathematically consistent with Eq. (6), the foregoing graphical analysis indicates why the data are in reasonably good agreement with both.

The straight line in Fig. 4, which is the most acceptable that could be drawn through the data points, has been extrapolated to the origin. The fact that a straight line passing through the origin fits the data, plotted on a $(1/\omega_0)\mu$-plane, demonstrates better than has been done heretofore that: (a) the relation between μ and ω_0 may be represented by a *true* hyperbola, and (b) the constant α is zero, and ω_0 has no additive constant. Furthermore, from Fig. 4 one is readily able to evaluate the constant in Eq. (6). Thus the data for the Nylon monofil, if they are regarded as representable by Eq. (6), lead to the relation

$$\mu\omega_0 = 2.47\times10^9 \text{ ergs/cm}^3. \tag{7}$$

An interesting sidelight emerges from the consideration of the constancy of the product $\mu\omega_0$, for, referring (5) to the equation

$$\mu = qF/s_m\omega_0, \tag{8}$$

it is seen that $\mu\omega_0 = \text{constant}$ implies that the displacement amplitude at resonance s_m is directly proportional to the amplitude of the applied force F, if the shape factor $q = L/2A$ remains constant. For a particular string, *strain*-amplitude is proportional to force-amplitude regardless of length L. Such a relationship appears entirely reasonable, though it is not part of the original dynamic theory. These considerations evidently place the product $\mu\omega_0$ in the role of a Young's modulus for the viscous component of the strain. This interpretation of $\mu\omega_0$ is brought out also (and without recourse to experiment) when the dynamics is expressed in complex notation.

COTTON CORD DATA

Following the latter treatment applied to the Nylon data, results on a cotton cord, taken from Fig. 6 of reference 4, have been plotted on a $(1/\omega_0)\mu$-plane, as shown in Fig. 5. Here again a straight line appears to represent the frequency dependence of μ. However, the line does not pass through the origin. The μ-intercept $(=-\alpha)$ is found to be -0.9. Evaluating the slope of the graph we get for the cotton sample,

$$(\mu+0.9)\omega_0 = 7.05\times10^9 \text{ ergs/cm}^3. \tag{9}$$

A natural question arises as to what theoretical interpretation is to be put on the finite value of α. In the light of the discussion on the Nylon data, it appears that no serious attempt to place a physical interpretation on α should be made. Evidently the vanishing of α in the Nylon case was quite fortuitous.

ACKNOWLEDGMENTS

The data upon which the present development rests are the results of the careful measurements and calculations of Mr. Irven B. Prettyman. The author has had the benefit of profitable discussions on the analytical aspects with Messrs. J. W. Liska and G. R. Thurman. The encouraging support of Firestone research management is gratefully acknowledged.

Equation of State for High Polymers

R. S. Spencer and G. D. Gilmore
The Dow Chemical Company, Midland, Michigan

In a former paper the authors suggested the following equation of state, $(P+\pi)(V-\omega)=RT$, where π is the internal pressure (or cohesive energy density) and ω is the volume at absolute zero. It was found that this equation was in good agreement with data on the thermal expansivity and isothermal compressibility of polystyrene.

The present paper reports isothermal compression measurements on polymethyl methacrylate, polyethylene, cellulose acetate-butyrate, and ethyl cellulose at temperatures within the fabrication range. The above equation of state is shown to apply equally as well to these thermoplastics as to polystyrene and values are given for the constants. The usefulness of this relationship is illustrated in a brief discussion of some phases of the injection molding process.

INTRODUCTION

In a former paper the authors suggested[1] the following modified van der Waals' equation of state,

$$(P+\pi)(V-\omega)=RT.$$

In this, P is the external pressure, π the internal pressure (or cohesive energy density), V is the volume, ω the volume at absolute zero, R the gas constant, and T the absolute temperature. It was found that this relationship was obeyed quite well by polystyrene, and served to correlate experimental observations of thermal expansion, isothermal compression, sound velocity, and cohesive energy density by swelling measurements.

This work was undertaken as part of a larger study of the fundamentals of the injection molding process, and most of our applications of this equation of state have been in that field. The desire to extend our findings to thermoplastics other than polystyrene has resulted in the present work, inasmuch as the equation of state is basic to further considerations in injection molding theory. This point will be illustrated briefly at the end of the discussion.

The pragmatic nature of our interest in this problem has limited considerably the scope of our investigation. No attempt was made to study the compressibility of these polymers below their apparent second-order transition temperatures, as the interest was centered on fabrication conditions. Preliminary attempts were made to observe time effects associated with pressure and temperature changes in the neighborhood of the apparent second-order transition,[2] but it was concluded that the apparatus used was unsuitable. It was noted, however, that polystyrene exhibits retarded isobaric volume changes, after a sudden change in pressure, as well as the retarded isothermal volume changes already reported.[2,3] It is hoped that this important phenomenon will be investigated further by other workers in the field.

We shall continue to use the hybrid units of reference 1 and express P and π in lb./sq. in., V and ω in cc/g, and T in degrees K.

EXPERIMENTAL METHODS

The basic apparatus used for isothermal compression measurements has been described elsewhere,[1] as follows: "It consists of a cylindrical specimen cavity, one square inch in cross-sectional area, with a close-fitting plunger for compressing the polymer. This plunger also contains a cavity which opens into a groove machined in the wall of the specimen cavity. This plunger cavity is filled with polymer, which is forced into the groove and acts as a seal for the sample in the main cavity. In operation, then, force is applied to the smaller central plunger, and the larger plunger directly contacting the sample *floats*."

Some slight changes have been made to facilitate operation. When it was desired to control temperature more closely than was possible with the electric heater the mold was placed inside a small insulated tank through which was pumped liquid from a thermostatted bath. The compression measurements were carried out with a Baldwin-Tate-Emery testing machine, which provided loads up to 20,000 lb. The compression strain was measured with a microformer-type (differential transformer) strain follower which operated the chart drive of a drum recorder. The pen movement was linked mechanically to the testing machine so as to record pressure. Thus, the recorder reproduced automatically the compression stress-strain curve. This arrangement effected a considerable speeding up of the measurements.

The polymethyl methacrylate used was a product of E. I. du Pont de Nemours and Company, designated as Lucite HM 140. The polyethylene was also a du Pont product, designated as P1000 PM 1. The cellulose acetate-butyrate was Tennessee Eastman's Tenite II, designated as 265-A. The ethyl cellulose formulation was a mixture of 15 percent plasticizer, 85 percent ethyl cellulose of degree of substitution 2.34. All of the samples were prepared by machining down cylinders to a firm press fit into the compressibility mold.

DISCUSSION

Broadly speaking, our measurements consist of parallel observations of pressure, P, and volume, V, at a fixed temperature, T. From such data we wish to deduce the probable values of the constants π, ω, and R.

This may be done, of course, by direct use of the equation of state in the form already given. However, there are experimental and theoretical advantages in considering only corresponding changes in pressure and volume, rather than absolute magnitudes. This procedure avoids the necessity of using the apparatus to measure thermal expansivity (for which it is not ideally suited), helps prevent the accumulation of errors, and is more sensitive in bringing out such things as the pressure-dependence of π.

In this differential method we eliminate ω, which can be calculated subsequently from a known value of the equilibrium volume at some temperature and pressure. The constants π and R remain to be determined from our data. If we knew the molecular weight, M, of an "interaction unit" of the polymer chain, we could calculate R, in our units, from our relationship $R=1206/M$. If the polymer is something like polystyrene or polymethyl methacrylate, having one bulky side-group per monomeric residue, it seems reasonable to assume that the interaction unit is just one residue. This appears to be true, within experimental error. Such polymers as polyethylene, with no side-groups, and cellulose derivatives, with several per residue, present much more ambiguous situations, however. It seems preferable, then, to begin by considering both π and R to be unknown constants. If the empirical value of R subsequently offers a suggestion as to the nature of the interaction unit, the data can be reworked accordingly.

The appropriate relationship to use in this approach is

$$[-T(\Delta P/\Delta V)]^{\frac{1}{2}}=[\pi/(R)^{\frac{1}{2}}]+[1/(R)^{\frac{1}{2}}]\cdot\bar{P}$$

where ΔV is the volume change resulting from a pressure change ΔP, and $\bar{P}$ is the average pressure over the interval ΔP. Probable values of the constants can be determined by drawing a straight line through a plot of $[-T(\Delta P/\Delta V)]^{\frac{1}{2}}$ *vs.* $\bar{P}$, or by a least-squares procedure, which was the method adopted.

If the monomeric residue is the interaction unit in polymethyl methacrylate, we should expect $R=12.05$. Applying a least-squares procedure to compression measurements at 175°C, we obtain $R=14.71$ and $\pi=35{,}300$ p.s.i. Assuming that the discrepancy in R is experimental error and taking $R=12.05$ as correct, the value of π can be computed over each pressure interval, as shown in Table I. The average value is $\pi=31{,}300$ p.s.i., the scatter is not excessive (there appears to have been an error in the volume of $P=9000$ p.s.i.) and there is no dependence of π on P over the range covered. The equilibrium volume-temperature coefficient would be $(\partial V/\partial T)_{P=0}=R/\pi=3.86\times10^{-4}$ cc/°C. The density at 25°C was 1.169 g/cc. Assuming this to be an equilibrium value, we calculate $\omega=0.740$ cc/g. If we calculate the density at the apparent second-order transition, using the data of Robinson, Ruggy, and Slantz,[4] and assume that to be a state of equilibrium, we obtain $\omega=0.734$. If we take the density at 30°C = 1.1818 g/cc, as given in reference 4, to be an equilibrium value, we get $\omega=0.728$. The last two values are probably preferable to the first one, only suitable equilibrium density measurements can resolve the question.

In the case of polyethylene at 178°C, the least-squares method gives $\pi=50{,}600$ p.s.i., $R=48.03$. This value of R is not far from 43.0, which corresponds to one ethylene residue as an interaction unit, so the latter value shall be taken as correct. Calculating for each pressure interval we obtain the results of Table II, which give as an average $\pi=47{,}600$ p.s.i. The equilibrium volume-temperature coefficient is $(\partial V/\partial T)_{P=0}=9.48\times10^{-4}$ cc/°C. The density at 25°C was found to be 0.9196 g/cc, from this $\omega=0.805$ cc/g. This is almost certainly not correct, however, due to the presence of considerable crystallinity at room temperature. Correcting the density to the melting point, using the data of Clash and Rynkiewicz,[5] we obtain $\omega=0.875$.

The least-squares values obtained with the data on ethyl cellulose at 196°C are $R=19.95$ and $\pi=34{,}800$ p.s.i. The value of R corresponds only to a fractional

part of a substituted glucose residue, as might be expected, therefore, we shall accept the least-squares value, having no better substitute. The scatter in the measurements is shown in Table III, where π is calculated for each pressure interval, using the above value of R. No trend of π with $\bar{P}$ may be noted. There appears to be an error in the volume observed at $P = 14{,}000$. The equilibrium volume-temperature coefficient is $(\partial V/\partial T)_{P=0} = 5.73 \times 10^{-4}$ cc/°C. The density at 25°C was observed to be 1.115 g/cc, giving $\omega = 0.725$. Correcting to the apparent second-order transition, using the data of Wiley,[6] gave $\omega = 0.720$.

In the case of cellulose acetate-butyrate at 181°C the least-squares values are $R = 22.18$ and $\pi = 41{,}300$ p.s.i. As with ethyl cellulose, the value of R corresponds to a fractional residue and will be accepted as given. In Table IV are shown the values of internal pressure for each pressure interval, calculated with the above value of R. The scatter and lack of dependence upon applied pressure are very much as has been noted in the preceding tables. The equilibrium volume-temperature coefficient is $(\partial V/\partial T)_{P=0} = 5.37 \times 10^{-4}$ cc/°C. The density at 25°C was 1.17 g/cc, giving $\omega = 0.695$. Correcting to equilibrium, using the data of Clash and Rynkiewicz,[5] gives $\omega = 0.688$.

The equation of state constants which have been determined to date are summarized in Table V, together with activation energies for viscous flow, taken from various sources.[4,7,8] The activation energy for flow seems to rise with increasing cohesive energy density, as might be expected, with the glaring exception of polyethylene. This exception is apparent rather than real, however. The units of π are energy per unit volume, while the units of activation energy are energy per mole. Taking the residue molecular weights into account, a fair correlation is found between cohesive energy per mole and activation energy per mole for all five polymers. In Eyring's picture of viscous flow[9] this would be interpreted as signifying that the number of residues per kinetic chain segment is roughly a constant for the different polymers. We estimate that it is in the general neighborhood of 15 residues per segment.

The order in which the polymers arrange themselves on the basis of cohesive energy density is not too surprising, again with the exception of polyethylene. Considering only chemical structure, one would be tempted to guess, *a priori*, that polyethylene would have a lower cohesive energy density than the other polymers, and just the reverse is true, of course. However, the polyethylene molecule exhibits a quality which the others do not, and that is great regularity of structure and the ability to form close-packed arrangements. It is just this factor which permits polyethylene to crystallize in spite of its non-polar nature. Thus, polyethylene contains many more monomeric residues per cc than the other polymers. If we calculate the cohesive energy per residue, or per interaction unit, the apparent discrepancy disappears.

In discussing a few examples of the important role which the equation of state plays in injection molding theory it will be necessary first to present a somewhat simplified picture of what occurs in an injection molding cycle.[10] In the more usual type of molding press the polymer is fed in at room temperature and is heated to molding temperature in the machine. In a subsequent cycle this hot polymer is forced through the channels of the press and mold, eventually filling the mold cavity. It is customary to maintain pressure on the ram of the press for some time after the mold is filled. During this interval several things are going on. The pressure in the mold builds up fairly rapidly to a

[a] Values uncertain owing to lack of reliable values for equilibrium density.

relatively stable value, which is usually appreciably lower than the ram pressure. Inasmuch as the mold is colder than the polymer, the polymer is being cooled from the time it enters the mold. The mass of the polymer in the mold increases slowly during this time. At the end of this interval the ram is returned to its starting position. The pressure difference between the mold cavity and the channels in the press has now reversed direction and there is certain amount of polymer discharged from the mold cavity. This discharge lowers the pressure in the mold and the discharge rate falls off until there is sufficient cooling at the constricted entrance to the mold cavity (usually called the "gate") to "solidify" the polymer and seal off the mold. Following the discharge period the polymer in the mold cools under conditions of constant mass until the mold is opened and the piece removed.

The cooling characteristics of the mold give us a relationship between polymer temperature and time. The equation of state then gives us the relationship between pressure, mass of polymer in the mold, and temperature. Thus, consideration of any question which involves calculating the pressure or the mass of polymer in the mold must rest on a knowledge of the equation of state. For example, under certain conditions volume defects, such as bubbles or sink marks, appear in the piece. These defects can be rendered unobjectionable by being sure that the mass of polymer sealed in the mold exceeds some minimum value under given sealing conditions. This condition can be set up in terms of controllable quantities by use of the equation of state. As another example, we note that behavior during release of the piece from the mold is determined primarily by the pressure remaining in the mold at the time the mold is opened. The force required to open the mold depends directly upon the residual pressure, as might be expected. If the pressure is too high it will not be possible to open the mold. At lower pressures the piece will stick in the female half of the mold and/or will be objectionably scored in removing from the mold. Finally, if the residual pressure is kept below a certain maximum, the piece releases reasonably easily. If, however, the pressure is allowed to become "negative," there is a tendency to stick on the male half of the mold, and even to crack. The application of the equation of state in considering such questions as the above should be obvious.

A more detailed discussion of these, and other, injection molding problems may be found in reference 10 and in publications to follow.

SUMMARY

The constants in a simplified van der Waal's equation of state have now been determined for the following polymers: polystyrene, polymethyl methacrylate, ethyl cellulose, cellulose acetate-butyrate, and polyethylene. Of these, polystyrene has the lowest internal pressure (or cohesive energy density) and polyethylene has the highest. The unexpectedly high internal pressure exhibited by polyethylene has been associated with the great regularity of the polyethylene molecule and its ability to form closely packed arrangements.

The application of the equation of state in the injection molding field has been illustrated by a very brief discussion of the roles played by pressure, temperature and polymer density in such phenomena as mold release and the formation of bubbles and other defects.

Behavior of Granulated Polymers under Pressure

R. S. Spencer, G. D. Gilmore, and R. M. Wiley
The Dow Chemical Company, Midland, Michigan

In such fabricating processes as extrusion and injection molding it is frequently necessary to force a granular polymer through a channel. Frictional forces between polymer and channel walls lead to a drop in pressure through the granular material. Simultaneously, the applied pressure causes a compaction of the granules.

Assuming that the granular mass has certain fluid-like properties, a simple theoretical expression for pressure transmission is derived. Comparison with data on saran powders and granular polystyrenes shows good agreement between theory and experiment. The effect of lubrication is shown also.

The compaction of granular polystyrene follows the same pattern as that observed in the earth's crust. The porosity decreases exponentially with increasing pressure. The "compressibility coefficient" for the porosity of granular polystyrene is comparable with that given for clays and shales.

INTRODUCTION

THE available literature relating to the behavior of granular solids under pressure is rather scanty. Inasmuch as the handling of some such materials is of considerable technological importance, the reasons for this deficiency are not immediately apparent. It can only be surmised that either an appreciable amount of unreported work has been done or else the practical importance of the problem has not been emphasized sufficiently to those who are in a position to study it adequately.

Most thermoplastics are marketed in granular form. In subsequent fabrication operations, such as extrusion or injection molding, it is usually necessary to force the granular polymer through some sort of channel. In given circumstances, then, one wishes to know what force it is necessary to apply in order to move the granular polymer against a specified resisting force, or, conversely, how much of the applied pressure is transmitted through the granular material. It is probably safe to say that lack of knowledge on this point is not least among the factors which have served to maintain polymer fabrication techniques in the realm of technological arts rather than applied sciences.

The problem to be considered in the present paper is that of the relationship between applied force and resisting force at either end of a plug of granular polymer which is just on the point of motion through a channel of constant, but arbitrary, cross section. That is to say, the conditions at the wall of the channel are those of static friction. The solution of this problem necessitates certain assumptions, which are set up largely by analogy with fluid behavior. This restricts application to those cases in which the particle size is considerably smaller than the dimensions of the channel. Two simple arrangements will be described by which the problem may be studied experimentally, each having certain advantages. Results obtained with saran powders and polystyrene granules will be presented and interpreted with the aid of the simple theory.

At relatively higher pressures, considerable compaction of the granular material may be effected, which is essentially irreversible as long as the plug is confined within the channel. This is taken account of in the assumptions underlying the theory and, experimentally, by always proceeding in the direction of increasing applied pressure. This compaction is of some interest in itself; therefore, a few data are presented and discussed to illustrate the pattern of behavior.

It is doubtless redundant to point out that the treatment throughout is simplified and the investigation undetailed. Our interest in this problem arose because of its place in a larger program of study of polymer fabrication processes. Many points, theoretical and experimental, await clarification. It may be hoped that this will not be too long forthcoming.

EXPERIMENTAL METHODS

The first arrangement, being that used to study saran powders, is shown in Fig. 1. The confining channel was a glass tube of circular cross section. The polymer sample rested upon a rod extending below the tube, and was confined from above by a weight representing the resisting force. Both weight and rod were smaller in diameter than the tube, flaring out to the tube diameter at the end contacting the polymer. This was to minimize binding which would otherwise be occasioned by the trapping of powder granules between the rod and tube. One arrangement utilized a tube of 1.1 cm internal diameter with weights of 17 and 35 g; another, a tube of 2.15 cm internal diameter with weights of 38 and 78 g.

The procedure followed was to assemble the apparatus, using a given amount of saran powder, and set it upright on the platform of a spring scale. Downward force was then exerted upon the glass tube, and the reading of the scale noted at the instant the polymer first began to slip. This was then repeated with different amounts of powder, resisting loads, and tube diameters.

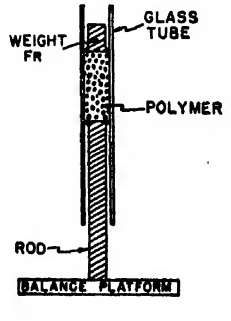

FIG. 1. Experimental arrangement used in the study of saran powders.

TABLE I. Coefficient of friction of saran powders.

Powder No.	D (cm)	μ
1	1.1	0.215
	2.15	0.239
2	1.1	0.144
	2.15	0.144
3	1.1	0.113
	2.15	0.167

It was found that all of the glass tubes examined were not perfectly cylindrical but had varying degrees of taper. It was necessary, then, to select those with the least taper, and to exercise the further precaution of always moving the polymer along the tube in the direction of increasing internal diameter, to avoid jamming. Relatively reproducible results could then be obtained with some care, although experimental errors with this apparatus must be considered to be rather large.

The apparatus used for the study of granular polystyrenes is shown schematically in Fig. 2. It consisted of a heavy-walled steel cylinder of 1.953 in. internal diameter, with two closely fitting pistons. SR-4 strain gauges were mounted on the lower piston and the unit calibrated in terms of force applied to the piston. It was found that any film on the surface of the cylinder wall adversely affected the reproducibility of measurement, therefore, the unit was carefully cleaned with carbon tetrachloride before use. It was then assembled, with the sample in place, and set between the platens of a 30-ton press. Force was applied through a hand-operated hydraulic jack, and the corresponding transmitted force determined from the strain gauge readings.

The saran powders used were commercial materials, denoted as *1*, *2*, and *3*, in order of increasing amount of lubricant in the formulation. The polystyrenes were also commercial materials, very similar to each other. The sarans were in the form of very finely divided powders, whereas the polystyrenes were much coarser, perhaps averaging around 0.15 in. particle diameter. One exception to this was polystyrene No. 2, which was that component of No. 1 which would pass through a U. S. No. 8 screen, and averaged considerably less than that in size, perhaps around 0.04 in.

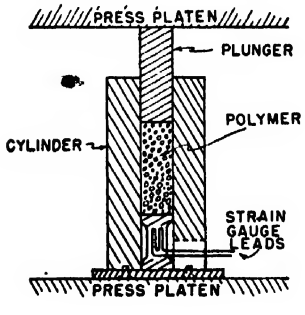

FIG. 2. Experimental arrangement used in the study of pressure transmission through granular polystyrenes.

DISCUSSION

The pressure-transmission problem to be solved has already been stated in the Introduction; it may be made a little clearer, perhaps, by referring to Fig. 3. A plug of granular polymer is confined within a channel of constant cross section. The applied force at one end of the plug is in opposition to the resisting force at the other end. What is desired is the relationship between the forces when the plug is just on the point of moving in the direction of the applied force.

It has been mentioned that increasing the applied force causes compaction of the granules. That is to say, the length of the plug decreases. The state of compaction may be defined by the porosity, or the initial and currently observed lengths of the plug, or by the initial length and the current pair of forces. In general, we must consider that the porosity will vary along the length of the plug; however, we shall be considering in our solution only the equilibrium situation in which the porosity at any point is not changing with time.

We shall define now the following quantities:

x = distance from the forward end of the plug to any plane normal to the axis of the plug.
μ = coefficient of friction of particle on wall.
n = number of particles per unit area contacting the wall at x.
n_0 = number of particles per unit area contacting the piston surfaces at the ends, or in contact over a cross section.
f = contact force between particles at x.
F = total force normal to the cross section at x.
$F_A(P_A)$ = applied force (pressure) necessary to just move the plug.
$F_R(P_R)$ = resisting force (pressure).
L = length of the granular plug in any given state of compaction.
L_0 = original length of the plug when the forces were very small.
C = perimeter of channel cross section.
A = area of channel cross section.
D = diameter of circular cross section
a, b = sides of rectangular cross section.

The principal assumptions to be made use of are the following:

(1) In a given state of compaction there is no tendency for particles to move with respect to each other, hence the only frictional forces to be considered arise from particle-wall contacts. (2) Contact forces are the same in all directions at a point, and are normal to the walls and ends. (3) The quantity n_0 is constant, independent of F and x. (4) The total number of wall contacts is constant, although, of course, n depends upon F (or upon x in a given state of compaction); further, that $n = n_0$ over the entire wall originally, when the forces are very small.

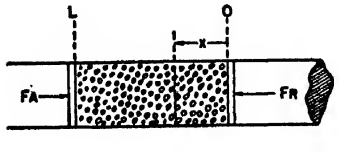

FIG. 3. Diagram defining quantities in the pressure transmission problem. A = area; C = perimeter.

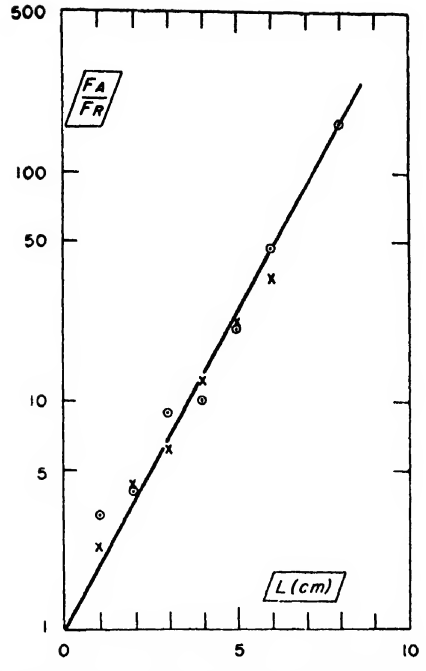

FIG. 4. Dependence of force ratio on length of sample of saran No. 2 in tube of diameter 1.1 cm. Circles represent $F_R=17$ g and crosses represent $F_R=35$ g.

Before proceeding, let us look over the assumptions quickly. There might be some temptation to replace (1) by the more usual assumption that the particles are hard and smooth, i.e., that there is no friction between particles. This is not true, however, as evidenced by the irreversibility of the compaction; thus we prefer the less general assumption (1). The second assumption is arrived at by considering the contact force to be analogous with pressure in a fluid. Actually, assumption (2) is more general than would be required, but it is felt that the analogy is clearer in the form as stated. The origin of assumptions (3) and (4) is more obscure and their plausibility less immediately discernible. It may help to picture the plug as a cylinder of some compressible material, on the surface of which is drawn an evenly spaced network representing the contact points. If this cylinder were compressed axially, while confined radially, the network spacing on the ends would remain unchanged, while the density of network on the sides would increase with the compression strain. Carrying this picture over to our granular material, we need only remember that in calculating the frictional force we are not concerned with the area of contact, but only with the contact force and the number of contacts.

With these preliminaries the solution is now quite straight-forward. Consider an element between x and $x+dx$. The frictional force at the wall is μf per particle, giving a total frictional force of $\mu fnCdx$. The change in F in going from x to $x+dx$ is $dF=An_0df$. By assumption (1) we can equate these two expressions and rearrange to give

$$dF/F=df/f=(\mu Cn/An_0)dx.$$

Integrating from $x=0$ to $x=L$, we obtain

$$\ln F_A/F_R=\frac{\mu C}{An_0}\int_0^L ndx.$$

To evaluate the integral on the right-hand side we utilize assumption (4) and equate the expressions for the number of wall contacts in the uncompacted state L_0 to the number of wall contacts in the compacted state. Thus,

$$n_0CL_0=\int_0^L nCdx$$

or

$$\int_0^L ndx=n_0L_0.$$

Substituting this in our previous equation, we finally arrive at

$$F_A/F_R=P_A/P_R=\exp(\mu CL_0/A).$$

We note that the exponent is merely the coefficient of friction times the ratio of the wall area (uncompacted) to the cross-sectional area. If the cross section is a circle of diameter D, we have

$$F_A/F_R=\exp(4\mu L_0/D).$$

If it is a rectangle of sides a and b, we have

$$F_A/F_R=\exp[2\mu(a+b)L_0/ab].$$

If the rectangle approaches a slit, so that $a\gg b$, our expression approaches

$$F_A/F_R=\exp(2\mu L_0/b).$$

With the above results of our semicontinuous-semiparticulate approach to the problem, let us look at the experimental observations. First, we shall consider the data obtained on saran powders with the arrangement of Fig. 1. In Fig. 4 $\log F_A/F_R$ is plotted against L_0, for constant tube diameter and two resisting forces, and it may be noted that a fairly good straight line is obtained, as predicted by the theory. In Table I the data on the saran powders are summarized in the form of values of the coefficient of friction, calculated from the slopes of lines like that of Fig. 4. The constancy of F_A/F_R for different values of F_R is evident in Fig. 4 and the point is not elaborated further in Table I. It must be concluded that the saran data bear out the predicted dependence of F_A upon F_R, L_0 and D. The coefficient of friction of saran on glass is not sufficiently well known to provide a further test, but at least the values in Table I seem reasonable and decrease with increasing lubricant.

In the work with polystyrene, using the apparatus of Fig. 2, data were obtained in somewhat different form. Here it was convenient to use a number of different loadings and thus check in greater detail the predicted constancy of F_A/F_R as the loading increased and compaction proceeded. Quite high loads were possible, so that compaction down to as little as 60 percent of the original volume was achieved, yet F_A/F_R remained relatively constant, as shown in Table II. The effect of original length is shown in Fig. 5, where the average F_A/F_R from Table II is plotted logarithmically against L_0. Not only does a fair straight line result, but it may be seen that all three polystyrenes fall along the same line, which corresponds to a coefficient of friction of $\mu=0.262$. In Table III, we see experimental values for

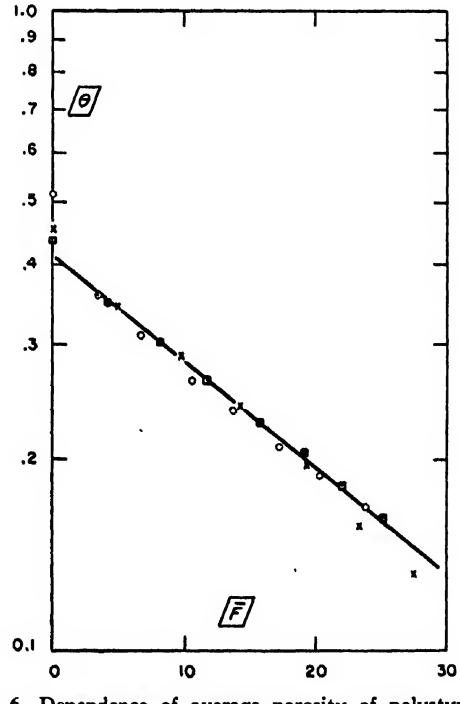

FIG. 6. Dependence of average porosity of polystyrene on average force. Circles represent 140 g of polymer No. 1, 90 g of No. 3, and squares, 140 g of No. 3.

the coefficient of friction of polystyrene on tool steel, as obtained by Roche.[1] Our value of 0.262 compares well with his value of 0.248 at 25°C, providing further evidence that the theoretical expression predicts observed behavior sufficiently well for practical applications.

It has been mentioned that it was necessary to clean the cylinder wall carefully in order to get reproducible results in the work with polystyrene. To see how great the effect of a lubricating film could be, one run was made with polystyrene No. 1 in which the wall was coated generously with Dow Corning No. 200 fluid. This reduced the coefficient of friction to 0.080. The effect of external lubrication on the polystyrene granules is similar. Different amounts of a lubricant in powder form were mixed thoroughly with polystyrene and the pressure transmission through a fixed size of sample determined. The results are shown in Table IV, where it is seen that increasing amount of lubricant reduces the coefficient of friction and thus reduces the ratio F_A/F_R.

Thus far little has been said about the compaction effect, except as incidental to the pressure-transmission problem. For some purposes a more quantitative formulation of the observed behavior may be desirable. The work of Athy[2] on the compaction of the earth's crust with depth suggests that a granular material may behave as if its free volume were characterized by a compressibility coefficient. That is, the porosity, θ, would follow the relationship $\theta=\theta_0 e^{-\beta P}$ where θ_0 is the initial porosity when the pressure, P, is zero, and β is a "compressibility coefficient." (Actually, we shall continue to talk about force, rather than pressure.) In our polystyrene experiments the force varies considerably over the length of the sample, and the porosity will vary accordingly. To correspond to the average porosity calculated from the length of the polymer plug we must calculate an appropriate average force, and this requires that we know the distribution of force along the plug. Assuming this to be of the form $F=F_R e^{kz}$ where k may be a function of L, L_0, etc., we find that the volume-average force is

$$\bar{F}=(F_A-F_R)/\ln(F_A/F_R).$$

Table V summarizes the results on compaction, and in Fig. 6 is plotted $\log\theta$ *vs.* $\bar{F}$. Except for an initial discrepancy, a straight line results which corresponds to a "compressibility coefficient" of $\beta=1.1\times10^{-4}$ in.²/lb. Using Athy's figures for compaction as a function of depth, and taking the mean density of the earth as 5.522 g/cc, we arrive at a value for the earth's crust of $\beta=1.25\times10^{-4}$ in.²/lb. One might surmise from this that the exact behavior in compaction of an aggregate of irregular particles is not very dependent on the nature of the particles.

SUMMARY

The problem considered was that of the relationship between the forces at the ends of a volume of granular polymer confined in a channel of constant cross section, when the granular mass is just on the point of motion. A solution of this problem was obtained on the basis of assumptions which were drawn, in part, from analogies with fluid behavior. Experiments were carried out with saran powders and granular polystyrenes which served to confirm the details of the theoretical expression within experimental error. The addition of lubricants to either the original polymer or the channel wall, was found to lower the coefficient of friction, as would be expected, and alter the forces correspondingly. As the forces at the ends were increased the length of the sample was observed to decrease. This compaction proceeds as if the average porosity of the sample were characterized by a compressibility coefficient, if an appropriate average force is taken. The magnitude of this coefficient for polystyrene is close to that observed in the compaction of the earth's crust, suggesting that it is the particulate nature of the material which is important, rather than the details of the individual particles.

Application of the Membrane Analogy to the Solution of Heat-Conduction Problems

L. H. Wilson* and A. J. Miles
Mechanical Engineering Department, Missouri School of Mines, Rolla, Missouri
(Received August 25, 1948)

This paper establishes the feasibility of applying the membrane analogy to the solution of two-dimensional steady-state heat-conduction problems. The membrane analogy is established, and the construction and the use of the apparatus for measuring the film are described. Inexpensive apparatus and simplicity of execution are the predominating features of this type solution.

NOMENCLATURE

t—temperature
x—space coordinate
y—space coordinate
z—vertical deflection of membrane
q—uniform pressure against membrane
S—surface tension of the membrane.

INTRODUCTION

In the solution of heat-conduction problems, the essential consideration is a determination of the temperature field. When irregular geometric configurations are encountered this problem becomes quite difficult and analytical approaches are laborious and at times impossible. As a result of this difficulty, recourse is made, when possible, to graphical or experimental methods, or to methods of analogy. It is the purpose of this paper to call to the attention of the reader a method of determining temperature fields in homogeneous heat-conducting members which has been heretofore neglected.

Consider a homogeneous membrane such as a soap film of any shape supported at the edges, subjected to a uniform tension at the edge, and subjected to a uniform lateral pressure. It may be shown that the mathematical expression for the membrane is as follows:

$$q/S=(\partial^2 z/\partial x^2)+(\partial^2 z/\partial y^2), \qquad (I)$$

where q is the pressure per unit area of the membrane, S is the uniform tension per unit length of its boundary, and z is the vertical deflection of the membrane. If there is no pressure exerted on either side of the membrane ($q=0$), the equation becomes

$$(\partial^2 z/\partial x^2)+(\partial^2 z/\partial y^2)=0. \qquad (II)$$

It was pointed out by Prandtl in 1903 that the equation which represents the torsion of an elastic bar of any cross section is identical with Eq. (I) as given above. In 1917, Taylor and Griffith (3)† first used the membrane analogy for the solution of torsion problems. They found that the maximum error encountered under specified conditions was 2 percent. The method was applied to determine the torsional stiffness and strength of cylindrical bars (4), flexure of beams (5), and the torsion and flexure of hollow shafts (6).

Work of a similar nature to that of Taylor and Griffith was performed by Trayer and March (14) with essentially the same equipment and comparable results.

In 1947, Neubauer and Boston (11) applied the membrane analogy to determine the torsional stress analysis of twist-drill sections.

The membrane analogy was used by Miles and Stephenson (9) in 1937 for the solution of a quite different problem. They recognized that the differential equation representing the pressure distribution about an oil or gas well is identical with Laplace's equation. They were able to determine the pressure distribution in oil and gas reservoirs of irregular shape when the reservoir was drained by a number of wells.

It was pointed out by Christopherson and Southwell (1) that every plane-potential problem has a membrane analog and that Prandtl's analog is merely a particular example which was concerned only with Laplace's plane-harmonic equation.

Consider the general equation for steady-state heat conduction in two dimensions.

$$(\partial^2 t/\partial x^2)+(\partial^2 t/\partial y^2)=0. \qquad (III)$$

From the foregoing discussion it may be seen that the membrane analogy is also applicable to the solution of two-dimensional steady-state heat-conduction problems. By comparing Eq. (II) with Eq. (III) it may be seen that the equations are identical when the temperature, t, in Eq. (III) is replaced by the vertical deflection of the membrane, z, in Eq. (II). Thus it is feasible that the deflection of the membrane represents, to some scale, the temperature distribution throughout the member under consideration, and if the boundary conditions are known (which is generally the case), a model of the heat-conducting member may be constructed accordingly.

DISCUSSION OF EXPERIMENTAL PROCEDURE

The apparatus employed was patterned after that used by Miles and Stephenson (9) except that the component parts were cast from aluminum. This change was made in order to reduce contamination of the film caused by oxidation of the metal. The instrument is shown in Fig. 1. The principal parts consisted of an aluminum shell constructed in two sections between which a plate may be inserted; an aluminum model of the member under consideration; a glass plate with a micrometer head projecting through the center of the glass, the plate being large enough to permit the micrometer gauge to be moved to any position in the shell without uncovering any portion of it; and a hinged target (which could always be brought down into the same position relative to the film under investigation), to which was clamped a paper disk on which points on contour lines were plotted. The base of the apparatus was equipped with three leveling screws to facilitate leveling or tilting to any desired angle. The micrometer head was ground to a point on the lower end so that it could be used as a probe to establish contact with the film. The upper end of the micrometer head was fitted with another needle point along the same axis as the lower point in order to mark the position of the probe on the paper target.

The soap solution used was prepared by mixing 2 grams of sodium oleate and 30 cc of glycerin in one liter of distilled water. Care should be taken to keep the soap solution free from impurities as these shorten the life of the membrane.

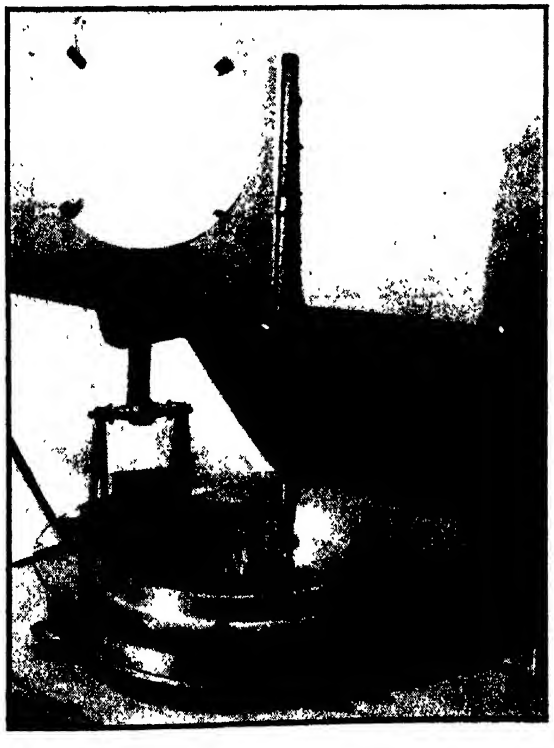

FIG. 1. Membrane apparatus with model of annulus-type heat-conducting member in place.

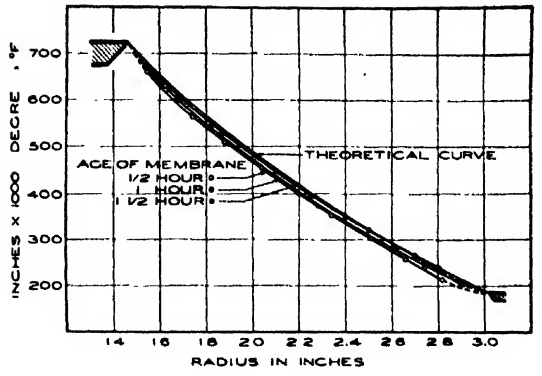

FIG. 2. Temperature distribution through thick-wall cylinder. $r_1 = 1.46$ in., $r_2 = 3.02$ in., $t_1 = 937°F$, $t_2 = 186°F$, slope of membrane = 48.2 percent, plate inclination 0.0°.

The models were constructed to some convenient scale geometrically similar to the heat-conducting member to be studied and in such a fashion that they provided a support for the membrane at the boundaries. These supporting edges were at different elevations such that they reproduced to some scale the temperature profile at the boundaries of the member under investigation. The membrane was then stretched across these boundaries, the elevation of the film at any particular point thereby representing the temperature at that point in the prototype of the member. Figure 1 shows a model of an annular-type heat-conducting member with isothermal boundaries, the inner boundary being at a higher temperature than the outer boundary. The model was made of aluminum to reduce oxidation, and the edges to which the membrane was to be attached were beveled in such a manner that the tangent to the membrane at its point of contact with the edge bisected the angle of bevel. This was necessary in order to reduce the possibility of the membrane's clinging to surfaces other than the beveled edge. When the model was set into the shell, the elevation of all edges representing isothermal conditions was checked with the micrometer head. If they were not level they were adjusted by using small jacks or weights to bring them into place.

With the model in place, a quantity of the soap solution was poured into the shell, care being taken to wet all surfaces of the model. With the aid of a Celluloid strip, a film was drawn over the model. All parts that come into contact with the soap solution were thoroughly cleaned and rinsed with distilled water beforehand. When the film had been drawn over the model, the glass plate was immediately placed over the equipment, since the carbon dioxide from the breath of persons present and also the dust in the air cause damage to the film. Arrangements were made during the manufacture of the model to provide ventilation holes. This was done in order that the pressure changes caused by temperature variation within the closed shell could

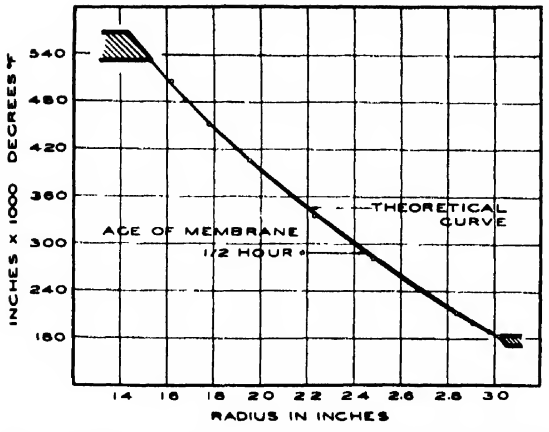

FIG. 3. Temperature distribution through thick-wall cylinder. $r_1=1.53$ in., $r_2=3.02$ in., $t_1=532.5°F$, $t_2=184°F$, slope of membrane=23.3 percent, plate inclination for drainage 3°, measurements taken on high side.

be equalized on both sides of the membrane. Small bubbles and excess liquid were removed from the membrane by using a saturated pipe cleaner or a soda straw. The membrane should have all such bubbles removed so that the surface is perfectly smooth.

In order to establish contour lines (isotherms) the micrometer was set at some specific height and the glass plate moved around until the lower tip of the micrometer touched the membrane at the desired point. The points of contact were found very accurately by having a light placed in such a position that the reflection of the lower point of the micrometer could be seen in the soap film near the place where the probe was expected to come into contact with the film. A distortion of the image showed that contact had occurred. This position was quite definite, and could be measured within plus or minus 0.001 inch. When contact had been made, the paper disk, which was clamped to the metal target, was brought down and touched lightly to the micrometer head. Contour lines were drawn by connecting all points on the isotherm. Extreme care must be exercised in keeping the lower point of the probe moistened with clean soap solution so that the film will not be destroyed when measurements are made.

Best results will be obtained if the apparatus is housed within a vibration-free building in which the temperature is kept nearly constant.

In order to compare experimental results with theoretical values, a problem for which the solution is known was first investigated.

Consider a hollow, thick-walled cylinder of inside radius, r_1, and outside radius r_2, and an inside temperature of t_1 with a lower outside temperature of t_2. It may be shown that the expression for the temperature, t, at any point, r, in the cylinder is as follows:

$$t=(t_2-t_1)\frac{\ln(r/r_1)}{\ln(r_2/r_1)}+t_1. \qquad \text{(IV)}$$

A model was constructed with an inside radius (r_1) of 1.45 inches and an outside radius (r_2) of 3.01 inches (see Fig. 1). The elevation of the outside shell was fixed at an elevation such that the reading on the micrometer head was 0.185 inch. The temperature at this point was assumed to be 185°F. The inner shell (r_1) was constructed such that the elevation could be varied; that is, the temperature drop through the cylinder could vary. It should be remembered that the difference in elevation of the two plates may represent any temperature difference desired, but in this experiment various elevations of the inside plate were used in order to determine the most appropriate slope of the membrane. Figure 2 shows typical results obtained when observations were made of the elevation of the membrane along a radius of the cylinder at various stages in the life of the membrane. Figure 3 shows the results of this test when the apparatus was tilted about 3° so that the membrane could drain. The maximum deviation from theoretical computations was found to be 2 percent with an average of less than 1 percent.

As an example of the application of the method in solving typical problems, the next problem considered was that of determining the temperature distribution through a rectangular thick-walled cylinder. A model was constructed in the same manner as the one for the circular cylinder, except that in this case the outer boundary was in the form of a 6-inch square at an elevation of 0.179 inch. The temperature here was assumed to be 358°F. The inside plate was 3 inches square at an elevation of 0.521 inch, and the temperature was assumed to be 1042°F. Thus a change of 0.001 inch elevation of the membrane represented a change in the temperature of 2°F. Figure 4 shows a contour map of the isotherms obtained from measurements taken on opposite corners.

The last experiment performed was an investigation of a problem as outlined by McAdams (8). Consider an insulator 4 inches thick, bounded on one side by an

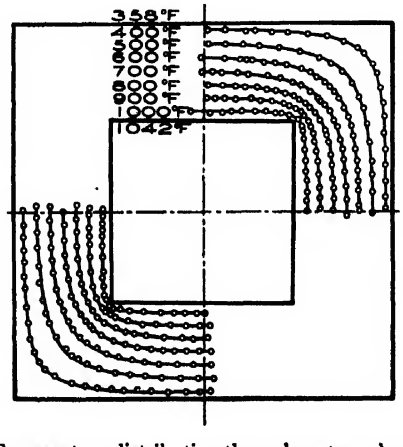

FIG. 4. Temperature distribution through rectangular thick-wall cylinder. Age of membrane 00:30 hr. to 2:00 hr. Model tilted 3° for drainage. Elevation of inside rectangle 0.521 in., outside rectangle 1.79 in.

isothermal metal plate at a temperature of 602°F, and on the lower side by another isothermal metal plate at 200°F. At intervals of 8 inches the lower part of the insulator is penetrated by metal ribs which extend 2 inches into the insulator. The ribs are also at 200°F, and there is no heat flow in the longitudinal direction of the insulator.

A model was constructed to the exact dimensions as those of the problem, except that the longitudinal dimension was made to be 4 inches since each 4-inch section would be symmetrical with the next section. On adiabatic sections of the boundary vertical plates were inserted and the membrane was allowed to seek its own level along the smooth surfaces of these plates. Figure 5 shows a plot of the isotherms obtained.

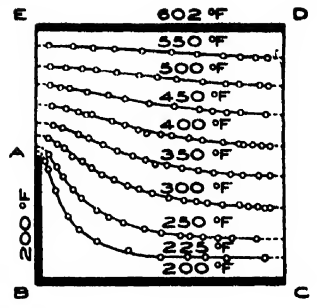

FIG. 5. Temperature distribution through an insulator. Insulator of thickness CD bounded by surface ED at a temperature of 602°F and by surface BC at a temperature of 200°F; at intervals of 2 BC the lower part of the insulator is penetrated by ribs AB also at a temperature of 200°F. Age of membrane 00:30 hr. to 2:00 hr. Model tilted 3° for drainage.

DISCUSSION OF RESULTS

From the results obtained in the investigation of the problem for which the analytical solution is known, it may be seen that under the proper conditions of test, the accuracy of the membrane analogy is well within the limits required in the solution of most heat-conduction problems. The age of the membrane produces an appreciable effect upon the results obtained, and it is recommended that the membrane be allowed to drain for at least one hour before any measurements are taken. If the measurements extend over a long period of time the membrane becomes fragile, but may be rejuvenated by placing a drop of soap solution on the probe and transferring the drop of solution to the membrane. We conclude from the results of the first tests that the optimum slope of the membrane is about 30 percent. When possible the whole apparatus should be tilted to an angle of about 3° in order that the section on which the measurements are being made may be drained of excess liquid.

In the solution of problems which require plotting of isotherms throughout the member, the greatest error to be encountered is the accuracy with which the model is constructed. Care should be taken to insure proper geometric similarity and a variation in elevation of the isothermal boundaries of less than 0.002 inch. It was found that towards the boundaries the values obtained in determining Q/k vary appreciably, but in the central region where greater accuracy is expected the values are in close agreement.

REMARKS

Although this type of solution is not suggested in competition with alternative methods, its utility lies in the solution of problems in which the geometric considerations produce tedious computations when numerical approaches are attempted. The equipment necessary for the execution of this type solution is quite simple and inexpensive as compared to the apparatus employed with electrical-geometrical analogues.

Further investigation of the membrane analogy is indicated in the realm of unsteady-state heat-conduction.

Work Functions of the Elements

HERBERT B. MICHAELSON
Product Development Laboratories, Sylvania Electric Products, Inc., Kew Gardens, New York
(Received September 6, 1949)

Like the chemical properties of the elements, the work function ϕ is a periodic function of atomic number, as shown clearly by a new compilation of published data for 57 elements. The progressive rise and fall of work function values throughout the table of the elements appears to be sufficiently regular to permit approximations to be made of values for the metallic and semimetallic elements on which no data has yet been published. Since the first ionization potential E_i and electrode potential E^0 exhibit a similar periodic function of atomic number, a striking resemblance exists among the respective plots of ϕ, E_i, and E^0.

I. INTRODUCTION

ALTHOUGH the published data on the work functions of metallic and semiconductor elements is by no means complete, the large number of measurements that have appeared in the literature indicate a well-defined periodicity of the values in the table of the elements. Several attempts have been made in recent years to establish relationships between work function and other periodic physical properties. Empirical equations of this type may provide a criterion for accurate values of work function, provided, of course, that they are derived from reliable data. Since, however, measurements of work function are extremely sensitive to the presence of surface impurities, particularly oxides and gases, there has been a rather large range of published values for each element. In addition, any comparison of published data is further complicated by the anisotropy[1,2] allotropy[3,4] and temperature dependence[5–8] of work function. Regardless of the difficulties in selecting a precise value of the work function for each element, the periodicity in the table of the elements can be shown clearly if *representative* values are cited for a large number of elements. Previously published lists of work functions have given data for less than half of the known elements,[9–16] while the present compilation provides values for 57 elements.

Most of the published methods of calculating work function ϕ have dealt with the relation to physical properties. The empirical formula of Rother and Bomke[17] expresses ϕ in terms of density, atomic weight, and electronic valence. According to Chittum[18] and Gombas,[19] ϕ is a function of the lattice energy in the crystal. Bartelink[20] derived an approximate relationship between work function and the reciprocal of atomic volume for the alkali metals. Another equation was developed by Wigner and Bardeen[21,22] for work functions of the univalent metals in terms of the heats of sublimation.

In addition, there have been a few attempts to correlate ϕ with other electrical measurements. Langmuir[23] observed for nine metals a general parallelism between thermionic work function and electrode potential E^0. This similarity was also noted by Scarpa[24] for 16 metals. More recently an interesting inverse relationship between hydrogen overpotential and ϕ was reported by Bockris.[25] In addition, Bedreag[26] has pointed out that for the alkali metals the first ionization potential E_i is equal to twice the work function. The purpose of this paper is to present a list of the work function data published during the past twenty-five years that have come to the writer's attention and to show graphically an apparent relationship between work function and other electrical data when plotted as a function of atomic number.

II. PERIODICITY OF WORK FUNCTION IN THE TABLE OF THE ELEMENTS

The relationship between work function and atomic number has been widely recognized in the literature.

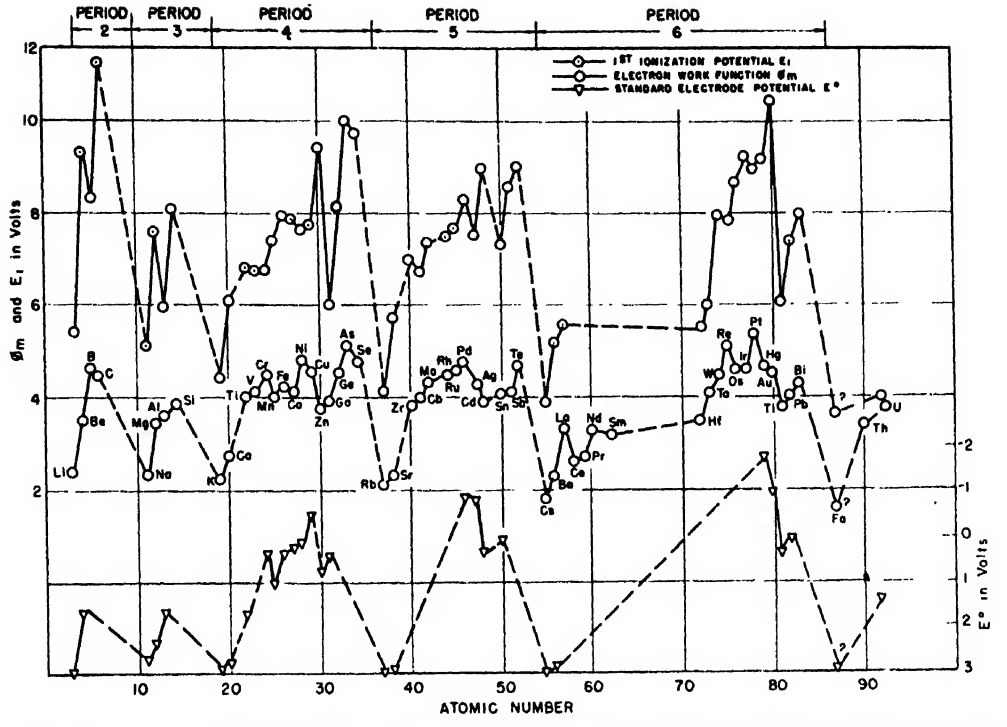

FIG. 1. Plots of work function, first ionization potential, and standard electrode potential *versus* atomic number.

Rother and Bomke,[17] Morecroft,[27] Klein and Lange,[28] and Scarpa[24] have all shown plots of ϕ as a function either of atomic number or atomic weight, the general shape of the curve being the same in either case. In Fig. 1 this previous work has been extended to include published data for a considerably larger number of elements. The data for work functions are taken from the appendix, which lists measurements published during the period 1924–1949. For most of the elements, values obtained by thermionic, photoelectric, or contact potential methods are about the same, and, to obtain *representative* values of work function, the unweighted mean ϕ_m of all data for each element was used for the plot in Fig. 1. For a few of the elements, some definite variance appears to exist among values obtained by different methods of measurement. Examples are the well-known discrepancies between photoelectric thresholds and thermionic work functions for the semiconductor elements.[29,30] These discrepancies, however, are not great enough to invalidate the representative values ϕ_m given here.

Since the temperature variation of ϕ for metals is quite small, the differences in temperature for the various measurements cited in the appendix are also of little consequence in considering the relationship between work function and atomic number. For example, the variation of ϕ with temperature for tungsten is only 3.4×10^{-5} ev/degree, according to Seely.[5]

The curve for ϕ_m in Fig. 1 exhibits a fairly regular rise and fall as it passes through each period in the table of the elements. When viewed from left to right on the periodic chart in Table I, the values in each period show a tendency to rise, except in the second-half of the periods 4, 5, and 6, where the elements in groups of *IB*, *IIB*, and *IIIB* have progressively lower work functions. The peculiar regularities in the various groups and periods are similar to the behavior of chemical and physical properties. A striking resemblance among the curves for ϕ, E_i, and E^0 is in evidence in Fig. 1, where the ionization potentials are from Hubbard and Meggers[31] and the electrode potentials* from Latimer and Hildebrand.[32]

The periodicity of work function in Fig. 1 and Table I appear to be sufficient to provide a basis for the prediction of values for elements on which no data has yet

[b] By field current method.

Compilation of Body Wave Velocity Data for Cubic and Hexagonal Metals

LOUIS GOLD
Brown University, Providence, Rhode Island
(Received October 14, 1949)

The directional variation of body wave velocities has been computed for cubic and hexagonal metals where stiffness coefficients are known; the essential data is presented in the form of tables and graphs. The results for aluminum, copper, gold, iron(α), lead and silver are tabulated in terms of the directional indices, and a stereographic coordinate system has been devised for presenting these data in the form of iso-velocity contours for the three wave vectors. The compressional and shear velocities for cadmium, magnesium, and zinc are plotted as a function of the angle formed by the direction of wave propagation and the hexagonal (c) axis from which have been derived the theoretical average velocities which may be compared with measured values for polycrystalline specimens.

1. INTRODUCTION

THE present report makes available for the first time a systematic summary of the velocity of body waves in a number of cubic and hexagonal metals for which the stiffness coefficients have been determined. Recent interest in ultrasonic wave propagation in solids,[1] particularly the question of the scattering of sound waves in polycrystalline metals,[2] has served to stimulate an orderly evaluation and presentation of such velocity data as are offered here. It is not unlikely that the tables and graphs will find application in delay-line design work, quantitative treatment of sound attenuation in polycrystalline aggregates, etc.

Two distinct graphical schemes were devised: a stereographic coordinate system is employed for the cubic metals, whereas a simple plot of velocity *versus* the angle defined by the hexagonal axis and the direction of wave propagation suffices for the hexagonal metals. The crystal symmetry of the hexagonal-close packed metals is such as to effect considerable reduction in the involved relation so that calculation of an average velocity is feasible; this is not true for the cubic metals.

Only those aspects of crystal elasticity theory directly pertinent to the details of the calculations are given. Adequate accounts are available for those who desire further elaboration.[3]

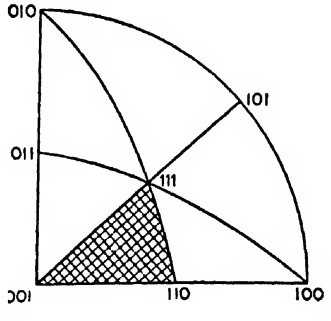

FIG. 1. Quadrant of standard projection for cubic crystal showing the six equivalent triangles of the type indicated by shaded area.

2. TREATMENT OF CUBIC METALS

The three roots of the equation

$$C_n^3 - I_1 C_n^2 + I_2 C_n - I_3 = 0 \qquad (1)$$

are related to the wave velocities by the familiar expression $v=(C_n/\rho)^{\frac{1}{2}}$. The coefficients I_1, I_2, and I_3 for crystals of any type of symmetry are defined below

$$\begin{aligned} I_1 &= k_{11}+k_{22}+k_{33} \\ I_2 &= k_{11}k_{22}+k_{22}k_{33}+k_{11}k_{33}-(k_{12}^2+k_{23}^2+k_{13}^2) \\ I_3 &= k_{11}k_{22}k_{33}+2k_{12}k_{13}k_{23}-(k_{12}^2k_{33}+k_{13}^2k_{22}+k_{23}^2k_{11}). \end{aligned} \qquad (2)$$

For crystals of cubic symmetry the k's are of the following nature . . .

$$\begin{aligned} k_{11} &= c_{11}\alpha^2+c_{44}(\beta^2+\gamma^2) \\ k_{22} &= c_{11}\beta^2+c_{44}(\alpha^2+\gamma^2) \\ k_{33} &= c_{11}\gamma^2+c_{44}(\alpha^2+\beta^2) \\ k_{12} &= (c_{44}+c_{12})\alpha\beta \\ k_{13} &= (c_{44}+c_{12})\alpha\gamma \\ k_{23} &= (c_{44}+c_{12})\beta\gamma, \end{aligned} \qquad (3)$$

where α, β, and γ are direction cosines.

* Velocities in 10^5 cm/sec.

One can readily appreciate the amount of computational effort required for the evaluation of the data in Table I. By proceeding step-wise with Eqs. (3) and (2), the undertaking reduces primarily to one of routine calculation of the coefficients of Eq. (1). The algebraic solution of the latter equation constitutes a distinct segment of the computing job and the final velocity results follow directly. The three parameters shown in Table I are associated with the longitudinal and two transverse waves, although it is understood that except

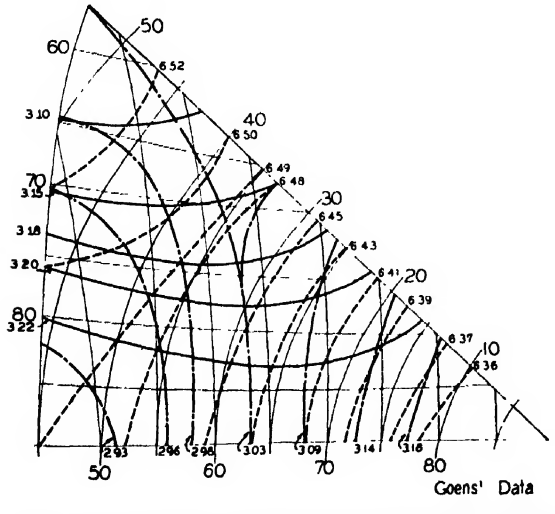

FIG. 3a. Stereographic plot of body wave velocities for aluminum showing iso-velocity contours. Velocities in 10^5 cm/sec. – – – – – – – – V_l; ———— V_{t_1}; ———— V_{t_2}.

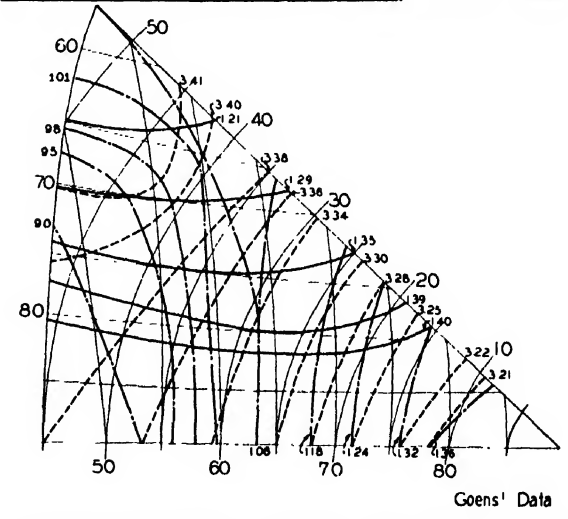

FIG. 3c. Stereographic plot of body wave velocities for gold showing iso-velocity contours. Velocities in 10^5 cm/sec. – – – – – – – – V_l; ———— V_{t_1}; ———— V_{t_2}.

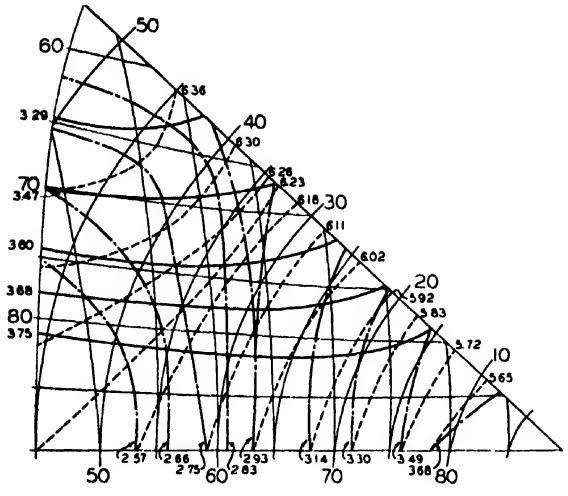
for the directions 100, 110, and 111, the strict meaning of these terms does not apply.

It is difficult to visualize the directional character of the body wave velocities directly from the tables given. The task of representing the data by some graphical scheme was considered. The use of a three-dimensional solid model, so popular for summarizing other directional crystalline properties, could have been invoked; but some thought was given to a two dimensional scheme, with the result that a stereographic coordinate triangle was devised for this purpose.

The underlying basis for this coordinate system may be understood in terms of the following discussion. If one considers a quadrant of a cubic crystal defined by



Goens and Schmid's Data

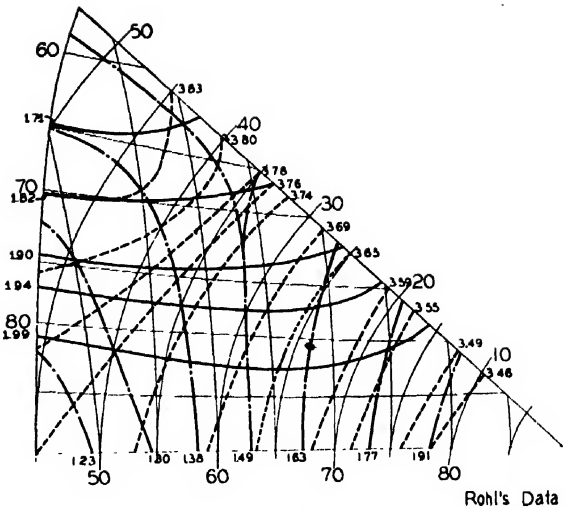
Goens and Weerts' Data

FIG. 3e. Stereographic plot of body wave velocities for lead showing iso-velocity contours. Velocities in 10^5 cm/sec. --------- Vt_1; —— Vt_1; —— —— Vt_2.

the appropriate [001] directions, then the vector along the 111 direction divides the quadrant into six equivalent regions, i.e., the directional properties are sixfold degenerate. In terms of the standard projection scheme, there are six equivalent stereographic triangles whose termini are the poles 001, 110, and 111 as shown in Fig. 1. Directional parameters such as the body wave velocities may all be plotted in one of the six triangles. To facilitate the location of each of the points within the triangle it has been found convenient to employ a coordinate system directly related to the Wulff net.

Figure 2 depicts the character of the coordinates in the stereographic triangle. The angles indicated are all



Rohl's Data

FIG. 3f. Stereographic plot of body wave velocities for silver showing iso-velocity contours. Velocities in 10^5 cm/sec. --------- Vt_1; —— —— Vt_1; —— —— —— Vt_2.

referred to the three [001] directions; the coordinate markings for two of the directions are obtained directly from the Wulff net, these being the rulings running essentially parallel to the edges defined by the 111–110 and 110–001 points. The third set of rulings is obtained by rotating the triangle through 90° and again making use of the latitude markings on the Wulff net; these lines also run along the edge 110–111, but have an opposite curvature. It may be readily verified that any point in the triangle fulfills the condition $\cos^2\alpha+\cos^2\beta$

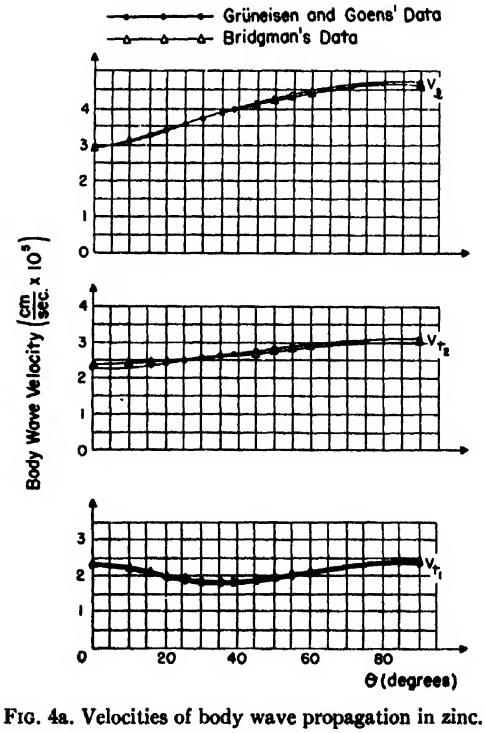


FIG. 4a. Velocities of body wave propagation in zinc.

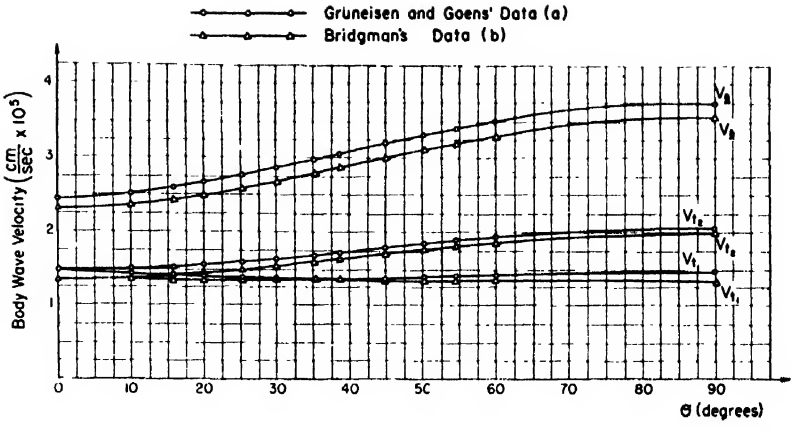

FIG. 4b. Velocities of body wave propagation in cadmium.

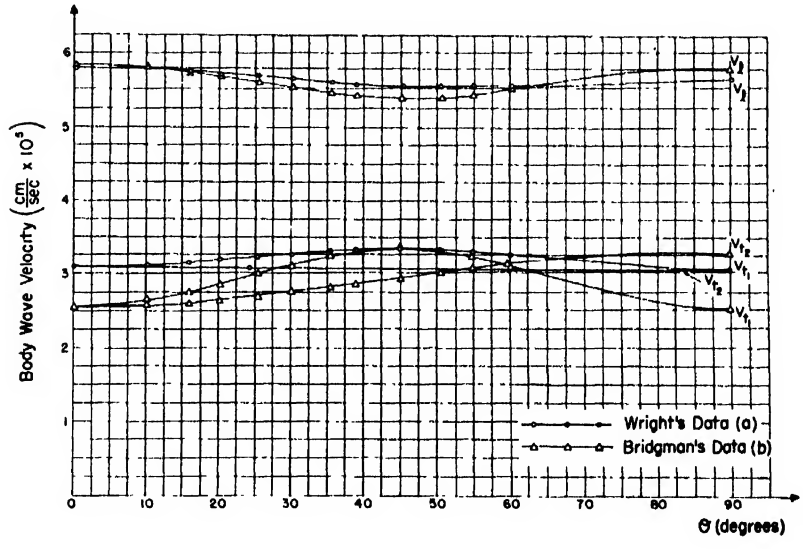

FIG. 4c. Velocities of body wave propagation in magnesium.

$+\cos^2\gamma = 1$, so that the triangle is a nomographic chart for this relation.

When the data of Table I are plotted in the stereographic triangle, it is found that lines of constant velocity can be drawn through the various points. Figures 3(a)–(f) show the common features of these iso-velocity contours for the series of metals, aluminum, copper, gold, iron, lead, and silver. One immediate application of these charts is the determination of mode separation along any given direction of propagation. Thus if one is interested in a particular compressional mode, the optimum orientation for minimizing interference from the shear modes may be inferred.

3. TREATMENT OF HEXAGONAL METALS

Hexagonal close-packed metals such as magnesium, zinc, and cadmium have symmetry which restricts the number of independent stiffness coefficients to five. It can be shown that for crystals of this kind the body wave velocities are only dependent upon the angle between the hexagonal axis and the wave propagation direction. By transforming from direction cosines to Eulerian angles the three roots of Eq. (1) become

$$\begin{aligned} C_{n1} &= \tfrac{1}{2}(c_{11}-c_{12})\sin^2\theta + c_{44}\cos^2\theta \\ C_{n2,n3} &= \tfrac{1}{2}\{(c_{11}+c_{44})\sin^2\theta + (c_{33}+c_{44})\cos^2\theta \\ &\quad \pm[(c_{11}-c_{44})^2\sin^4\theta + (c_{33}-c_{44})^2\cos^4\theta \\ &\quad + 2\sin^2\theta\cos^2\theta\{(c_{11}-c_{44})(c_{44}-c_{33}) \\ &\quad + 2(c_{13}+c_{44})^2\}]^{\frac{1}{2}}. \end{aligned} \quad (4)$$

The computations of the three wave velocities are clearly much simpler for the hexagonal metals than for the cubic metals. Figures 4(a)–(c) contain two sets of body wave curves based upon the independent c_ij

Light Energy and Spectral Distribution for Some Important X-Ray Screens

HOLGER SKÖLDBORN
Department of Physics, Lund University, Sweden

(Received December 12, 1949)

The absolute energy of the light (ergs/cm² per *r*-unit) and its spectral distribution have been determined for four different types of x-ray fluorescent screens: Patterson *E*-2, Patterson *B*-2, Patterson *D*, and Neossal. The investigation was performed in accordance with an objective spectrophotometric process with the aid of a tungsten ribbon filament lamp as a standard, a light attenuator of reflection type, monochromator, multiplier photo-tube, and galvanometer.

The application of the method employed to the weak light intensities in question is made possible on account of the enormous light sensitivity of the multiplier photo-tube and the possibility of reproducible continuous variation of this sensitivity within very wide limits. The method has proved speedy and accurate and appears to be well suited for investigations of similar character, within the spectral range which may be measured by the commercial types of multiplier photo-tubes.

IN spite of the immense importance and varied applications which the x-ray fluorescent screens have developed in the last decades, one will search in vain for exact information concerning the absolute energy and spectral distribution of the emitted fluorescent light from different types of screens. The present investigation, which was planned early in 1947 after a proposition put forward by medical quarters, is intended to provide these desirable data for some of the most important commercial types of screens. We have chosen three of the firm du Pont's latest makes, Patterson *D*, Patterson *B*-2, and Patterson *E*-2, and the Neossal screen (of German make), which is probably still the most commonly used for fluoroscopy in Sweden. The physical properties of calcium tungstate x-ray screens have been treated in detail by Coltman, Ebbighausen, and Altar in an earlier article in this Journal.[1]

APPARATUS

The main problem of the investigation consisted in the determination of the spectral energy distribution of the fluorescent light from different x-ray fluorescent screens at a given x-ray radiation quality and a given measured *r*-intensity by comparison with the known spectral energy distribution from a temperature calibrated tungsten ribbon filament lamp. Integration of the spectral curves obtained in this way gives the absolute energy of the fluorescent light per *r*-unit incident on the screen.

When choosing the method of investigation we were guided by the following points of view. A practicable way for an investigation at these weak light intensities is, of course, the method of comparing in a microphotometer spectrograms recorded from the standard lamp, or the x-ray screen. To give reliable results, however, this method requires among other things an extremely elaborate technique for variable reduction of the filament brightness to a value closely approximating to that of the fluorescent screen at different wavelengths (on account of reciprocity failure of the photographic emulsion). RCA's latest extremely sensitive photo-cells of the multiplier type seemed to suggest the possibility of applying an objective spectrophotometric method, though the light output of the screen under the planned experimental conditions could not be expected to amount to more than 10–100 erg/cm²/sec. After a great number of preliminary experiments, comprising recording of spectrograms of several types of screens, testing of different photo-cells in connection with an appropriate monochromator etc., the final form of the apparatus was such that the method could be regarded as fully satisfactory for the present investigation. The apparatus employed will now be described in greater detail.

A tungsten ribbon filament lamp provided with a quartz window was used as standard source. The ribbon filament is about 10 mm long and 2 mm wide, and is supported in the bulb by heavy nickel leads. The current could easily be kept constant within 0.1 percent.

The lamp was temperature calibrated to the standard of the Physics Laboratory of the University of Lund with the aid of its optical pyrometer. At 13.00 amperes the brightness temperature outside the quartz window was determined at 2244°K for a point midway along the

[1] Coltman, Ebbighausen, and Altar, J. App. Phys. 18, 530–544 (1947).

filament. This current was used all through the investigation.

When computing the spectral distribution of the radiation emitted by the ribbon filament lamp one must know the true temperature of the filament inside the bulb, the spectral emissivity of tungsten, and the spectral transmission of the quartz window within the intended working range of wave-lengths (4000–7000A). For the spectral emissivity the values determined by Hamaker[2] were used. For the spectral transmission of the quartz window the value 0.92 was used within the whole range of wave-length in question. The error possibly introduced in this way (the lamp was an unused specimen) is, according to Hamaker's results from measurements of absorption in quartz windows of different conditions,[2] not likely to exceed 0.5 percent anywhere. The conversion from the brightness temperature to the true temperature was accomplished by the following formula, derived from Planck's radiation formula:

$$\frac{1}{T_t}=\frac{1}{T_{BO}}+\frac{\lambda}{0.4343C_2}\log_{10}(\epsilon_\lambda\cdot t_\lambda), \tag{1}$$

where T_t = true temperature of the filament, T_{BO} = brightness temperature of the filament outside the window as determined by the optical pyrometer, λ = mean effective wave-length in cm of the red filter used in the optical pyrometer, C_2 = the second constant in Planck's radiation formula, ϵ_λ = the spectral emissivity of tungsten at λ, and t_λ = the spectral transmission of the quartz window at λ.

With $T_{BO}=2244$°K, $\lambda=6650\times10^{-8}$ cm, $C_2=1.435$, $\epsilon_\lambda=0.430$, $t_\lambda=0.920$, the true temperature of the filament is 2483°K.

The spectral energy distribution outside the lamp was obtained by substitution of the above value of the true temperature in Planck's radiation formula, and correcting the result for the spectral emissivities of tungsten and for the spectral transmission of the quartz window:

$$B_\lambda d\lambda=\frac{C_1\lambda^{-5}}{e^{C_2/\lambda T}-1}\epsilon_\lambda t_\lambda d\lambda. \tag{2}$$

In the above formula $B_\lambda d\lambda$ denotes the brightness in ergs/cm²/second per unit solid angle within the wave-length interval $d\lambda$ (λ in cm and C_1 its corresponding value).

An area of 5 mm×0.3 mm of the central portion of the filament was used for projection on the slit of the monochromator. At the pyrometric calibration no temperature differences were observed within this central portion. From Planck's radiation law one derives the percentage change in emitted energy at a given wave-length for a change in true temperature to be

$$\left(\frac{dE_\lambda}{E_\lambda}\right)\text{percent}=100\left(\frac{C_2}{\lambda T^2}\right)dT. \tag{3}$$

For a true temperature of 2483°K the percentage change of E_λ per degree is 0.58 percent at 4000A and 0.36 percent at 6500A. The error in the true, pyrometrically determined temperature is estimated to ±3°K. This means an error in E_λ of 1.7 percent at 4000A and 1.1 percent at 6500A. Considering all sources of error it appears that the combined error in the computed energy varies from about 4 percent at 4000A to about 3 percent at 6500A with an average for the middle of the spectrum of about 3.5 percent.

To make possible a spectrophotometric comparison (in the wave-length range 4000–7000A) between the brightness of the standard lamp filament and the fluorescent screen, the brightness of the former had to be reduced by a factor, which turned out to be of the order of 10^{-5}. The sensitivity of the type of multiplier photo-tube used being variable continuously and reproducibly within very wide limits, this reduction could be obtained by a suitable non-variable light "attenuator" and further reduction arrangements avoided.

A light attenuation of the order of magnitude desired can be accomplished by successive reflections from four air-glass surfaces, and an apparatus designed and constructed according to this principle is described in an article cited above.[1] We constructed such an attenuator with great care of four crown glass prisms, arranged as in Fig. 1, inside a brass box. The principle is immediately clear from the figure; concerning the details we will be as brief as possible, in our reference to the article mentioned. All the prism surfaces, except the ones used for reflection, were covered with a highly absorbent coating of carbon black silted up in zapon lacquer. The non-reflecting and absorbing coating obtained serves to remove to a very high degree the light transmitted into the prism.

According to Fresnel's formula one obtains for the light polarized in the plane of incidence after four successive reflections the following expression for the

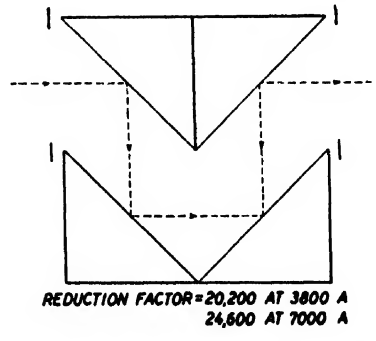

FIG. 1. Schematic arrangement of reflection-type attenuator.

[2] H. C. Hamaker, "Reflectivity and Emissivity of Tungsten," Diss. Utrecht (1934).

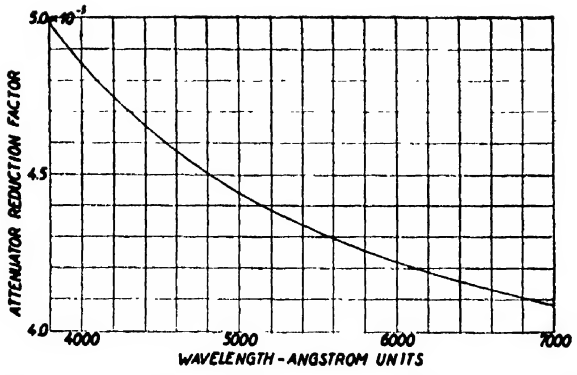

FIG. 2. Reduction factor of attenuator as a function of wave-length

intensity:

$$R(I)=\tfrac{1}{2}\left[\frac{\sin(i-i')}{\sin(i+i')}\right]^{8}. \tag{4}$$

The polarization being practically complete, the intensity of the light polarized at right angles to the plane of incidence can be neglected (it turns out to be about 9000 times fainter than the other component).

With i fixed at 45° the above formula may be written:

$$R(I)=\tfrac{1}{2}[\tan(45-i')]^{8}, \tag{5}$$

where i' depends upon n (Snell's law), which in its turn varies with the wave-length. R is thus itself a function of the wave-length, on account of which it was necessary to determine the dispersion curve of the prism material for the range of spectrum to be studied. For this purpose n was determined for one of the prisms for each of the three mercury lines 4046.6, 4358.3, and 5460.7A. The resulting indices were, respectively 1.5302, 1.5367, and 1.5187. This determination was carried out with a Gaertner spectrometer type 568; each value had a standard deviation of 1 unit in the fourth decimal place. With the values of the wave-length and their respective indices, stated above, the constants of the Hartmann interpolation formula were obtained:

$$n=1.4977+\frac{83.969}{\lambda-1462.9}. \tag{6}$$

With intervals of 100A n was determined from (6) for the range 3800–7000A, after which i' from Snell's law and finally the reduction factors from (5) were obtained as a function of the wave-length. The last-mentioned relation is represented by the curve in Fig. 2. The curve in Fig. 3, obtained by applying these reduction factors to the spectral energy distribution curve of the filament outside the lamp, shows the resulting spectral brightness of the standard lamp filament as seen through the attenuator.

As mentioned above the light from the attenuator is practically completely polarized, while the light from the fluorescent screen is unpolarized. To avoid errors which may arise, if the light loss in the monochromator is not the same for both sources, the attenuator was mounted so that the plane of the normals of the reflecting surfaces made an angle of 45° with the slit. In this way the light received by the monochromator may be regarded as isotropic.

The errors in the computed reduction factors are evaluated as follows:

1. An error of 1 unit in the fourth place of $n-1$ results in an error in R of less than 0.1 percent.
2. The error in R to be expected in consequence of the dispersion curve being calculated from only three index determinations is estimated to at most 0.1 percent for the range 4000–7000A.
3. The beam through the attenuator, as defined by a rectangular stop on the collimator lens and the focal distance of this lens, had an angular size of about 5°×3°. Since R was determined for a constant angle of incidence of 45°, it was necessary to obtain an estimate of the error introduced by assuming $i=45°$ for the whole beam. Calculation shows that the error, which is negative, amounts to about 0.5 percent. When this deviation in the reduction factors has been corrected of, any possibly remaining error is unlikely to exceed 0.2 percent.
4. The construction as well as the alignment of the attenuator was performed with great care so that the resulting error in R due to want of accuracy is probably less than 0.5 percent.

From these points we may conclude that the attenuator functions with an accuracy of 1 percent.

The dispersing instrument used was a "Hilger Constant Deviation Wave-Length Spectrometer," type D 187. It has $f=285$ mm for both lenses, and an angular aperture of 1:9. An additional rectangular stop of the size 25 mm×14 mm was fitted close to the collimator lens. Both slits were adjusted to a width of 0.3 mm and a height of 5 mm. The reliability of the wave-length scale was tested with the aid of a line spectrum. After a careful adjustment of the prism it appeared that the wave-length readings for the range of 4000–6500A showed a maximum error of about ±1A. Thus the accuracy is entirely satisfactory for our purpose.

The experimental arrangement is shown in Fig. 4. By means of a mirror and a condensing lens, either the filament or the screen sample could be projected on to the collimator slit at a magnification of 1:1. The mirror (an aluminized plane mirror) could be rotated 90° and mounted in two accurately fixed positions. The alignment was checked by illuminating the emergent slit of the monochromator by a strong light source, the slit then being imaged at the center of the filament.

The photo-cell was a RCA type 1P21 multiplier photo-tube. The light sensitive surface is made up of a cesium-antimony layer on a nickel base and the spectral response curve is of the S-4 type. A number of photocells of the multiplier type often show great, individual differences with respect to sensitivity and dark current. The cell employed was a selected specimen with a high value of the signal-to-noise ratio. We considered a minimizing of the dark current by reducing the temperature,[3] but this was found to be unnecessary for the

[3] R. W. Engstrom, J. Opt. Soc. Am. 37, 420 (1947).

present investigation. The photo-cell was placed in a suitable light-proof brass holder that was screwed on to the site of the eyepiece of the monochromator. The distance from the slit to the photo-cathode was about 28 mm.

The dynode voltage of the photo-cell was provided from a voltage-stabilized mains-connected supply circuit, designed and constructed by Stigmark[4] at the Physics Laboratory. The potential dividers for the dynodes consisted of 9 exactly equal 50,000 ohms wire-wound resistors. The current through these resistors could be continuously varied from 1 to 2 milliamperes and read on a milliammeter, 2 milliamperes corresponding to a voltage drop of 100 volts per stage. When checking the properties of the voltage supply it was found that a change of the mains voltage (220 v) of ± 10 v caused a change of the total dynode voltage (1000 v) of 0.05 percent, corresponding to a variation of the anode output current of about 0.5 percent. This accuracy was considered to be quite satisfactory.

The anode output current was measured by a "Multiflex" mirror galvanometer with a sensitivity of $5 \cdot 10^{-10}$ ampere/mm. The length of the scale being 200 mm, full deflection corresponded to 0.1 microampere.

After the voltage supply had been tested and found to be sufficiently constant, it remained to investigate the fatigue effects of the photo-cell and the linearity of response of the photo-cell-galvanometer combination. Considering what has been written about the fatigue of multiplier photo-tubes,[3, 5] we decided from the beginning not to use higher anode current than 0.1 microampere, especially as this could be done without actual inconvenience during the present investigation. From repeated tests made at constant illumination corresponding to an anode current of the order of magnitude mentioned, it appeared that the fatigue effect must be given due attention even at this low light intensity. The galvanometer deflection decreased 3 to 5 percent during the first half-hour; thereafter, however, the fatigue proceeded extremely slowly. At the performance of the investigation we took this fact into account by fatiguing the photo-cell at 0.1 microampere for about one hour before each series of observations. Moreover the series of observations were carried out according to a scheme which ensured that a continued, slight fatigue effect could have practically no influence on the result.

The proportionality between the intensity of the incident light and the deflection of the galvanometer was checked according to a method given by Hamaker,[2] the principle of which will be clear from Fig. 5. By means of the condensing lens L two light sources LS and LS' were focussed on the slit of the monochromator, LS directly and LS' by way of the reflecting glass plate G; S and S' are two shutters. The check simply consisted of observing whether the sum of the deflections caused by the separate intensities was equal to the deflection caused by the sum of the intensities. The advantages of this method are evident; no changes in the experimental arrangements are needed, the stopping down of the light beam remains unaltered and all we have to do is to use the shutters and vary the electric current through the light sources LS and LS'.

By this method the proportionality of deflection and intensity was checked for 10 different positions on the galvanometer scale. Three such series of observations were carried out for three different wave-length settings of the monochromator (4500, 5400, and 6300A). From these checks it was clear that the deflection of the galvanometer varied proportionally with the intensity of the incident light within 0.5 percent for deflections between 20 and 200 mm (full deflection). The small deviations discovered most certainly originate from the galvanometer employed; concerning the photo-multiplier tube there is no reason to doubt a strict proportionality between light intensity and anode current until above 100 microamperes.

At a distance of 35 cm from the focus of the air-cooled x-ray tube there was a lead stop with a hole 5 cm square. Behind this stop an additional filter of 1 mm Al was applied, and in front of the stop, at a distance of 37.5 cm from the focus of the tube, the screen sample was placed in a holder (Fig. 4). The x-ray intensity was measured at the exact place of the screen by means of an ionization chamber (so-called secondary standard), which, for the radiation quality employed, had been specially calibrated to the primary standard of the Radiophysical Institute in Stockholm.

EXPERIMENTAL PROCEDURE

Before the light intensity measurement could suitably commence, there remained the determination of the relative sensitivity of the photo-cell as a function of the applied dynode voltage. Preliminary experiments showed

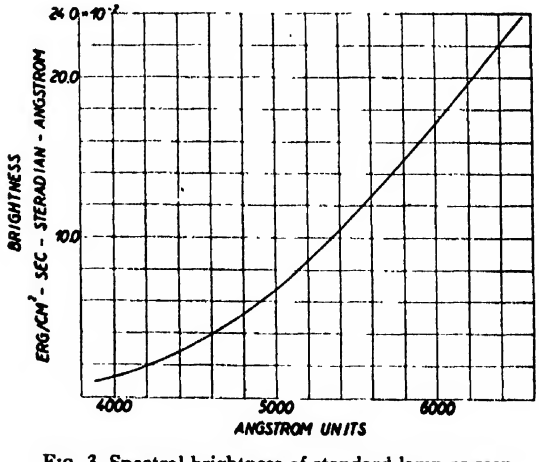

FIG. 3. Spectral brightness of standard lamp as seen through attenuator.

[4] K. Lidén, and L. Stigmark, "Some Experiences from Investigations of the Spectral Intensity Distribution of Weak Light Sources by Means of Multiplier Photo-Tubes," (Manuscript 1948).

[5] K. G. Kessler and R. A. Wolfe, J. Opt. Soc. Am. 37, 133 (1947).

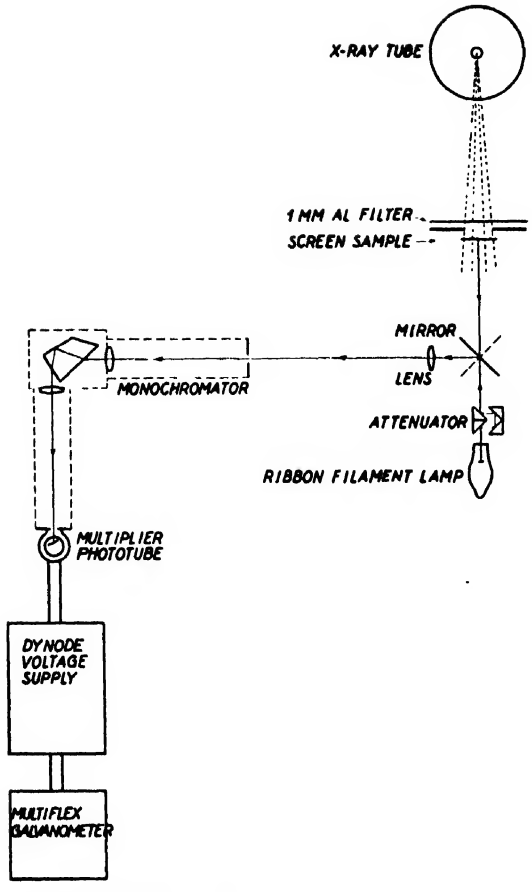

FIG. 4. Experimental arrangement.

that to obtain sufficient galvanometer deflection from both the screen sample and the standard lamp (seen through the attenuator) within the wave-length range to be studied, a variation of the dynode voltage from about 50 to 90 volts per stage was required. The upper limit was determined by the fact, that the signal-to-noise ratio of the photo-cell employed was rather unfavorable at higher voltages. As the accuracy and reproducibility of the sensivity curve of the photo-cell was of decisive importance for our method of measuring, the determination of this curve was given special attention. Sensitivity curves were determined for five different photo-multiplier tubes, and their reproducibility was investigated with respect to the fatigue effects, etc. on several occasions. It was evident from these experiments that the relative sensitivity as a function of the dynode voltage was independent of the fatigue effects and reproducible within limits of error exclusively determined by the accuracy of observation of the instruments.

When determining these sensitivity curves the following method was employed, which, among other things had the advantage of being applicable without change of the experimental arrangements. The electric current through the standard lamp filament was regulated in such a way that the galvanometer showed full deflection at a dynode voltage of 90 volts, after which the deflection was observed for successively lower dynode voltages, as far as the scale of the galvanometer permitted. Then the intensity of the lamp was increased, until full deflection was achieved at a lower dynode voltage, and so forth. Three different light intensities permitted a variation of the dynode voltage from 90 to 50 volts; in this way the curve was joined at two points, the factor of the joint being obtained as the average of two or three double readings. The sensitivity curve of the photo-cell employed (Fig. 6) was computed from the average of four such series of readings. The relative amplification factor varies from 100.0 to 0.910 at a variation of the dynode voltage from 90 to 50 volts. The error in the ratio of two arbitrary values of the curve was calculated to be at most 2 percent.

The determination of the spectral energy distribution of the fluorescent screens was now performed in the following way. After the photo-cell had been fatigued for about an hour and the standard lamp had been allowed to assume temperature equilibrium, the readings for two complete series were performed according to the scheme: $LSL'S'SLS'L'$. The readings were taken with intervals of 100A for the lamp as well as the screen. L and S denote readings of the deflections for the intensities of the standard lamp and the fluorescent screen, respectively, starting at the violet end of the spectrum; L' and S' readings for the same wave-length starting at the red end of the spectrum. This scheme was used in order to eliminate completely the fatigue effect on the average of each determination. To read the deflection for the standard lamp as well as for the screen point by point turned out to be unpractical, as in such a case the dynode voltage had to be readjusted very often. With the above method several readings often could be made in succession before readjusting the dynode voltage to a new value.

In connection with each series of readings three measurements of the x-ray intensity were carried out at the position of the screen according to the scheme $RLSRL'S'R$, where R denotes an r-measurement. The x-ray intensity could be kept constant within 1 percent (temporary fluctuations of the tube current). The accuracy of a separate r-intensity measurement was about 1 percent. The measured x-ray intensity was on an average 0.901 r-unit per second.

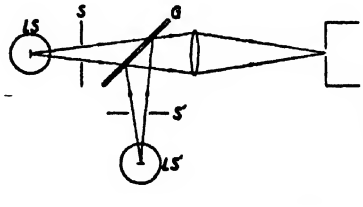

FIG. 5. Arrangement for check of proportionality between light intensity and galvanometer deflection.

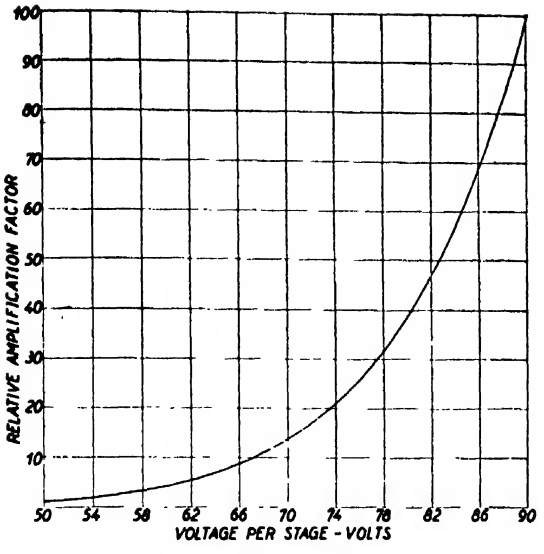

FIG. 6. Variation of relative amplification factor with applied voltage per stage for 1P21 tube used.

EXPERIMENTAL RESULTS

The spectral energy distribution of the screens investigated is plotted in Fig. 7. The spectral curves are given in terms of light energy emerging from the screen per r-unit incident on the screen. All results refer to the same x-ray quality, *viz.* 80 kv constant potential x-rays, filtered by one mm Al (tube current 9 mA). The filter equivalent of the wall of the x-ray tube was about 1.0 mm Al. The experimentally determined points succeed each other so smoothly that every point, if plotted, would be found on the drawn lines in Fig. 7.

The values of the absolute energy of the emerging fluorescent light obtained by numerical integration of the curves in Fig. 7 are given in Table I. The second column of this table gives the measured brightness of the screens in ergs/cm²/unit solid angle/r-unit incident on the screen. This applies to light emitted in the direction of the normal. The values of the total light emission in the third column have been calculated on the assumption that the departure from Lambert's law is represented by a factor of 0.92. This value was found by Coltman, Ebbighausen, and Altar[1] for a $CaWO_4$ screen excited by 80 kv constant potential x-rays, filtered by 0.5 mm Cu and 1 mm Al. In the present case, however, this value may be inaccurate with an error of one or two percent, owing to variation with radiation quality and material of the screen.

Of the screen samples investigated Patterson *D*, Patterson *B*-2, and Patterson *E*-2, were fresh samples obtained directly from the manufacturer (the Patterson Screen Division of E. I. du Pont de Nemours & Company, at Towanda, Pennsylvania). The Neossal screen, on the other hand, was a several years old sample, which, however, was unused and kept light-proof. All the screens were of the ordinary type with the phosphor layer applied to a white mounting card. The phosphor layer of the Neossal and the Patterson type *E*-2 screens were covered with a protective film of lacquer. On the Patterson type *D* screen, which fairly recently was developed for photo-fluorography, the fluorescent layer is composed of silver-activated zinc sulfide; the other three, which are mostly used for fluoroscopy, may be classed as zinc-cadmium sulfide screens. The Patterson type *B*-2, which was commercially available early last

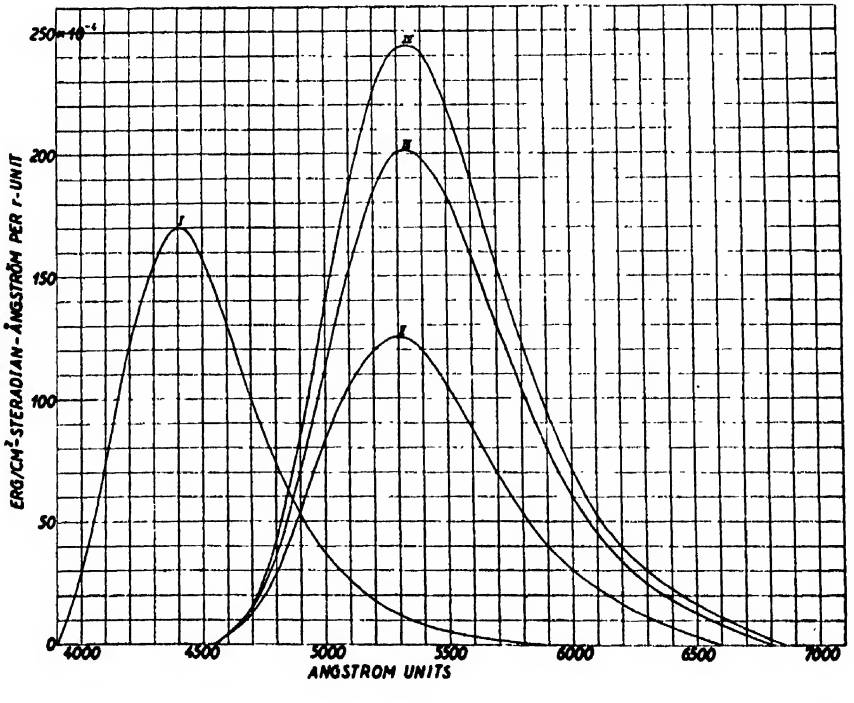

FIG. 7. Fluorescent spectra of four important x-ray screens, excited by 80 kv constant potential x-rays, filtered by 1 mm aluminium. I: Patterson type *D*. II: Neossal. III: Patterson type *B*-2. IV: Patterson type *E*-2.

TABLE I. Brightness and total emission of light of four x-ray fluorescent screens (calculated from Fig. 7).

Screen	Brightness ergs/cm²/steradian/r-unit	Total light emitted from screen ergs/cm²/r-unit
Patterson type *D*	11.8	34.0
Neossal	11.0	31.8
Patterson type *B*-2	18.4	53.2
Patterson type *E*-2	22.1	64.0

year was stated to be 40 percent brighter than the next preceding type Patterson *B*, a statement that we have had the opportunity of verifying. We have also included the results for the Patterson type *E*-2, which is stated to be of the same character as the type *B*-2, but with a protective cleanable surface, owing to the fact that it was found to be not less than 20 percent brighter than the type *B*-2 of the samples received at the same time. The Patterson type *D* with unprotected surface is also manufactured with a protective cleanable surface, and then called type *D-C*. These two variants turned out to be of equal brightness.

The accuracy of an investigation of this kind depends on several factors. If the contributions from all sources of error are summed up according to the calculations and estimates imparted at the description of the corresponding part of the apparatus, and of the experimental procedure, it appears that the results stated above will be correct with a maximum error of about 9 percent.

Unbalanced Terminations on a Shielded-Pair Line*

K. TOMIYASU
Division of the Sperry Corporation, Great Neck, New York
(Received December 7, 1949)

Theoretical calculations indicate that the unbalanced component of current on a two-wire or shielded-pair transmission line can be determined by comparing the different standing-wave distributions on the line conductors. The measurement of reflected components from an unbalanced radiative termination on a slotted shielded-pair line is described. The existence of a condition of minimum unbalanced reflected component from end-coupled antennas is shown experimentally.

INTRODUCTION

SHIELDED-PAIR and two-wire transmission lines differ from coaxial lines in that the former can support simultaneously two transverse electromagnetic (*TEM*) propagating modes. One of the modes called the balanced mode is the conventional transmission line mode where the currents on the two conductors are *opposite* in phase and equal in magnitude at all cross sections. For the other mode called the unbalanced mode, the currents are *in* phase and equal in magnitude and hence the scalar potential difference between the conductors is zero at all cross sections. The unbalanced mode radiates energy from an open two-wire line but does not radiate from a shielded-pair line. Whether the waves are standing or progressive the usual physical effect of the coexistence of the balanced and unbalanced modes is that the currents on the two conductors are unequal in magnitude and of arbitrary phase at all cross sections. This further indicates that the standing-wave distributions will be different on the two inner conductors if a shielded-pair line is excited by a balanced mode and terminated in an unbalanced structure. The reflected balanced and unbalanced modes can be measured from this difference. Measurements have been made on a slotted shielded-pair line which was terminated in unbalanced radiative terminations. Some of the representative measurements are included in this paper.

INCIDENT AND REFLECTED WAVES

The difference between the standing-wave distributions on the two conductors which yields the total characteristics of an unbalanced termination is dependent on the relative phases and amplitudes of four modes or waves: balanced and unbalanced, incident and reflected modes. Since these modes can be added as well as decomposed readily the complex voltage components on the conductors can be written as follows.

$$V_{1BI} = -V_{2B1} = A_0 \exp(-\gamma_B X + j\omega t), \quad (1)$$

$$V_{1BR} = -V_{2BR} = B_0 \exp(\gamma_B X + j\omega t), \quad (2)$$

$$V_{1UR} = V_{2UR} = C_0 \exp(\gamma_U X + j\omega t), \quad (3)$$

$$V_{1UI} = V_{2UI} = D_0 \exp(-\gamma_U X + j\omega t), \quad (4)$$

where B stands for balanced; U stands for unbalanced; I stands for incident; R stands for reflected; A_0, B_0, C_0, D_0 are complex constants; $\gamma = \alpha + j\beta$ is the complex propagation constant; $+X$ is the direction away from generator. γ_B may differ from γ_U for dielectric-filled shielded-pair lines as well as open two-wire lines. The time factor $e^{j\omega t}$ may be omitted for convenience. The

* The research reported in this document was made possible through support extended Cruft Laboratory, Harvard University, jointly by the Navy Department (ONR), the Signal Corps of the U. S. Army, and the U. S. Air Force, under ONR Contract N5-ori-76, T. O. 1.

resultant voltages on each line are

$$V_1 = V_{1BI} + V_{1BR} + V_{1UR} + V_{1UI} = V_{1B} + V_{1U}, \quad (5)$$

$$V_2 = V_{2BI} + V_{2BR} + V_{2UR} + V_{2UI} = V_{2B} + V_{2U}. \quad (6)$$

The addition of these voltage components is illustrated in Fig. 1. Since $V_{1B} = -V_{2B} = 1/2(V_1 - V_2)$ and $V_{1U} = V_{2U} = 1/2(V_1 + V_2)$ as shown in Fig. 1, the balanced and unbalanced components can be determined provided the amplitudes and phase difference of V_1 and V_2 are known.[1] The standing-wave distribution curves which can be obtained from $|V_1|$ and $|V_2|$ of Eqs. (5) and (6) are symmetrical within each half-wave-length for all values of the complex constants.

The desired reflection coefficients which characterize the unbalanced termination can be obtained by considering each line separately. For the general case of four modes, the reflection coefficients can be defined for the terminations as

$$\Gamma_1 = \left|\frac{V_{1BR} + V_{1UR}}{V_{1BI} + V_{1UI}}\right| \underline{/\phi_1'} = \left|\frac{V_{1R}}{V_{1I}}\right| \underline{/\phi_1'}, \quad (7)$$

$$\Gamma_2 = \left|\frac{V_{2BR} + V_{2UR}}{V_{2BI} + V_{2UI}}\right| \underline{/\phi_2'} = \left|\frac{V_{2R}}{V_{2I}}\right| \underline{/\phi_2'}. \quad (8)$$

For this case of balanced and unbalanced, incident and reflected modes on a line where $\gamma_B = \gamma_U$, six unknowns must be determined for the complex constants, A_0, B_0, C_0, and D_0. Since no additional information on an unbalanced termination can be obtained by having an unbalanced *incident* mode, it is mathematically and experimentally convenient to require D_0 to be equal to zero. This reduces the number of unknowns to four, and these can be obtained from the standing-wave ratios and positions of voltage minima of the standing-wave distributions. The other two unknowns necessary for the general case may be the time-phase difference[2] and relative magnitudes of the distribution extremes.

When $D_0 = 0$, the reflection coefficients at the load after arbitrarily assigning a zero phase angle for A_0, are

$$\Gamma_1 \equiv \frac{B_1}{A_0} = \frac{B_0 + C_0}{A_0} = \frac{|B_0 + C_0|}{A_0} \underline{/\phi_1}, \quad (9)$$

$$\Gamma_2 \equiv \frac{B_2}{A_0} = \frac{B_0 - C_0}{A_0} = \frac{|B_0 - C_0|}{A_0} \underline{/\phi_2}, \quad (10)$$

where

$\phi = 2\beta X_{\min} \pm \pi$,

$\beta = 2\pi/\lambda$ = phase constant,

$X_{\min}$ = distance from the load to a voltage minimum

[1] See, for example, R. King, "Coupled antennas and transmission lines," Proc. I.R.E. 31, 626–640 (November, 1943).

[2] For measurement of time-phase differences, see, for example, T. Morita, Cruft Laboratory Technical Report No. 66, Harvard University, Cambridge, Massachusetts.

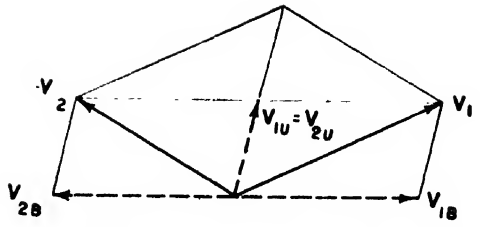

FIG. 1. The components of two unequal voltages.

and the voltage standing-wave ratios are

$$VSWR_1 = \frac{1 + |\Gamma_1|}{1 - |\Gamma_1|}, \quad (11)$$

$$VSWR_2 = \frac{1 + |\Gamma_2|}{1 - |\Gamma_2|}. \quad (12)$$

Defining

$$V_I \equiv A_0, \quad (13)$$

$$V_{BR} \equiv \frac{B_1 + B_2}{2} = B_0, \quad (14)$$

$$V_{UR} \equiv \frac{B_1 - B_2}{2} = C_0 \quad (15)$$

the following equations may be written

$$\frac{V_{BR}}{V_I} = \frac{\Gamma_1}{2} + \frac{\Gamma_2}{2} = \Gamma_1\left(\frac{1}{2} + \frac{1}{2}\frac{\Gamma_2}{\Gamma_1}\right) = \Gamma_1 F \equiv \Gamma_B, \quad (16)$$

$$\frac{V_{UR}}{V_I} = \frac{\Gamma_1}{2} - \frac{\Gamma_2}{2} = \Gamma_1\left(\frac{1}{2} - \frac{1}{2}\frac{\Gamma_2}{\Gamma_1}\right) = \Gamma_1 G \equiv \Gamma_U, \quad (17)$$

where

$$F \equiv \frac{1}{2} + \frac{1}{2}\frac{\Gamma_2}{\Gamma_1}, \quad (18)$$

$$G \equiv \frac{1}{2} - \frac{1}{2}\frac{\Gamma_2}{\Gamma_1}. \quad (19)$$

The quantity Γ_U is actually a "transfer" reflection coefficient since the usual connotation implies that the reflected mode is the same as the incident. The complex parameters F and G can be redefined as:

$$F = \tfrac{1}{2} + \tfrac{1}{2}M\underline{/\alpha} = |F|\underline{/\theta_F}, \quad (20)$$

$$G = \tfrac{1}{2} - \tfrac{1}{2}M\underline{/\alpha} = |G|\underline{/\theta_G}, \quad (21)$$

where

$$M = \frac{|\Gamma_2|}{|\Gamma_1|},$$

$$\alpha = \phi_2 - \phi_1,$$

$$|F| = +\tfrac{1}{2}(1 + M^2 + 2M\cos\alpha)^{\frac{1}{2}}, \quad (22)$$

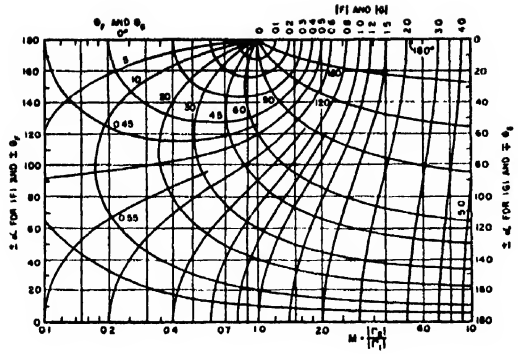

FIG. 2. Parametric plots of $|F|$, $|G|$, θ_F, and θ_G as functions of α and M.

$$|G| = +\tfrac{1}{2}(1+M^2-2M\cos\alpha)^{\frac{1}{2}}, \tag{23}$$

$$\theta_F = \tan^{-1}\frac{M\sin\alpha}{1+M\cos\alpha}, \tag{24}$$

$$\theta_G = \tan^{-1}\frac{-M\sin\alpha}{1-M\cos\alpha}. \tag{25}$$

Orthogonal parametric plots of $|F|$, $|G|$, θ_F and θ_G which are functions of M and α are shown in Fig. 2. Using these plots and Eqs. (16) and (17), the balanced and unbalanced reflected modes can be determined from the measurable quantities $|\Gamma_1|$, $|\Gamma_2|$, ϕ_1, and ϕ_2. It is evident from the plots that there is only one condition for a completely balanced termination: $|\Gamma_1| = |\Gamma_2|$ and $\phi_1 = \phi_2$ simultaneously ($M=1$, $\alpha=0$).

EQUIVALENT TERMINATING IMPEDANCES

From Eqs. (9)–(10) and (16)–(17) it can be seen that the reflections from an unbalanced termination may be represented by either Γ_1 and Γ_2 or Γ_B and Γ_U. Since the termination can be completely represented by two independent impedances related to Γ_1 and Γ_2, a third impedance as required for example in a delta-network is unnecessary. When the generator supplies power in only the balanced mode, Γ_B is a measure of all losses due to both balanced and unbalanced modes. It may be considered incidental if the unbalanced reflected mode propagates along the input line.

COUPLING OF VOLTAGE PROBE TO OPPOSITE LINE

When used on a shielded-pair or two-wire line, a voltage probe will respond to electric fields due to the charges on both conductors. If the coupling to the remote conductor is significant the probe will not yield the true standing-wave distribution on the near conductor. The true reflection coefficients can be determined from the measured reflection coefficients if the "opposite-conductor" coupling is known.

Assuming that the two voltage probes are equally coupled to the shielded-pair line, the effective voltages at the probes are

$$V_1' = A_0(1-K_1)e^{-i\beta X} + B_0(1-K_1)e^{i\beta X} + C_0(1+K_2)e^{i\beta X}, \tag{26}$$

$$V_2' = -A_0(1-K_1)e^{-i\beta X} - B_0(1-K_1)e^{i\beta X} + C_0(1+K_2)e^{i\beta X}, \tag{27}$$

where K_1 = fractional *decrease* caused by coupling of charges of opposite polarity and K_2 = fractional *increase* caused by coupling of charges of same polarity. The modified and measurable reflection coefficients are

$$\Gamma_1' = \frac{B_0(1-K_1)+C_0(1+K_2)}{A_0(1-K_1)} = \Gamma_B + \frac{1}{K_0}\Gamma_U, \tag{28}$$

$$\Gamma_2' = \frac{B_0(1-K_1)-C_0(1+K_2)}{A_0(1-K_1)} = \Gamma_B - \frac{1}{K_0}\Gamma_U, \tag{29}$$

where

$$K_0 \equiv \frac{1-K_1}{1+K_2}. \tag{30}$$

Therefore, the true reflection coefficients are

$$\Gamma_B = \frac{\Gamma_1'+\Gamma_2'}{2} = \Gamma_1'\left(\frac{1}{2}+\frac{1}{2}\frac{\Gamma_2'}{\Gamma_1'}\right), \tag{31}$$

$$\Gamma_U = K_0\frac{\Gamma_1'-\Gamma_2'}{2} = K_0\Gamma_1'\left(\frac{1}{2}-\frac{1}{2}\frac{\Gamma_2'}{\Gamma_1'}\right). \tag{32}$$

Except for the factor K_0 and the primes, the equations are identical to the previous coefficients given in (16)

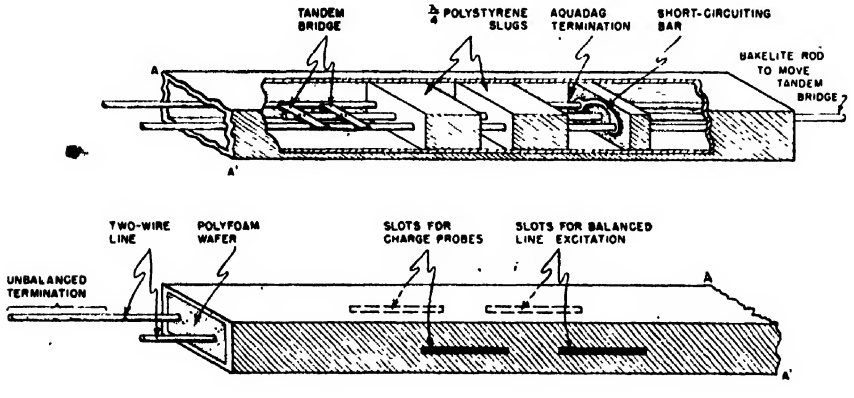

FIG. 3. Slotted shielded-pair transmission line with open end.

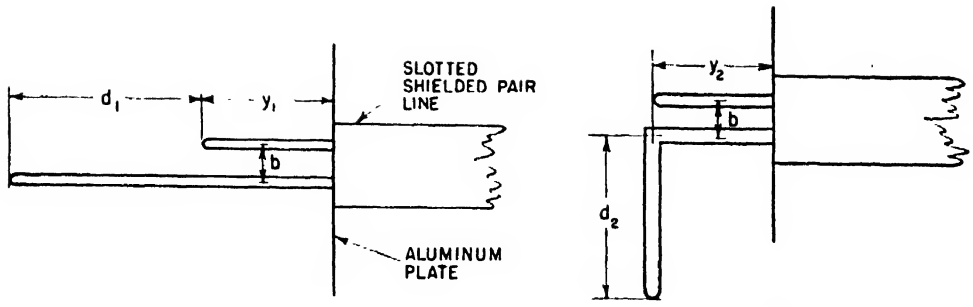

FIG. 4. (a) Collinear end-coupled antenna. (b) Perpendicular end-coupled antenna.

and (17). The quantity K_u can be determined experimentally. Moreover, in the presence of opposite-conductor coupling, the distribution curves are symmetrical within each half-wave-length.

RATIO OF VOLTAGE MAXIMA

Occasionally the *VSWR* on one conductor may be exceedingly large so that the minimum deflection is masked by the inherent noise of the detector system. For the case of zero incident unbalanced wave, the reflection coefficient on one line is related to both the reflection coefficient of the other line and the ratio of the two voltage maxima. This relationship is written as

$$\frac{|V_{2\,\max}|}{|V_{1\,\max}|}=\frac{|A_0|+|B_2|}{|A_0|+|B_1|}=\frac{1+|\Gamma_2|}{1+|\Gamma_1|}. \tag{33}$$

For a square-law detector, the ratio can be expressed in units of decibel as

$$S_m=40\log_{10}\frac{1+|\Gamma_2|}{1+|\Gamma_1|}\text{db}. \tag{34}$$

For convenience, Eq. (34) can be plotted for parametric values of $|\Gamma_2|$ or $|\Gamma_1|$. The maximum range of S_m is ± 12 db. If the measured S_m, $|\Gamma_1|$ and $|\Gamma_2|$ do not satisfy Eq. (34) there exist *both* incident and reflected unbalanced modes.

THE SLOTTED SHIELDED-PAIR LINE

The reflection coefficients of unbalanced terminations were measured on a slotted shielded-pair line. A cutaway view of the measuring line is shown in Fig. 3. The shielded-pair line consists of a standard $\frac{1}{2}$ in.$\times$1 in. *X* band copper wave guide and $\frac{1}{8}$ in. O.D. brass inner conductors spaced 0.495 in. between centers. An unbalance squelcher[3] in the generator circuit gave assurance that the balanced mode would be predominantly excited on the line. The 750 mc/sec. r-f signal was amplitude modulated at 1050 c.p.s. With an *SPDT* coaxial switch in the dual charge-probe circuit, standing-wave distributions could be measured on either conductor.[4] From an unbalanced termination the reflected balanced mode does not proceed beyond the tandem bridge, however, the reflected unbalanced mode is completely absorbed at the matched load provided by the Aquadag termination and two quarter-wave-length polystyrene slugs.[5]

With the inner conductors supported only by Polyfoam wafers, the characteristic impedances of the two modes of transmission were determined by measuring capacitances at an audiofrequency.[1] The measured characteristic impedances of the air-dielectric line for the balanced mode was $R_{cB}=165$ ohms and for the unbalanced mode $R_{cU}=39.3$ ohms. The opposite-conductor coupling was also determined under the same conditions in the following way. The line conductor to which the probe is coupled is connected to one output terminal of the audio oscillator. The second line conductor can be connected to either of two potentials: (a) to the other

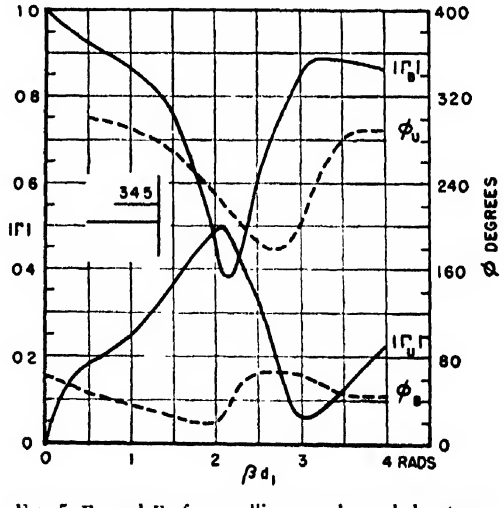

FIG. 5. Γ_B and Γ_U for a collinear end-coupled antenna when $y_1=34.5$ cm.

[4] K. Tomiyasu, Cruft Laboratory Technical Report No. 86, Harvard University (September 6, 1949).

[5] K. Tomiyasu, "Double-slug impedance matching," Cruft Laboratory Technical Memorandum No. 6, Harvard University (August 1, 1949)

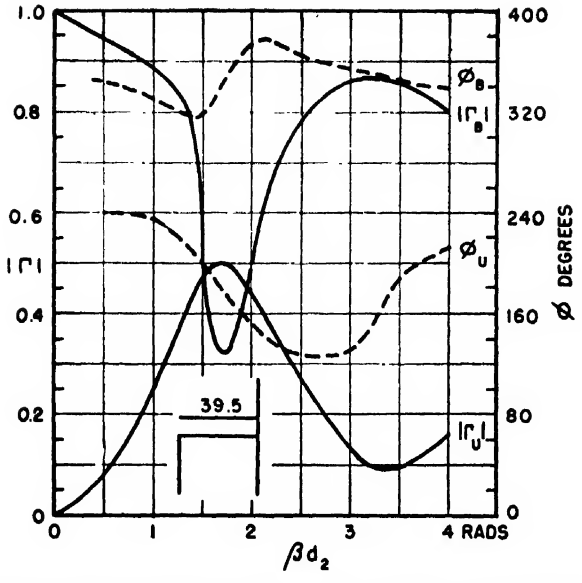

FIG. 6. Γ_B and Γ_U for a perpendicular end-coupled antenna when $y_2=39.5$ cm.

output terminal of the oscillator; or (b) to the same terminal. The shield is connected to the center tap of the oscillator output. The quantity K_0 in Eq. (30) is the ratio of the deflections when connections (a) and (b) are made in that order. For the experimental line, K_0 was found to be equal to unity, signifying that each conductor provided a very effective shield from electric fields due to charges on the other line.

This measuring line was rather difficult to operate. The probe couplings for example were not constant for the lengths of the slots. The optimum conditions for line excitation could not be maintained throughout. Due to the several sources of error the experimental data cannot be considered accurate but are included to show representative information.

UNBALANCED RADIATIVE TERMINATIONS

The reflected balanced and unbalanced components of voltages were measured for two types of unbalanced end-coupled antennas, *viz.*, collinear (or extended) antenna, and perpendicular antenna. This is shown in Fig. 4. For various fixed values of y_1 and y_2, "antenna" lengths d_1 and d_2 were varied by inserting threaded sections. The ends of the $\frac{1}{8}$-in. O.D. brass conductors were semispherical in shape. The $\frac{1}{32}$-in. thick 40×42.3-cm aluminum plate minimized the currents on the outside of the slotted line.

In Figs. 5 and 6, Γ_B and Γ_U are plotted for two different structures as a function of "antenna" lengths. These are the *apparent* reflection coefficients of the unbalanced terminations having a reference plane $\lambda/2$ from the aluminum plate. The simultaneous increase in $|\Gamma_U|$ with decrease in $|\Gamma_B|$ implies that additional balanced-mode power is necessary to supply the unbalanced-mode losses. It can be seen that a minimum of $|\Gamma_U|$ occurs when the antenna length is near $\lambda/2$.

Shear Stress in a Turbulent Boundary Layer*

DONALD ROSS AND J. M. ROBERTSON
Ordnance Research Laboratory, The Pennsylvania State College, State College, Pennsylvania
(Received December 9, 1949)

The method initiated by Fediaevsky for evaluating the shear stress distribution in a turbulent boundary layer under the action of an adverse pressure gradient is improved upon. Use is made of a more suitable polynomial and boundary conditions which include the concept that the turbulence which produces the shear at any point has its origin at the surface upstream from its present location. This "history" theory predicts that the transverse shear gradient in the outer portion of the boundary layer remains constant as the boundary layer develops. Comparison with shear distributions measured at the National Bureau of Standards along a simulated airfoil shows good qualitative agreement and appreciable improvement over Fediaevsky's theory.

INTRODUCTION

IN analyzing the flow of a fluid in a diffuser, along the surface of an airfoil, or along the after portion of a streamlined body, the major problem is the evaluation of the effect of the adverse pressure gradient on the flow conditions in the boundary layer. The critical feature of these flows is the occurrence of separation, which results in high losses and other deleterious effects. Despite the common occurrence of this type of incompressible, turbulent boundary-layer flow, the physics of adverse-pressure-gradient effects is still incompletely understood. Undoubtedly, the ultimate solution of this problem will involve a statistical theory of turbulence, but a reasonably useful theory can be developed through the use of the older methods based on the mean motion. The objective of any boundary layer theory is the prediction of the rate of growth of and distribution of the velocity in the boundary layer. As the growth can be found from the von Karman momentum equation if the shapes of the velocity profiles are known, the problem reduces to the prediction of the velocity distributions.

Various researchers have shown that the velocity profiles can be characterized by single form parameters. However, attempts to correlate these parameters with local flow conditions have not been particularly successful. Thus, the methods of analysis developed by Buri[1] and Gruschwitz[2] have only limited application, and they do not appear to be fundamentally sound.[3,4] More recent analyses,[4,5] based on empirical relations for the rate of change of the velocity form parameter, are more successful. In none of these methods, however, is an attempt made to understand the inner mechanics of the flow phenomena.

As the velocity variation in a boundary layer is a result of turbulent shearing motions, a more fundamental understanding of the problem should evolve from a study of shear stress distributions and the origin of the shear. A first attempt at a shear stress theory was made by Fediaevsky[6] in Russia in 1936. He expressed the shear stress as a power series, with the coefficients evaluated in terms of boundary conditions. Comparison of his shear stress profiles with experiment has indicated serious discrepancies; but in spite of this, the method seems so fundamental that the discrepancies may probably be attributed to the boundary assumptions. The shear stress theory presented in this paper, although

inspired by Fediaevsky's work, differs from it in several important respects.

FEDIAEVSKY'S THEORY

Fediaevsky[6] used a rational method for determining the form of the velocity distribution for two-dimensional boundary layers from expressions for the shear stress and mixing length distribution. He expressed the transverse form of the shear stress as a power series:

$$\tau/\tau_w = A_0 + A_1(y/\delta) + A_2(y/\delta)^2 + A_3(y/\delta)^3 + \cdots, \quad (1)$$

where τ is the local turbulent shear, τ_w is the wall shear stress, y is the distance from the wall, δ is the disturbance thickness of the boundary layer. He evaluated the coefficients of the first few terms by applying the boundary conditions which must hold at the solid surface and at the outer edge of the boundary layer. At the wall ($y=0$), the function and its first derivative are defined by the following conditions:

(1) $\tau = \tau_w$ by definition of τ_w,
(2) $\partial\tau/\partial y = dp/dx$ from the momentum equation written for the wall streamline.

At the outer edge of the layer ($y=\delta$),

(3) $\tau = 0$ by definition of δ,
(4) $\partial\tau/\partial y = 0$ from the assumption that the derivative with respect to x of the total head is a continuous function.

The derivative of the momentum equation for the wall streamline yields a fifth condition:

(5) $\partial^2\tau/\partial y^2 = 0$ at $y=0$,

By assuming that only the first three conditions are significant, Fediaevsky evaluated the coefficients for a quadratic and obtained

$$\tau/\tau_w = 1 + (\delta/\tau_w)(dp/dx)(y/\delta) - [1 + (\delta/\tau_w)(dp/dx)](y/\delta)^2, \quad (2)$$

while by assuming all five conditions, he obtained the quartic

$$\tau/\tau_w = 1 + (\delta/\tau_w)(dp/dx)(y/\delta) - [4 + 3(\delta/\tau_w)(dp/dx)](y/\delta)^3 + [3 + 2(\delta/\tau_w)(dp/dx)](y/\delta)^4. \quad (3)$$

Although Fediaevsky states that he found fair agreement between his theory and the experimental data of Gruschwitz,[2] Dryden[7] found poor correlation with data obtained at the National Bureau of Standards.

ORIGIN OF SHEAR STRESS

One of the shortcomings of Fediaevsky's theory is its failure to consider the origin of the turbulent motions causing the shear and the ensuing mechanism of transfer. For the case of flow with zero or small pressure gradients, the flow conditions and the wall shear stress do not vary significantly in the direction of flow, and one can correlate the entire boundary layer distribution with local conditions. However, when the flow conditions vary, as in a diffuser or along an airfoil surface, this simple correlation does not hold. The motions which cause the shear forces originate at the wall and are diffused into the fluid stream through the action of turbulence. As this diffusion occurs relative to the moving fluid, the shear at any point in the boundary layer has its origin at a point on the surface upstream from its present location. Thus, the shear in the outer-boundary layer region is governed by the previous history of the flow, while near the solid surface, local conditions control.

The concept of the effect of space-history on the flow in the outer region of a boundary layer was proposed by Schultz-Grunow[8] and was suggested by the experiments of Jacobs.[9] Jacobs measured the change in the velocity profile along a smooth surface preceded by a rough surface. An analysis of these profiles yielded the shear stress distributions at several stations. As shown in Fig. 1, Jacobs found that the shear stress gradient in the outer portion of the boundary layer retained the value which it had had over the rough surface for a considerable distance along the smooth surface, while the wall shear fell almost immediately to its smooth-surface value. Jacobs also studied the flow from a smooth to a rough surface, and he again found that the upstream shear stress gradient persisted for a considerable distance, the rough-surface shear gradually being diffused across the boundary layer as the flow proceeded downstream. As noted by Schultz-Grunow, these experiments clearly establish the importance of the history of the flow.

Recent studies on the flow along the surface of a large simulated airfoil were made in the wind tunnel at the National Bureau of Standards and were reported by Dryden.[7] In these experiments, the shear stresses were measured more directly with hot wires. The manner in which the NBS shear stress profiles vary in the adverse pressure gradient is shown in Fig. 2. The slope of the

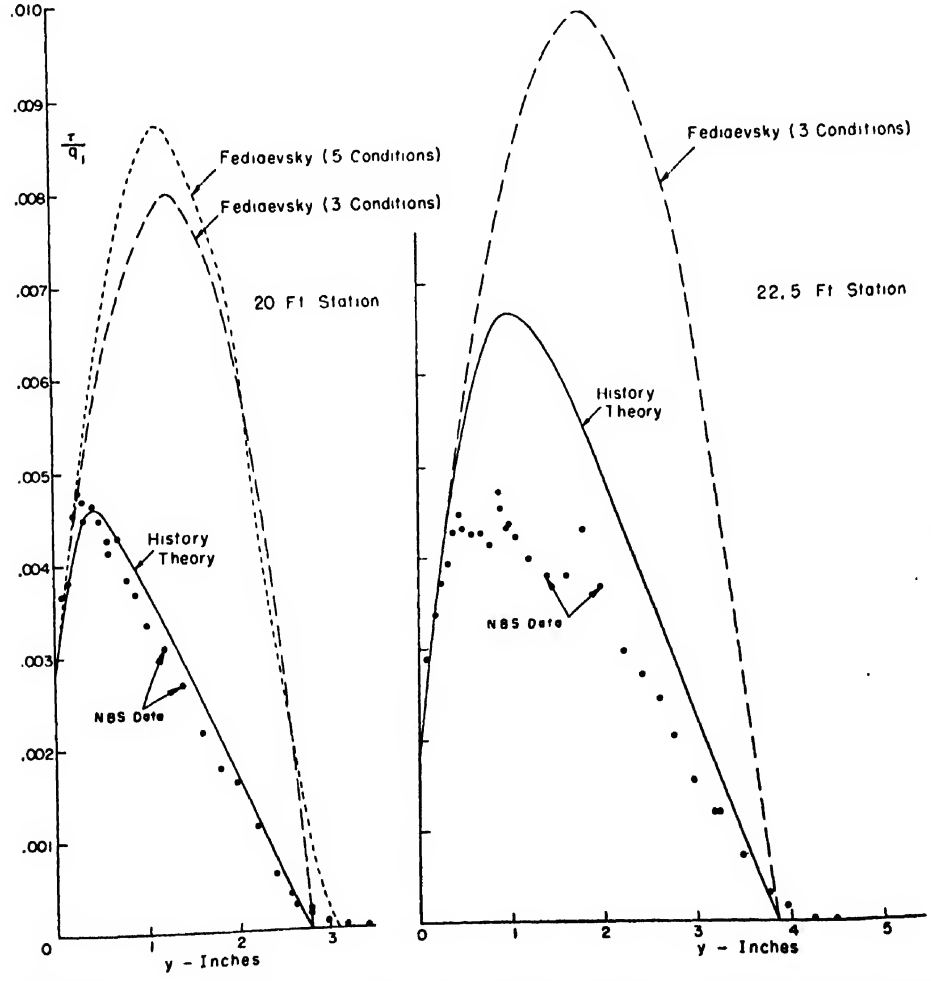

FIG. 3. Comparison of History and Fediaevsky theories with NBS experimental shear measurements for locations near the beginning of the adverse pressure gradient and midway toward separation.

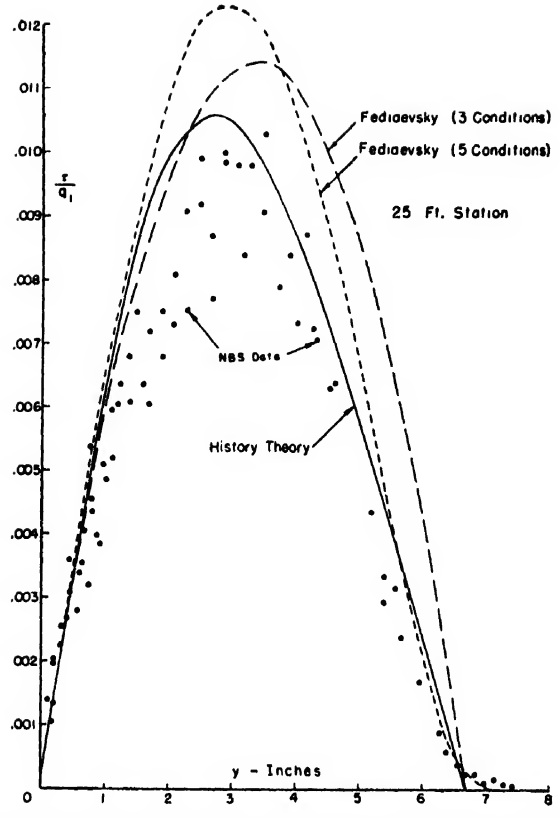

FIG. 4. Comparison of History and Fediaevsky theories with NBS data for station near separation.

shear at the start of the pressure gradient is seen to be carried along in the outer portion of the boundary layer, in qualitative agreement with the history concept.

THE HISTORY THEORY

A theory for the shear stress distribution in a turbulent boundary layer can be derived in a manner similar to that of Fediaevsky but taking into account the space-history effect. Thus, four of the five assumed boundary conditions on the shear stress function presented in Table I agree with those of Fediaevsky. Only the fourth condition, which is for the first derivative of the shear stress function at the outer edge, differs from his assumption. The derivative of the shear stress function is actually zero at the outer limit of the boundary layer, as assumed by Fediaevsky; however, as a polynomial having only a few terms is to be used, the value of the slope over a larger region should be considered. This condition for the slope of the shear stress function at the outer edge of the boundary layer should express the history concept, namely that the slope should have the same value as it had at the beginning of the adverse pressure gradient, where the shear curve is essentially linear.[10] The subscript zeros in condition 4 refer to values at the beginning of the pressure gradient.

As the predominant term in the shear stress function is the linear history term, the shear stress is expressed as a polynomial in terms of the distance from the edge of the boundary layer. To give flexibility to the shape of the curve, while using only a few terms, a function with adjustable exponent has been chosen:

$$\tau = a_0 + a_1[1-(y/\delta)] + a_n[1-(y/\delta)]^n + a_{n+1}[1-(y/\delta)]^{n+1}. \quad (4)$$

Using conditions 1 through 4, the coefficients may be evaluated in terms of the known flow parameters and the exponent n:

$$a_0 = 0,$$
$$a_1 = \tau_{w_0}(\delta/\delta_0),$$
$$a_n = (n+1)\tau_w + \delta(dp/dx) - n\tau_{w_0}(\delta/\delta_0),$$
$$a_{n+1} = -[n\tau_w + \delta(dp/dx) - (n-1)\tau_{w_0}(\delta/\delta_0)].$$

The value of the exponent n may then be fixed from condition 5, yielding

$$n = \frac{2\delta(dp/dx) + \tau_{w_0}(\delta/\delta_0) + \tau_w}{\tau_{w_0}(\delta/\delta_0) - \tau_w}. \quad (5)$$

The resultant expression for the shear stress distribution is

$$\tau = \tau_w(\delta/\delta_0)[1-(y/\delta)] - [\delta(dp/dx) + \tau_{w_0}(\delta/\delta_0)] \times [1-(y/\delta)]^n + [\delta(dp/dx) + \tau_w][1-(y/\delta)]^{n+1}, \quad (6)$$

where n is given by (5). At the start of a region of adverse pressure gradient, the exponent n is very large and the equations yield an essentially linear shear profile. As the boundary layer grows, the exponent decreases and the linear term is relegated to the outer portion of the boundary layer. In this manner, the space-history effect governs the essential characteristics of the shear stress distributions.

EXPERIMENTAL CONFIRMATION

A quantitative check of the history theory can be made by comparison with the shear stress data measured at the National Bureau of Standards[7] and introduced in Fig. 2. Detailed comparisons for stations near the beginning of the adverse pressure gradient, near separation, and midway are shown in Figs. 3 and 4. In each case, the results of the Fediaevsky theory are included for comparison. In these figures, the shear stress is expressed in terms of q_1, the dynamic pressure at the edge of the boundary layer, while in Fig. 2, the initial dynamic pressure q_{10} was used. Near the beginning (20-foot station), the agreement is excellent, and the improvement over Fediaevsky's theory is striking. At the second location (22.5 feet), the history theory is not such a good fit, but is a considerable improvement over the older theory. Although both theories agree reasonably well with experiment near separation (Fig. 4), the

[10] This involves a discontinuity in the shear stress and velocity distributions at the outer edge of the boundary layer. As in the case of the turbulent boundary layer along a flat plate, this discontinuity does not introduce any gross discrepancies.

history theory offers only a small improvement. From this limited comparison, it is apparent that the history theory gives reasonable agreement with experiment, especially in the beginning of the adverse pressure gradient where the older theory was most unsatisfactory.

In obtaining the theoretical shear stress distributions shown in Figs. 3 and 4, experimental values of the boundary layer thickness and the wall shear stress had to be used. Near the beginning of the pressure gradient, the wall shear has essentially the flat-plate value, whereas at separation the value is zero. For completeness, a theory is needed which will yield the local wall shear in terms of its initial value and the other flow parameters.

SUMMARY

A satisfactory theory for the shear stress distribution in a turbulent boundary layer has been developed from consideration of the space-history of the turbulence. This theory evolved from Jacobs' observations that the shear stress gradient in the outer portion of the boundary layer is constant, even when the external flow conditions vary in the direction of flow. Following Fediaevsky's method, boundary values are used to determine the coefficients of an arbitrary polynomial. The theory yields a linear shear profile at the beginning of the adverse pressure gradient; and as the boundary layer progresses, this linear characteristic is relegated to the outer part and the shear in the inner region is determined by local conditions. Comparison with shear measurements made at the National Bureau of Standards shows good agreement and appreciable improvement over Fediaevsky's theory. A more complete theory of the shear variation in a boundary layer under an adverse pressure gradient should consider turbulence decay and should also evaluate the wall shear stress.

Propagation of the TM_{01} Mode in a Metal Tube Containing an Imperfect Dielectric*

DAVID L. HETRICK

Department of Physics, Rensselaer Polytechnic Institute, Troy, New York

(Received September 20, 1949)

The TM_{01} mode in a circular dielectric-filled wave guide, where dielectric losses and metal wall losses are considered simultaneously, is analyzed from the viewpoint of the boundary value problem. General expressions for the attenuation and phase constant are obtained, and the percentage errors introduced by (1) neglect of wall losses and (2) assumption that the total attenuation is the sum of dielectric attenuation and approximate wall loss attenuation are computed for a particular case.

INTRODUCTION

THE problem of the propagation of electromagnetic waves in a uniform metal tube has usually been solved for the case where the metal of the tube itself is approximated by a perfect conductor. Even when losses in the enclosed dielectric are considered by retaining the imaginary part of the complex dielectric constant, the analysis does not become difficult.

When losses arising from the penetration of the fields into the metal sheath are to be taken into account, two approaches are available. One may assume that the field configurations are not appreciably altered from those obtained with perfect walls, and, knowing the intrinsic impedance of the bounding medium, compute the power loss and attenuation. The total attenuation is then taken to be the sum of attenuations arising from dielectric losses and wall losses separately.

The more general approach is the boundary value problem wherein the continuity of tangential fields leads to expressions for the attenuation and phase constant. Again, certain approximations are necessary, but these have negligible effect on the accuracy of the results. Insofar as the author is aware, the solution as a boundary value problem has not been carried out previously where dielectric losses and wall losses are considered simultaneously. The object of this investigation is to obtain general expressions for the attenuation and phase constant and to show for a particular case how the results differ from those obtained when (1) the wall losses are neglected and (2) the total attenuation is taken to be the sum of dielectric attenuation and approximate wall loss attenuation. For simplicity, only the circularly symmetric TM mode is considered.

The method followed was first employed by Carson, Mead, and Schelkunoff,[1] and by Barrow.[2] This phase of the problem was investigated in more detail by Linder,[3] though only the wall losses for an air-filled guide were considered in these papers. Recently[4–8] several papers

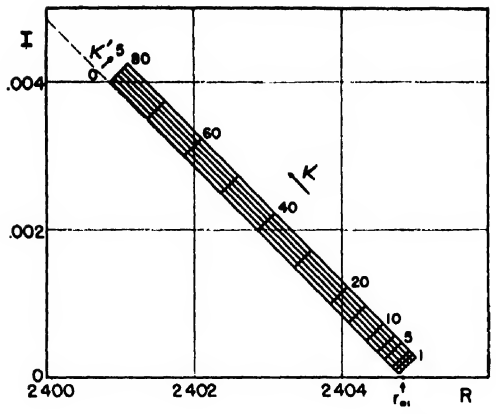

FIG. 1. Curves of constant κ and κ' in the complex ρ_1 plane; $\lambda_0/a=2\pi$, and a free-space wave-length of 1 cm is assumed.

have been published discussing the use of wave guide methods in measuring complex dielectric constants. It is important to know how great an error is introduced into the results when the wall losses are neglected, particularly if these results are to be used in deducing the structures of complex organic molecules.

THE BOUNDARY EQUATION

The fields whose continuity must be preserved at the walls of the wave guide may be expressed as[9] (MKS units)

$$E_{1z}=Ak_1^2J_0(k_1r)\exp(j\omega t-\gamma z), \tag{1}$$

$$E_{2z}=Bk_2^2H_0^{(1)}(k_2r)\exp(j\omega t-\gamma z), \tag{2}$$

$$H_{1\phi}=j\omega\epsilon_{c1}Ak_1J_1(k_1r)\exp(j\omega t-\gamma z), \tag{3}$$

$$H_{2\phi}=j\omega\epsilon_{c2}Bk_2H_1^{(1)}(k_2r)\exp(j\omega t-\gamma z), \tag{4}$$

where

$$k^2=\gamma^2-j\omega\mu(\sigma+j\omega\epsilon), \tag{5}$$

and the propagation constant γ is

$$\gamma=\alpha+j\beta=\alpha+j(2\pi/\lambda).$$

The subscripts 1 and 2 refer to the enclosed dielectric and the metal sheath respectively. These are taken to be regions containing no free charges and having conductivity σ, permittivity ϵ, and permeability μ; α is the attenuation constant, β the phase constant, λ the guide wave-length, ω the angular frequency $2\pi\nu$, A and B arbitrary constants, $J_n(kr)$ and $H_n^{(1)}(kr)$ the Bessel function and Hankel function of the first kind respectively. The complex permittivity ϵ_c is defined as

$$\epsilon_c=\epsilon-j\sigma/\omega. \tag{6}$$

Cylindrical co-ordinates r, ϕ, and z are employed, where z is the direction of the wave guide axis.

Note that $\gamma_1=\gamma_2$ in order to satisfy the boundary conditions for all z and t. The argument kr must be taken as having a positive imaginary part; it can be shown that this leads to no loss of generality.

With the use of Eq. (5), assuming $\mu_1=\mu_0$,

$$k_1=[\gamma^2+(2\pi/\lambda_0)^2(\kappa-j\kappa')]^{\frac{1}{2}} \tag{7}$$

where $\kappa=\epsilon/\epsilon_0$, $\kappa'=\sigma_1/\omega\epsilon_0$, and λ_0 is the free-space wave-length. In the metal, $\omega\mu_2\sigma_2\gg\gamma^2$ and $\omega\mu_2\sigma_2\gg\omega^2\mu_2\epsilon_2$. Assuming $\mu_2=\mu_0$,

$$k_2=2\pi/\lambda_0[-j\sigma_2/\omega\epsilon_0]^{\frac{1}{2}}. \tag{8}$$

Setting $\rho_1=k_1a$ and $\rho_2=k_2a$, where a is the inner radius of the metal sheath, one obtains from the continuity of tangential fields at the boundary

$$\frac{\epsilon_{c1}J_1(\rho_1)}{\rho_1J_0(\rho_1)}=\frac{\epsilon_{c2}H_1^{(1)}(\rho_2)}{\rho_2H_0^{(1)}(\rho_2)}. \tag{9}$$

This condition is sufficient to determine the constants of propagation. In general, a superposition of *TM* and *TE* waves is necessary to satisfy the boundary conditions, but in the circularly symmetric case no new mode is introduced.[9]

The values of ρ_2 justify the use of the asymptotic expansion[10]

$$H_1^{(1)}(\rho_2)/H_0^{(1)}(\rho_2)=e^{-j\pi/2}. \tag{10}$$

Replacing ϵ_{c1}/ϵ_0 by κ_c, and making use of Eqs. (6), (8),

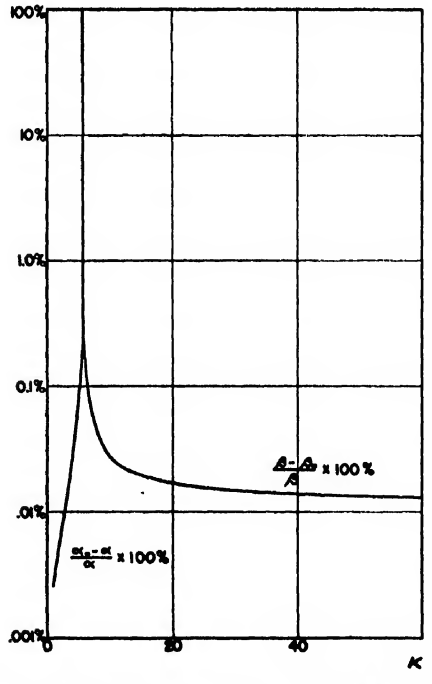

FIG. 2. Percentage errors in attenuation and phase constant introduced when metal wall losses are neglected; $\lambda_0/a=2\pi$ and $\kappa'=0$.

[9] J. A. Stratton, *Electromagnetic Theory* (McGraw-Hill Book Company, Inc., New York, 1941), p. 521 *et seq.*

[10] R. I. Sarbacher and W. A. Edson, *Hyper and Ultrahigh Frequency Engineering* (John Wiley & Sons, Inc., New York, 1943), p. 231 *et seq.*

and (10), Eq. (9) becomes

$$\frac{\kappa_c J_1(\rho_1)}{\rho_1 J_0(\rho_1)} = \frac{\lambda_0}{2\pi a}\left[\frac{\sigma_2}{2\omega\epsilon_0}\right]^{\frac{1}{2}}(1+j). \tag{11}$$

Since $\kappa_c = \kappa - j\kappa'$, divide by κ_c to obtain

$$J_1(\rho_1)/\rho_1 J_0(\rho_1) = c + jd \tag{12}$$

where

$$c = \frac{\lambda_0}{2\pi a}\left[\frac{\sigma_2}{2\omega\epsilon_0}\right]^{\frac{1}{2}}\frac{\kappa-\kappa'}{\kappa^2+\kappa'^2} \tag{13}$$

and

$$d = \frac{\lambda_0}{2\pi a}\left[\frac{\sigma_2}{2\omega\epsilon_0}\right]^{\frac{1}{2}}\frac{\kappa+\kappa'}{\kappa^2+\kappa'^2}. \tag{14}$$

In order to solve Eq. (12) for ρ_1, replace the Bessel functions by the first two terms of their complex Taylor series expansions

$$J_1(\rho_1) = J_1(r_{01}) + (\rho_1 - r_{01})J_1'(r_{01}) + \cdots,$$
$$J_0(\rho_1) = J_0(r_{01}) + (\rho_1 - r_{01})J_0'(r_{01}) + \cdots,$$

where $r_{01} = 2.404,825,558$, the root[11] of rank one of $J_0(k_1 a) = 0$, and the limiting value of ρ_1 as σ_2 becomes infinite.[10] This yields expressions for the TM_{01} mode.

One obtains a quadratic

$$[c+jd]\rho_1^2 - [(r_{01}c + 1/r_{01}) + jr_{01}d]\rho_1 + 2 = 0 \tag{15}$$

having the solution

$$\rho_1 = R + jI, \tag{16}$$

where

$$R = \frac{r_{01}}{2} + \frac{c}{2r_{01}(c^2+d^2)} + \left[\frac{L}{2} + \frac{1}{2}(L^2+M^2)^{\frac{1}{2}}\right]^{\frac{1}{2}}, \tag{17}$$

$$I = -\frac{d}{2r_{01}(c^2+d^2)} + \left[-\frac{L}{2} + \frac{1}{2}(L^2+M^2)^{\frac{1}{2}}\right]^{\frac{1}{2}}, \tag{18}$$

$$L = \frac{r_{01}^2}{4} + \frac{c^2 - d^2 - 6cr_{01}^2(c^2+d^2)}{4r_{01}^2(c^2+d^2)^2}, \tag{19}$$

$$M = \frac{3dr_{01}^2(c^2+d^2) - dc}{2r_{01}^2(c^2+d^2)^2}, \tag{20}$$

and c and d are defined by Eqs. (13) and (14).

The ambiguity in sign arising in the solution of the quadratic is removed by observing the effect of allowing σ_2 to increase without limit. The sign has been chosen so that $\rho_1 \to r_{01}$; the alternative leads to the impossibility $\rho_1 \to 0$.

Figure 1 is a typical set of curves of constant κ and κ' in the complex ρ_1 plane showing the departure from the case of perfect walls. The curves are for a copper tube, assuming a free-space wave-length of 1 cm and a ratio $\lambda_0/a = 2\pi$. Note that the curve for $\kappa' = 0$, when extended, passes through the point $R = r_{01}$, $I = 0$. For $I < 0.002$, the curves of constant κ' approach straight lines.

ATTENUATION AND PHASE CONSTANT

From Eq. (7),

$$\rho_1^2 = (R+jI)^2 = a^2[(\alpha+j\beta)^2 + (2\pi/\lambda_0)^2(\kappa - j\kappa')].$$

Equating real and imaginary parts, a quadratic in $(a\alpha)^2$ is obtained. Choosing only positive real values for α, one obtains

$$a\alpha = 2^{-\frac{1}{2}}[q_1 + (q_1^2+q_2^2)^{\frac{1}{2}}]^{\frac{1}{2}}, \tag{21}$$

where

$$q_1 = R^2 - I^2 - (2\pi a/\lambda_0)^2\kappa,$$
$$q_2 = 2RI + (2\pi a/\lambda_0)^2\kappa'.$$

The phase constant is given by

$$a\beta = q_2/2a\alpha. \tag{22}$$

Equations (21) and (22) will be convenient for numerical computations only in the "region of attenuation" where $(\lambda_0/a)\kappa^{-\frac{1}{2}} > 2\pi/r_{01}$. In the "region of propagation" a quadratic in $(a\beta)^2$ yields

$$a\beta = 2^{-\frac{1}{2}}[-q_1 + (q_1^2+q_2^2)^{\frac{1}{2}}]^{\frac{1}{2}}. \tag{23}$$

Once the phase constant is known from Eq. (23), Eq. (22) may be employed to obtain the attenuation.

In the limiting case of perfectly conducting walls where $R \to r_{01}$ and $I \to 0$, these general expressions yield the attenuation and phase constant for the case of dielectric loss only. If, in addition, $\kappa' \to 0$, one obtains the expressions for the completely lossless case.[10]

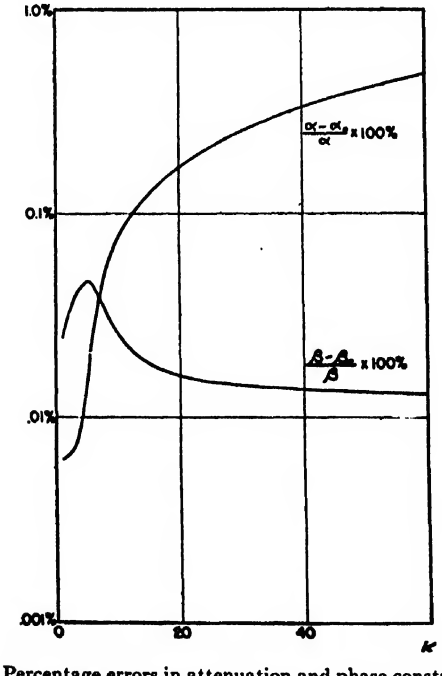

FIG. 3. Percentage errors in attenuation and phase constant introduced when metal wall losses are neglected; $\lambda_0/a = 2\pi$ and $\kappa' = 3$.

[11] Gray, Mathews, and MacRobert, *A Treatise on Bessel Functions* (MacMillan & Company, London, 1922), p. 244.

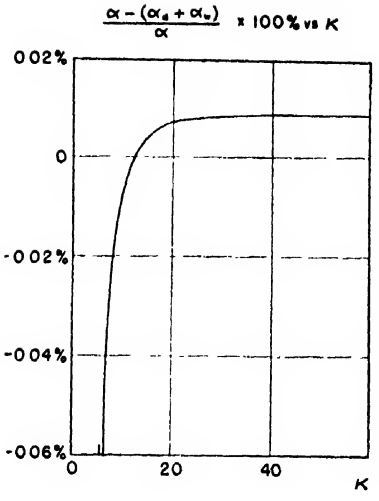

FIG. 4. Percentage error in attenuation introduced by assuming $\alpha=\alpha_d+\alpha_w$; $\lambda_0/a=2\pi$ and $\kappa'=3$.

NUMERICAL RESULTS

The percentage errors in attenuation and phase constant introduced by neglecting wall losses are shown in Figs. 2 and 3, where $\kappa'=0$ and 3 respectively. The subscript 0 on α and β denotes the completely lossless case, and the subscript d denotes values obtained from Eqs. (21) through (23) for dielectric loss only. Values obtained from these equations when wall losses are included are indicated without subscripts. The critical point, or transition from attenuation to propagation for the lossless guide, is found at $\kappa=5.78$ for the case chosen.

The errors arising from the assumption that the total attenuation is $\alpha_d+\alpha_w$, where α_w represents the approximate wall loss attenuation as computed from power flow considerations,[10] are shown in Fig. 4.

Two remarkable effects will be noted. In Fig. 2, where no dielectric loss is present, the attenuation decreases when wall losses are added; $\alpha_0>\alpha$. This seems contrary to expectation at first glance. A qualitative explanation may be offered as follows: α_0 is a purely reactive attenuation. When wall losses are added, the penetration of the fields into the metal causes an effective change in the field configuration which reduces the reactive attenuation. This is evidently more than enough to compensate for the resistive attenuation caused by the metal walls.

The second interesting effect is that the error curve in Fig. 4 changes sign; there is one value of κ for which $\alpha=\alpha_d+\alpha_w$ exactly.

While these curves apply to a specific set of parameters, one may conclude in general that the assumption $\alpha=\alpha_d+\alpha_w$ is an excellent approximation anywhere in the "region of propagation" except in the immediate neighborhood of the critical point; the relative error in attenuation remains of the order of magnitude of 10^{-4} for most of the range of operation. On the other hand, the wall losses cannot be entirely neglected in this range of operation where relative errors less than 10^{-3} are desired. The order of magnitude of the errors involved will not vary greatly as the cross-sectional configuration of the wave guide is altered.

DIELECTRIC CONSTANT AND POLAR MOLECULES

It can be shown[12] that if the real and imaginary parts of the dielectric constant of a polar liquid are known, much information may be gained about the molecular structure of the liquid. For example, the polarizability, dipole moment, and relaxation time of the dipoles may be calculated if κ and κ' are known with sufficient accuracy.

The κ' referred to here arises from polarization losses only. If ionic conduction is present, its effect must be subtracted.

The values of κ and κ' may be obtained from wave guide measurements of attenuation and phase constant in the following way: Suppose that curves of $a\alpha$ and $a\beta$ *vs.* κ for various κ' are available.** If horizontal lines are drawn on each set of curves corresponding to measured values of $a\alpha$ and $a\beta$ respectively, data for curves of constant $a\alpha$ and $a\beta$ in the complex κ_c plane are obtained. The intersection determines κ and κ'.

ACKNOWLEDGMENT

The author wishes to express his appreciation to Professor Philip Rosen of the Department of Physics of Rensselaer Polytechnic Institute for his suggestion of this investigation and for his assistance in its completion. Particular thanks are due to Professor Alfred W. Jones of the Department of Mathematics and to Professor Robert M. Whitmer of the Department of Physics for their invaluable aid.

[12] Glasstone, Laidler, and Eyring, *The Theory of Rate Processes* (McGraw-Hill Book Company, Inc., New York, 1941), pp. 544–546.

** It is not necessary that the only term in κ', as used in preceding sections, be the term $\sigma_1/\omega\epsilon_0$. The introduction of a polarization loss in the dielectric does not alter the wave guide equations.

Ultra Speed Tensile of Rubber and Synthetic Elastomers*

D. S. VILLARS†
General Laboratories, United States Rubber Company, Passaic, New Jersey
(Received October 6, 1949)

A high speed stress-strain machine has been developed which is capable of recording the stress-strain curve of elastomers at elongation rates up to 270 percent/msec. Data are reported on two series of gum and tread stocks of hevea and of the synthetic elastomers, GR-S, Hycar OR, butyl, Perbunan, and Neoprene GN. The second (elastomer) series was also run at 150°C. In general, stress-strain curves fall into two classes. Stocks of elastomers which are known to crystallize on stretching tend to show tensiles which decrease with increasing speed up to about 10 percent/msec., pass through a minimum and rise more or less drastically to values 100 percent (or more) greater than the Scott tensile. Elastomers which do not crystallize on stretching tend to show a steady rise in tensile with increasing speed. Elongation at break curves show a maximum with crystallizing stocks and no maximum with non-crystallizing stocks. The shape of the modulus *versus* speed curves is accounted for on the hypothesis of different types of slipping bonds with different characteristic relaxation times. The shift of curves for tread stocks with temperature allows the estimation of a heat of activation of slippage. This comes out to be of the order of 3 kg cal.

INTRODUCTION

A MACHINE has been developed which is capable of recording the stress-strain curve of rubber at rates of elongation up to 9000 times that used in the Scott tensile test. This is over 100 times faster than any rate previously attained in any rubber tests. Availability of such high speed, which shall hereinafter be designated as "ultra speed," enables one now, for the first time, to study the relationship to service behavior of fundamental physical properties of commercial rubber stocks. The present paper presents a brief description of the machine and surveys the speed dependence of tensile strength, elongation at break, modulus and breaking energy of rubber and synthetic elastomers.

Other investigators have attempted to measure short time stress strain and tensile of rubber. Albertoni[1] described a pendulum impact tester which measured energy expended to stretch individual samples to definite predetermined elongations and to break. Roth and Holt[2] built a clever guillotine type of machine which stretched samples by means of a vertically falling weight. Dart, Anthony, and Wack[3] devised a fast stress-strain machine working on "the principle of a mechanical balance."

Objections to the foregoing types of machine are: (1) Time of break is not short enough. (2) Too much calculation is required to obtain the stress-strain curve (excessive calculation precludes large volume of investigation). (3) Rate of elongation in Roth-Holt machine is not uniform. (4) A different sample is tested for each point on the stress-strain curve when using the Albertoni machine.

Our present new machine overcomes each of these objections. It gives times of break down to $\frac{1}{2}$ msec. with constant rates of elongation almost 100 times that of the Albertoni machine, 200 times the mean rate of the Roth and Holt apparatus, 1000 times that obtained with the highest frequency dynamic hysteresis apparatus (Naunton and Waring,[4] *ca.* 1000 cycles/sec.) and 9000 times that of the Scott tensile machine. It gives direct photographs of the complete stress-strain curve of a particular sample, without any reduction by integration or differentiation.

Description of Ultra Speed Machine

The machine (cf. Fig. 1) consists of a rotating wheel, on the circumference of which a pin strikes the middle enlarged part of a double dumbbell test piece hanging in the form of a loop. This dumbbell was designed especially for this machine. The two narrow parts are 0.1 in. wide and 17/64 in. long. The total length of test piece is $5\frac{7}{32}$ in. The stress produced is communicated mechanically to a piezoelectric crystal which generates an electrical potential directly proportional to the stress. This potential is amplified and recorded on an oscillograph screen. The oscillograph trace, which is the

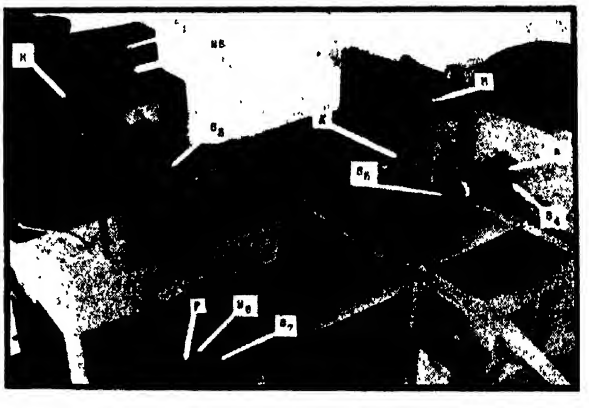

FIG. 1. Ultra speed machine.

stress-strain curve, is photographed on 35-mm film. Calibration is carried out by suddenly applying a steady force upon the crystal by means of an electromagnet. The strength of the latter is in turn determined by weighing the force necessary to break the armature away from the magnet. By means of a variable speed transmission, and speed reducing pulleys, all wheel speeds between 60 and 1700 r.p.m. can be obtained. The corresponding elongation rates in rubber samples vary from 9.3 to 270 percent/msec. The output of the machine is 13 to 16 stress-strain curves per day.

It is planned to submit a detailed technical description of the machine to *The Review of Scientific Instruments*.

Stocks

Two series of stocks are considered in this paper. In the first, called the "Replication series," standard tread stocks, containing 50 parts carbon black (per hundred of elastomer), and standard gum stocks, omitting all carbon black, were compounded and cured. The second series is of six different elastomers, without and with 21 volumes channel black per 100 volumes matrix (rubber plus soluble components). Table I gives formulas of the second series.

RESULTS

Shape of Stress-Strain Curve

A typical ultra speed stress-strain curve taken at 57 percent/msec. is reproduced in the upper half of Fig. 2. It is approximately linear. Figure 3 plots the average of three stress-strain curves of a rubber gum stock taken at 36 percent/msec. At highest ultra speeds, the stress-strain curves assume a wave form (lower half of Fig. 2), sometimes multiple in character. The reason for this multiplicity is not known. It may have something to do with slippage of the samples in the holders. It may be associated with resonance chattering oscillations in the crystal holder or crystal itself. That it is not due to each wave representing individual non-simultaneous breaks of the two sample sides was shown by the fact that samples with one side cut beforehand also showed double loops.

Velocity of Sound

At the greatest ultra speeds the possibility has been taken into consideration of perturbing effects which might be introduced by the wave character of stress response whenever the rate of elongation approaches too closely the velocity of sound in the sample. For zero hysteresis the stress recorded at the held end of a uniform sample elongated at a constant rate should increase with time by finite perpendicular steps.[5] Al-

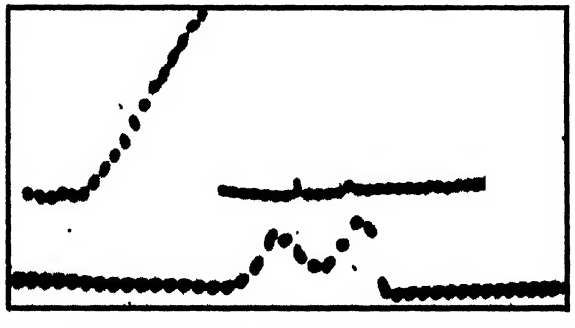

FIG. 2. Ultra speed stress strain curves. Upper curve: rubber tread; elongation rate: 57 percent/msec.; timing frequency: 2000 c.p.s.; tensile: 3530 lb./in^2.; elongation at break: 325 percent; time of break: 5.7 msec. Lower curve: special rubber tread; elongation rate: 238 percent/msec.; timing frequency: 5000 c.p.s.; tensile: 6600 lb./in^2.; elongation at break: 143 percent; time of break: 0.6 msec.

[5] Fourier analysis of the equation

$$(\partial^2 y/\partial \tau^2) = (\partial^2 y/\partial \xi^2)$$

for the boundary conditions,

$$\begin{aligned} y &= 0 \quad \text{at } \tau = 0, \\ (\partial y/\partial \tau) &= 0 \quad \text{at } \tau = 0, \\ y &= 0 \quad \text{at } \xi = 0, \\ y &= \alpha\tau \quad \text{at } \xi = 1, \ \tau > 0 \end{aligned}$$

though we know that we are dangerously near the velocity of sound at highest speeds, no elastomer curves have yet been observed which have the step shape predicted by wave theory. This fact indicates that none of our conclusions are subject to modification because of wave phenomena. However, it is still possible that large specific acoustic absorption effects at the frequencies concerned might reduce the steepness of the "steps." This could result in the steps being overlooked.

Preworking

Possibility of an effect of preworking was checked by running a series of rubber tread stocks, half of the samples of which were preworked by (hand) stretching ten times out to the "hardening" point and back. The order of testing these and unworked controls was random. Results (Table II) indicate no great effect on either tensile or elongation.

Comparison of High and Low Speed Stress-Strain Curves

Figure 3 compares the average of three ultra speed curves (elongation rate 36 percent/msec.) of rubber gum stock with a slow speed stress (single pull—no pre-

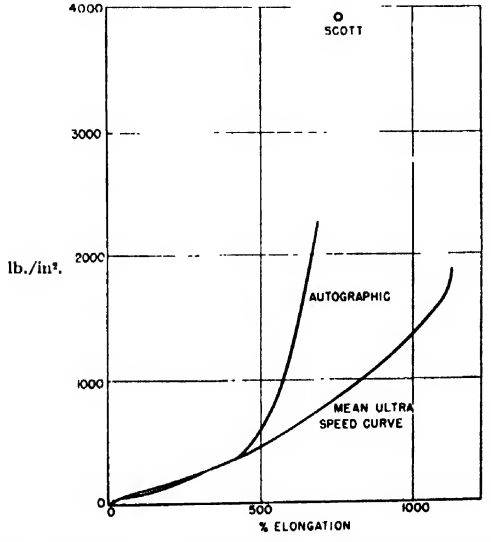

FIG. 3. Comparison of ultra speed with autographic stress-strain curve—rubber gum. Times of break—ultra speed: 28 msec.; Scott: 30 sec.; autographic: 88 sec.

gives:

$$y = \alpha\xi\tau + \frac{2\alpha}{\pi^2}\sum_{m=1}^{\infty}\frac{(-1)^m}{m^2}\sin m\pi\xi\,\sin m\pi\tau.$$

In these equations the dimensionless quantities are defined as:

$$y = u/L;\quad \xi = x/L;\quad \tau = t/(L/v);\quad \alpha = a/v,$$

where u is the displacement of a point in the sample of total length L, originally at a distance x from the fixed end, t is time, a is the uniform velocity of displacement of the other end of the sample and v is the velocity of sound in the rubber (taken as constant). The local elongation $\partial y/\partial\xi$ at $\xi = 0$ (and hence stress) may be shown to represent a series of perpendicular steps, each of height 2 dimensionless units and of length 2 units of τ.

working) strain curve of a sample from the same slab of rubber, as recorded by an autographic stress strain machine designed by H. M. Smallwood, H. T. Battin, and W. Moorman. This machine uses ring-shaped test pieces, 1.373 in. o.d. and 1.173 in. i.d. Such test pieces never give the full value of the tensile strength, probably "because of uneven distribution of stress over the cross section caused by the fact that the inside of the ring is stretched more than the outside during elongation and because of the effect of the clamp pulleys on the portions of the ring passing over them."[6] However, the autographic curve, Fig. 3, is seen to head for the Scott tensile value, also determined on pieces from the same slab. It breaks away from the ultra speed curve at about 400 percent elongation.

Reproducibility of Measurement

To obtain an accurate estimate of the variability of measurement, triplicate mixes of Hevea and GR-S gum and tread stocks were mixed in random order and cured. Each test slab was $6\frac{1}{2}\times 6\frac{1}{2}\times 0.1$ in. and can supply five ultra speed stress-strain, four Scott, and one autographic stress-strain test pieces. In this test, five speeds were investigated and each mix-speed combination was run in random order until each combination was represented. Such a "block" was then repeated in a new random order until five blocks were completed.

In carrying out such a program plan, stress-strain curves are occasionally missed. This is sometimes caused by faulty synchronization, sometimes by failure of the sweep trigger mechanism, not to speak of human failures to open the camera shutter or turn the film on to the next frame. Such missing values were filled in by the method of Yates.[7]

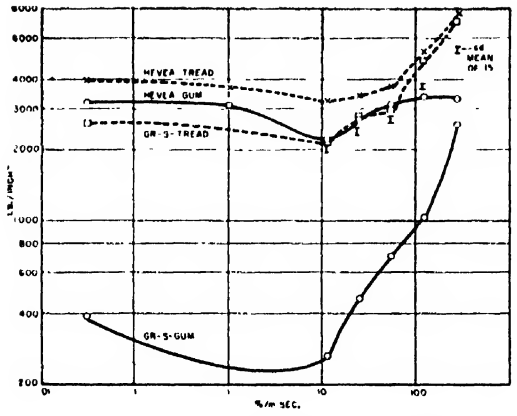

FIG. 4(a). Tensile—Replication series AEG-J.

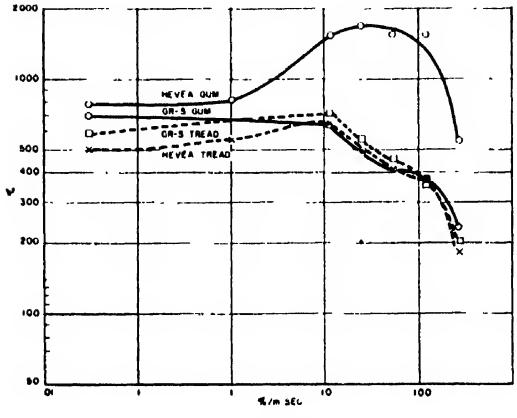

FIG. 4(b). Elongation at break—Replication series AEG-J.

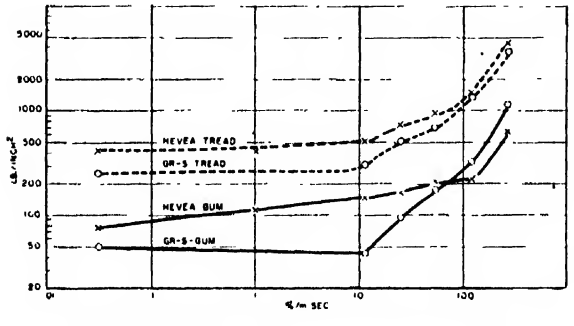

FIG. 4(c) Modulus—Replication series AEG-J.

The standard deviations of testing error were determined separately for each individual rate of elongation. See Table III. It may be seen from the I-shaped marks on Fig. 4(a) that the standard deviation of tensile strength tends to vary in direct proportion with the value of the tensile (coefficient of variation is more constant than the standard deviation).

No mixing error (significantly greater than testing error) was found except at speed 120 percent/msec. This means that testing error is the predominant source of variability.

TENSILE STRENGTH

Dependence on Speed

Figure 4(a) plots the results of ultra speed tensile measurements on the first (replication) series of Hevea gum and tread and GR-S gum and tread. The abscissae are logarithms of elongation rates. At the left of the graph is the Scott tensile value, plotted at 0.03 percent/msec. Each of the ultra speed values (in this series only) is the mean of five samples each of three independent mixes of the same stock and the standard deviations, listed in Table III as for means of 5, are indicated by the limits of the I-shaped figures on the graphs (after converting to means of 15). From these limits one may judge visually the significance of the trends exhibited.

Roth and Holt[2] values for Hevea are inserted at 1 percent/msec. Their tread compound contained 40 parts channel black, while ours contained 50 parts. That particular point falls reasonably on our curve, as if variation in carbon black loading in that range makes little difference at that low a speed.

It may be seen that for our stocks there is a significant drop in tensile with increasing speed up to about 10 percent/msec. Somewhere near this speed (before it if not at it) the tensile goes through a minimum and rises more or less drastically until at the highest speeds observed it is, for the tread stocks, 100 percent (or more) greater than the Scott tensile. The Hevea gum tensile at highest speed is about the same as the Scott tensile, but the tensile of the GR-S gum is multiplied sevenfold.

Effect of Curing

Figure 5(a) shows ultra speed tensiles obtained on raw Hevea gum and tread stocks. The samples for these runs were interspersed in random order among those of the replication series. It may be seen that raw smoked sheet, which has zero Scott tensile, attains a tensile of 900 lb./in.^{2} at highest speed. Compounded (but uncured) tread stock has a Scott tensile of 530 lb./in.^{2}. This increases to 4200 lb./in.^{2} at highest ultra speed.

Dependence on Elastomer

Tensile data on the elastomers of the second series are to be found plotted in Figs. 6(a)–11(a). In this series GR-S does not show a minimum in tensile (it shows a slight minimum in the Replication series), but a steady rise as speed is increased. Hycar OR and Perbunan also show a steady rise. The other synthetics show the minimum as Hevea does.

It is to be noted that the stocks which exhibit the minimum (except for GR-S) are ones which are known to crystallize at ordinary slow rates of stretch. The other stocks do not crystallize. The minimum in the first GR-S series may be related to an orientation, of lower order than crystallization.

Dependence on Temperature

Figures 6–11(a) also show the results of a study of effect of temperature on ultra speed tensile. In general,

ultra speed tensile of gum stocks at 240 percent/msec. is reduced by 67 to 75 percent by heating to 150°C; of tread stocks, it is reduced only by 20 to 50 percent (exception: possibly Perbunan). At 150°C, gum GR-S has such a poor ultra speed tensile that the pin on the wheel knocks out from the sample by a clean cut an exact replica of the pin.

ELONGATION AT BREAK

Dependence on Speed

Figure 4(b) gives the elongation at break obtained from measurement of the replication series. It shows at 1 percent/msec. elongation values of Roth and Holt. The Hevea stocks, especially the gum, show a maximum in elongation at break twice that at Scott speed, between 10 and 30 percent/msec. The GR-S stocks do not exhibit this phenomenon to as marked an extent, if at all. At highest ultra speed all stocks become drastically shortened.

Effect of Curing

See Fig. 5(b). Elongation at break of the uncured smoked sheet and tread compound shows curves similar to those of the cured stocks, except for an upward displacement of the tread stock. The ultra speed values of the uncured smoked sheet agree fairly closely with those at the same speeds for the cured gum stocks.

Dependence on Elastomer

See Figs. 6(b)-11(b). The different elastomers, in general, are classifiable into two groups; one in which the elongation at break passes through a maximum at an intermediate ultra speed (such as Hevea, and Butyl) and one for which it steadily decreases with increasing speed of break. Except for Neoprene GN, this classification is the same as that of elastomers which do or do not crystallize on stretching.

Dependence on Temperature

Ultra speed elongation at break at 150° seems, in general, to be greater for tread stocks than for gum stocks at all speeds except the highest. Heating to 150° *reduced* elongation of all stocks except butyl tread.

Modulus

The ultra speed modulus was computed from the tensile and elongation at break on the approximation that the ultra speed stress-strain curve is linear. For Scott speed the modulus was arbitrarily taken as the slope of the line between the origin of the (single-pull) autographic stress-strain curve and the point of inflection. This value thus does not include the subsequent increase in modulus which many elastomer stocks undergo at higher elongations (usually ascribed to orientation). It lies between the Wall-Young's modulus and the shearing modulus as computed from Young's modulus by dividing the latter by three. Within this range, the comparability of the low speed values with the ultra speed values is somewhat uncertain.

Dependence on Speed

Figure 4(c) gives modulus measurements obtained from the Replication series. It contains at 1 percent/msec. modulus values of Roth and Holt. Modulus is almost independent of elongation rate up to 10 percent/msec., above which speed it rises rapidly.

Effect of Curing

Modulus of uncured smoked sheet and of uncured tread compound shows curves similar to those of the

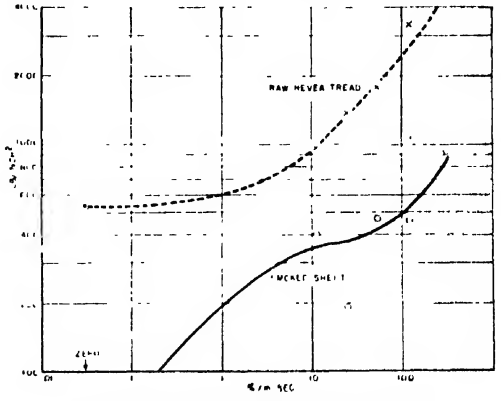

FIG. 5(a). Tensile—unvulcanized Hevea.

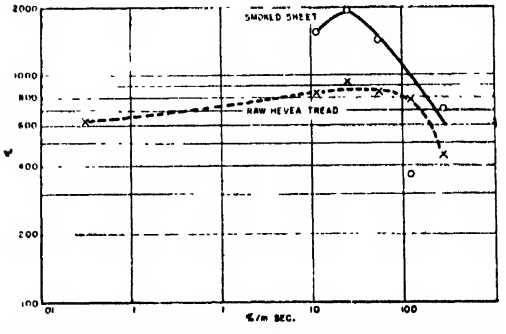

FIG. 5(b). Elongation at break—unvulcanized Hevea.

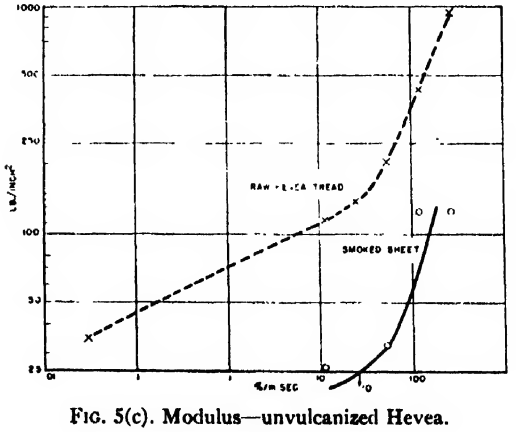

FIG. 5(c). Modulus—unvulcanized Hevea.

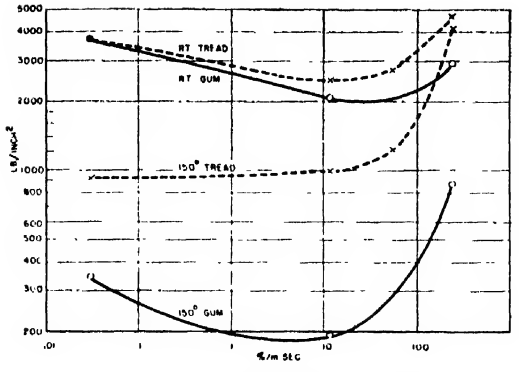

FIG. 6(a). Tensile—Hevea ADJ, K.

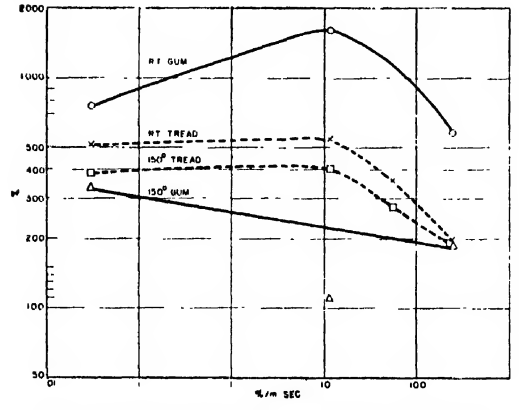

FIG. 6(b). Elongation at break—Hevea ADJ, K.

cured stocks, except for a downward displacement in value. See Fig. 5(c).

Dependence on Elastomer

Plots of moduli of the elastomer series, in general, show that modulus is more or less constant until the ultra speeds are reached, when it starts to increase with an accelerated pace.

Dependence on Temperature

Modulus of gum stocks is little affected by increasing temperature to 150°; that for tread stock is shifted to the side of higher elongation rate. Exceptions to this last generalization are Hevea and Neoprene, where the curves for tread stocks rise to the same modulus at highest speed.

Energy of Break

Ultra speed energy of break was computed from the tensile and elongation at break on the approximation that the ultra speed stress-strain curve is linear. For Scott speed, energy of break was obtained by integrating (by planimeter) the complete single-pull autographic stress-strain curve after extending it to the Scott tensile and elongation at break. The slow speed energy thus includes the contribution of all orientation effects. Energy of break values appear to be subject to an excessively large error. They fluctuate so greatly that no trends with speed appeared significant.

Independent Determination of Energy of Break

Energy of break was checked independently by measuring the instantaneous drop in wheel speed occurring when the sample is broken. This was measured by connecting the oscillograph to give a changing pattern, the frequency of which was the difference between the wheel frequency and an adjustable reference frequency. The difference between this difference frequency before and immediately after breaking a sample was combined with the moment of inertia of the wheel to compute the energy of break.

Two values obtained are 18.5 and 15.6 ft. lb. for rubber tread. These values, determined at 25 cycles/sec. wheel speed, are to be compared with the total energy of break, 10.12 ft. lb., given by a stress-strain curve at 23 cycles, of a similar sample. The latter figures include 1.69 ft. lb. kinetic energy of the end thrown off. The high tensiles indicated by our measurements of the stress-strain curves are thus independently confirmed.

DISCUSSION

Crystallization and Relaxation

In explaining the observed effects of elongation rate on the stress-strain properties of elastomers, it is necessary to consider two phenomena which can be induced in an elastomer by stretching, but which require finite

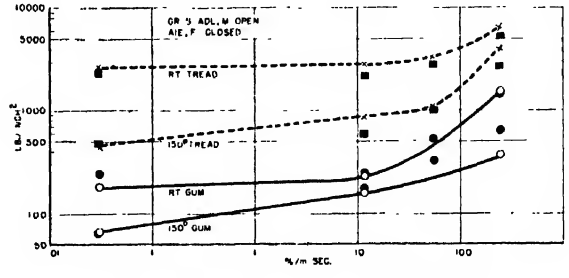

FIG. 7(a). Tensile—GRS. ADL, M; AIE, F.

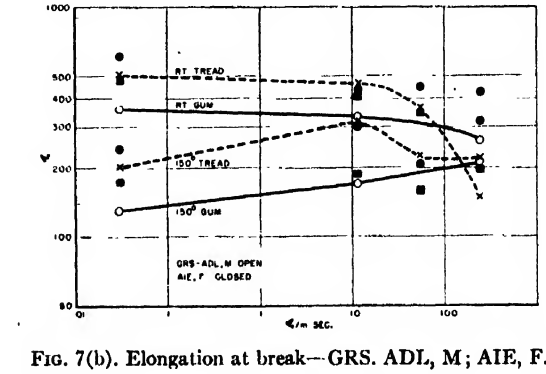

FIG. 7(b). Elongation at break—GRS. ADL, M; AIE, F.

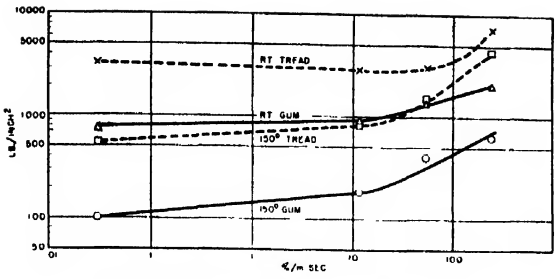

FIG. 8(a). Tensile—Hycar OR. ADN, O.

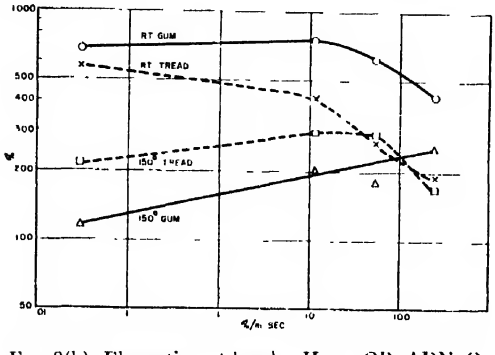

FIG. 8(b). Elongation at break Hycar OR, ADN, O

time for completion. These phenomena are, first, crystallization and, second, relaxation.

The fact that rubber crystallizes on stretching is familiar to all rubber chemists. Many, if not most, attribute the upbend in the ordinary stress-strain curve to onset of crystallization. According to Acken, Singer, and Davey,[8] a minimum time of the order of 1.2 sec. is required after stretching before enough crystallization develops to show up in a x-ray picture. As our ultra speed curves are produced in times of lower order of magnitude than this, it is plausible to attribute differences between those obtained at the lesser ultra speeds and those obtained at slow speed to lack of time for crystallization to develop. This lack of time would account for the approximate linearity of the ultra speed stress-strain curves.

This theory may be used to account for the differences in tensile and elongation at break between the slow autographic stress-strain and the mean ultra speed curve of Fig. 3. Since the latter was produced in an average time of 28 msec., presumably much too short for crystallization, we may conclude that crystallization increases tensile strength but shortens the elongation at break.

A corollary of the hypothesis of a finite time requirement for completion of crystallization is of interest to problems of abrasion resistance. Inasmuch as abrasion processes generally occur in cycles shorter than 20 msec., it appears questionable whether the crystallization characteristics of a tread stock can have any direct effect on its abrasion resistance.

Relaxation, the second phenomenon invoked to explain the ultra speed results, is the loss of stress with time in a sample held at a constant deformation. It is thought to be due to a slow intermolecular slippage within the rubber, accompanied sometimes by a reversible, sometimes irreversible, breaking of bonds. Kuhn[9] and others have suggested that many properties of rubber may be explained by postulating more than one type of slippage bonds, the different types being distinguished by different relaxation rate constants.

Now, if the time of test is made shorter than the relaxation time of the rapidly relaxing components they contribute more and more toward the total modulus. This is how we account for the increase in modulus as rate of elongation increases to 200 percent/msec. and greater. The increase in tensile with increasing speed implies that the slipping bonds also add to strength when not given time to slip.

The minima in tensile and maxima in elongation observed with crystallizing stocks now may be interpreted as the point of balance between decreasing importance of crystallization and increasing importance of slipping bonds that fail to slip as speed is increased. If the 90 percent drop in tensile of gum Hevea which is observed at Scott speed on heating from room temperature to 150° is a measure of the contribution of crystallinity, the formation of only about one-third of the total crystallinity is prevented by stretching at the lower ultra speeds.

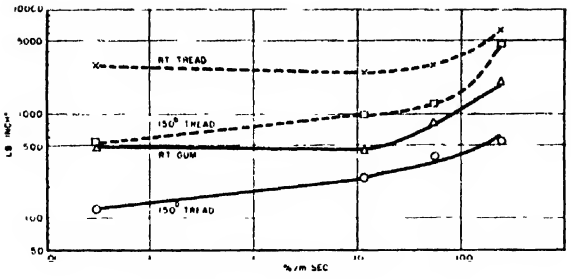

FIG. 10(a). Tensile—Perbunan, ADR, S.

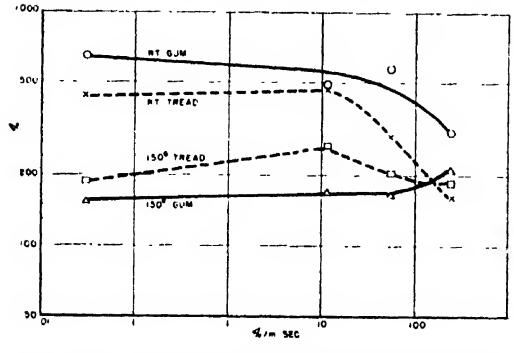

FIG. 10(b). Elongation at break—Perbunan, ADR, S.

On the slipping bond hypothesis the elongation rate at which the sharp rise occurs, 200 percent/msec., qualitatively gives the order of magnitude of the relaxation time as 0.5 msec. It is believed that many service processes may occur within times of this order of magnitude. For example, Markwick and Starks[10] report high frequency oscillations of 1400 cycles/sec. in tread rubber retracting from a dry road. As far as we know, no one has reported confirmation of this observation and it may possibly be a spurious mechanical effect. However, if an important part of the strength of a stock originates from rapidly relaxing elements, it is clear that a completely successful correlation between laboratory and service can never be expected until the time of test is reduced to that characteristic of the service condition.

Heat of Activation of Slippage

If the above hypothesis be true that the rise in modulus and tensile may be attributed to bonds, which ordinarily completely relax within the time of stretching, not having time to relax completely at the higher ultra speeds, then it would be reasonable to expect to find a particular curve to shift bodily to the side of higher elongation rate on going to higher temperature. For, if one used as abscissae the parameter, speed/relaxation rate (or speed×relaxation time), increase of temperature increases relaxation rate, so to find the same modulus one should look for it at a greater speed. A complete shift of the curve without change in shape is too much to expect, inasmuch as it could occur only in the unlikely event of only one relaxation type. With more than one type, the modulus contribution of each would be shifted by a different amount corresponding to its different change in relaxation rate. This would bring about a change in shape of the composite curve which is the sum of the individual components.

We have noted the above shift for the case of carbon black stocks. A heat of activation may therefore be roughly computed from the ratio of rates at 150° and at room temperature. A list of such values is given in Table IV.

It may be seen that the heat of activation is of the order of magnitude of 3 kg cal. This may be compared with 10.3 kg cal. heat of adsorption of benzene on graphite[11] (the nearest similar process to adsorption of rubber on carbon black on which there are published data), 10 kg cal. heat of activation of shear in raw rubber,[12] 15 kg cal. for shear in raw GR-S,[13] 15 kg cal. for transient relaxation in cured rubber, and 15 kg cal. for steady relaxation in cured rubber.[14] The considerably lower value of 3 kg cal. is in accord with a "slide-fastener" mechanism of slippage of rubber molecules along a carbon black surface proposed by the present author. In this mechanism the attached segments of rubber are supposed to slip with moderate resistance along the surface of the black from one end to the other

without pulling away free from it. When the rubber-black bond reaches the end of the "zipper" it is fairly permanently resistant to complete separation.

The failure to find a shift in the gum stock curves means, on the above hypothesis, that the heat of activation of slippage for the other types of slippage is very low; i.e., the relaxation rates involved have too low a temperature coefficient to be measurable within the accuracy of the experiment.

ACKNOWLEDGMENT

Appreciation is herewith expressed to the various members of the staff who have been consulted in the development of the machine; in particular to Drs. E. M. Grabbe, M. Mooney, and S. A. Black. Mr. R. B. Frost designed and supervised the original construction of the machine and Mr. T. J. Rhodes designed several of the later modifications. The experimental work of operating the machine was carried out by Mr. O. K. Laible.

Relations Concerning Wave Fronts and Reflectors

K. S. KELLEHER
Naval Research Laboratory, Washington, D. C.

(Received October 20, 1949)

By means of a vector notation for surfaces, relations are derived among an incident wave front, reflector and reflected wave front. A method is introduced for evaluating the deviation of a wave front surface from a plane. Problems are included in order to indicate the simplicity and utility of the analysis.

INTRODUCTION

IN working with microwave antennas, it is desirable to know the characteristics of their wave fronts. Some knowledge can be obtained by employing geometrical optics principles to trace a few selected rays. It is the intention of the present paper to consider the reflection of a normal congruence of rays, defined by a wave front surface.[1] The problem presented and solved is: Given any two of the three surfaces, incident wave front, reflector and reflected wave front, find the third.

THE REFLECTED WAVE FRONT

The incident wave front surface $X(u, v)$[2] and the reflector $R(s, t)$ are indicated in Fig. 1. The reflected wave front $Y(u, v)$ can be obtained by using the definition that all points of $Y(u, v)$ lie at equal ray path length from $X(u, v)$ together with the fact that rays are orthogonal to the wave front surfaces. From the figure, two values of the general reflected ray can be obtained and equated.

$$Y-R=(C-|R-X|)\xi, \tag{1}$$

where C is the total ray path length from X to Y; $|R-X|$ is the length of the incident ray; and ξ is a unit normal to the reflected wave front, Y.

The vector, ξ, is determined[3] from the fact that incident and reflected angles at the reflector surface are equal.

$$\xi=r-2\eta(\eta\cdot r) \tag{2}$$

where $r=(R-X)/|R-X|$ and η is the unit normal to the reflector at the point of incidence.

Placing (2) in (1) and reducing, there results

$$Y=C\xi+X+2\eta[\eta\cdot(R-X)]. \tag{3}$$

For most practical purposes, it is convenient to consider the reflected wave front surface at zero path length ($C=0$) from the incident wave front. This fictitious wave front is a parallel surface[4] to any actual reflected wave front and therefore can be used to define the reflected congruence of rays. Such a wave front could be subjected to further reflections in the same way that X was reflected from R.

Substituting $C=0$ in (3), the reflected wave front is

$$Y(u, v, s, t)=X(u, v)+2\eta(s, t)[\eta(s, t)\cdot\{R(s, t)-X(u, v)\}]. \tag{3a}$$

The parentheses are used to indicate the dependence of the functions on the various parameters involved. A relation between u, v and s, t is required in order that Y should be a function of only two parameters. This is obtained from the condition that the incident rays are normal to the incident wave front. Using tangent vectors to the surface, this condition is written

$$(R-X)\cdot X_u=0 \quad \text{and} \quad (R-X)\cdot X_v=0, \tag{4}$$

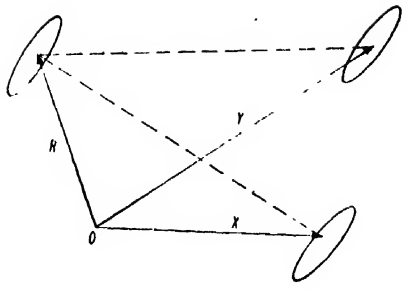

FIG. 1.

where the subscripts denote partial differentiation. From these expressions $s=s(u, v)$ and $t=t(u, v)$ can be obtained and when they are substituted in (3a) yield the desired reflected wave front surface $Y(u, v)$.

Since the incident and reflected wave fronts could be interchanged without altering the above treatment, there remains only the problem of determining the reflector which transforms a given incident wave front into a given reflected wave front.

THE REFLECTOR

In order to find this reflector, use (1) with the sign of the unit normal reversed, so that ξ points toward the reflector.

$$R=Y+(C-|R-X|)\xi. \tag{5}$$

As before, ξ is the normal to the wave front $Y(p, q)$, and $X=X(u, v)$ is the second wave front surface. In this expression, $|R-X|$ can be evaluated by subtracting X from both sides and taking the scalar product of each side with itself. The result reduces to

$$|R-X|=\frac{C^2+(Y-X)^2+2C(Y-X)\cdot\xi}{2[C+(Y-X)\cdot\xi]}.$$

Using this, (5) becomes

$$R(u, v, p, q)=Y+\xi\frac{[C^2-(Y-X)^2]}{2[C+(Y-X)\cdot\xi]}=Y+\xi G. \tag{5a}$$

R is obtained as a function of u and v alone through use of the condition that $(R-X)$ is normal to the surface X.

$$(R-X)\cdot X_u=0 \quad \text{and} \quad (R-X)\cdot X_v=0,$$

or

$$(Y-X+\xi G)\cdot X_u=0 \quad \text{and} \quad (Y-X+\xi G)\cdot X_v=0. \tag{6}$$

These two equations are solved for $p(u, v)$ and $q(u, v)$ which when substituted in (5a) gives R as a function of u and v alone.

DEVIATION FROM A PLANE WAVE

Given a wave front surface, it is normally desirable to know its deviation from a plane, since such knowledge gives an indication of the far field radiation pattern. Referring to Fig. 2, let the wave front be represented as $Y(u, v)$ and designate a unit normal to the plane as N. Introduce a constant vector Y_0 from the origin to a point of tangency of the plane with the surface. From the figure, it is evident that the deviation, Δ, is the projection of the vector $(Y-Y_0)$ on N. Analytically stated,

$$\Delta(u, v)=|Y-Y_0|\cos\beta=(Y-Y_0)\cdot N. \tag{7}$$

Therefore, for any point (u, v) of the surface, the deviation can be determined.

CONICAL WAVE FRONT AND PARABOLIC CYLINDER

A line source with linear phase distribution produces a conical wave front.[5] If the source is positioned along the

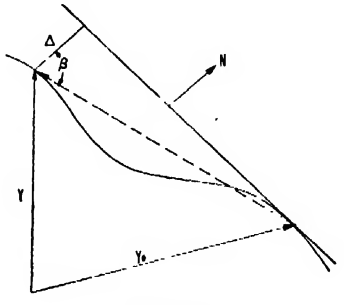

FIG. 2.

focal line of the reflector (Fig. 3), the incident wave front may be written

$$X=Fi+uj+vk$$

where

$$F=[(h-v)^2\tan^2\alpha-(u-f)^2]^{\frac{1}{2}}.$$

The reflector is

$$R=si+(s^2/4f)j+tk.$$

The normal to the surface R can be obtained from the vector product of two tangent vectors.

$$R_s\times R_t=[i+(s/2f)j]\times k.$$

The unit normal then is

$$\eta=[si-2fj][s^2+4f^2]^{-\frac{1}{2}}.$$

Upon substitution of these values in (3a), the reflected wave front becomes

$$Y=i\frac{[s(s^2+4uf)-(s^2-4f^2)F]}{s^2+4f^2}+j\frac{[s^2(u-2f)-4uf^2+4fsF]}{s^2+4f^2}+kv.$$

This expression for Y involves three parameters, so that a given point on the incident wave front $X(u, v)$ does not yield a single value of Y, but rather a value which depends on s. It is therefore necessary to find an auxiliary

[5] K. S. Kelleher, "Antenna Wavefront Problems," Naval Research Laboratory Report R-3530.

relation between s, u and v. This relation, obtained from the condition $(R-X)\cdot X_u=0$ is $(s^2-4f)F=4fs(u-f)$. Substituting this and reducing, Y becomes

$$Y=si+[(f-u)\sec\theta-f]j+vk$$

where

$$\sec\theta=(f+s^2/4f)/(f-s^2/4f).$$

From Fig. 4, the angle θ can be related to the cone angle α.

$$(f-u)\sec\theta=(h-v)\tan\alpha.$$

Thus the reflected wave front can also be written

$$Y=si-[(f-h\tan\alpha)+v\tan\alpha]j+vk.$$

This surface is a plane, intersecting the $x-y$ plane in the line $y=-(f-h\tan\alpha)$ and at an angle $\pi-\alpha$. (This can be verified by using (7) to show that the deviation of this Y surface from such a plane is zero.)

POINT SOURCE AND SPHERICAL REFLECTOR

When a point source is used to feed a spherical reflector, it is possible to obtain a nearly plane wave front characteristic by placing the feed near the half-radius point of the reflector.[6] The positioning of the feed as well as the deviation of the wave front from a plane can be found using (3a). Choose a spherical reflector with center at the origin. For convenience, normalize all points to the radius of the sphere. Then the reflector, unit normal and feed vectors may be written:

$$R=xi+(1-r^2)^{\frac{1}{2}}j+zk,$$
$$\eta=R,$$
$$X=jd,$$

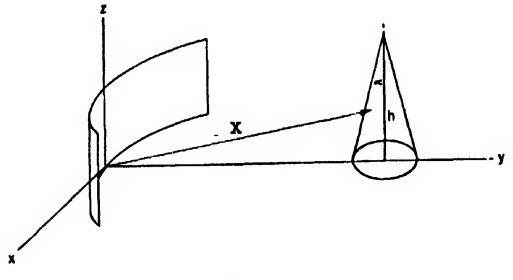

FIG. 3.

where

$$r^2=x^2+z^2.$$

The wave front, Y, is found by substituting these vectors in (3a)

$$Y=Dxi+[D(1-r^2)^{\frac{1}{2}}+d]j+Dzk,$$

where

$$D=2-2d(1-r^2)^{\frac{1}{2}}.$$

The deviation of this wave front from a plane is found by using (7) with $N=j$ and $Y_0=(2-d)j$

$$\Delta=2(1-r^2)^{\frac{1}{2}}+2(dr^2-1).$$

It is evident that $\Delta(0)=0$, but this deviation will also vanish at another value of r if d, the feed position, is properly chosen. Setting $\Delta=0$ and solving for d, there results,

$$d=[1-(1-r^2)^{\frac{1}{2}}]/r^2.$$

Therefore, given a value of r for which the deviation, Δ, should vanish, the required feed position, d, can be immediately determined.

Once the value of d has been established, it is possible to find the maximum value of $\Delta(r)$ in the usual manner. The result is

$$\Delta_{max}=2(d-0.5)^2/d$$

for a reflector of unit radius.

REFLECTORS WHICH YIELD VIRTUAL POINT SOURCE

Occasionally in microwave antenna design it is advisable to use a virtual point source feed.[7] A catalog of the reflectors which will produce a spherical wave front from a point source feed, can be obtained from Eq. (5a). From the analysis, the reflector desired is

$$R=Y+\frac{C^2-(Y-X)^2}{2[C+(Y-X)\cdot\xi]}\xi \qquad (5a)$$

where Y and X in this case are points. Let $X=0$ and $Y=ai$; the unit normal to the Y wave front is

$$\xi=(x-a)i+yj+zk$$

where

$$y=[1-z^2-(x-a)^2]^{\frac{1}{2}}.$$

Substituting these values, the reflector becomes

$$R=\frac{[(x-a)(C^2+a^2)+2aC]i+y(C^2-a^2)j+z(C^2-a^2)k}{2[C+a(x-a)]}.$$

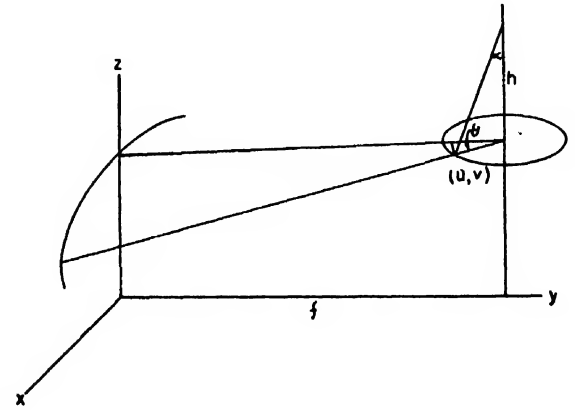

FIG. 4.

[6] J. Ashmead and A. B. Pippard, "The Use of Spherical Reflectors as Microwave Scanning Aerials," J. Inst. Elec. Eng. 93, 627 (1946).

[7] R. F. Rinehart, J. App. Phys. 19, 862 (1948).

In terms of components, r, s and t along the x, y and z axes,

$$R=ri+sj+tk.$$

It is possible to eliminate the parameters x, y and z and obtain

$$\frac{(r-a/2)^2}{C^2/4}+\frac{s^2+t^2}{(C^2-a^2)/4}=1.$$

From inspection of this equation, the following tabulation may be made:

For $C>|a|$, the reflector is an ellipsoid, unless $a=0$ in which case it is a sphere of radius $C/2$. For $C<|a|$, the reflector is a hyperboloid of revolution, unless $C=0$ in which case it is the plane, $x=a/2$. For $C=a$, the result is $r=0$ or $r=a$, and so has no practical meaning.

REFLECTOR WHICH WILL PRODUCE A PLANE WAVE

A less trivial application of (5a) is had when it is desired to find the reflector which will transform an arbitrary incident wave front $X(u, v)$ into a plane wave front $Y(p, q)$.

If the general wave front surface is given by $y=y(x, z)$, in vector notation it can be written

$$X=ui+F(u, v)j+vk.$$

Let the plane wave front be the $x-z$ plane so that

$$Y=pi+qk$$

and the unit normal to this wave front, $\xi=j$. When these values are substituted into (5a), there results

$$R=Y+G\xi=pi+Gj+qk. \tag{8}$$

Here

$$G=\frac{C^2-(Y-X)^2}{2[C+(Y-X)\cdot\xi]}=\frac{C^2-(p-u)^2-F^2-(q-v)^2}{2[C-F]} \tag{9}$$

where C is the constant path length from wave front X to wave front Y.

In order to obtain R as a function of only two parameters, use (6) which relates the four parameters u, v, p, q.

$$(R-X)\cdot X_u=(p-u)+(G-F)F_u=0,$$

and

$$(R-X)\cdot X_v=(q-v)+(G-F)F_v=0. \tag{10}$$

The substitution of values from (10) into (9) yields

$$2G(C-F)=C^2-F^2-(G-F)^2(F_u^2+F_v^2).$$

Subtract $2F(C-F)$ from both sides and the equation becomes a quadratic in $(G-F)$,

$$2(G-F)(C-F)=(C-F)^2-(G-F)^2(F_u^2+F_v^2)$$

which has the solution

$$G-F=(F-C)[1\pm(1+F_u^2+F_v^2)^{\frac{1}{2}}][F_u^2+F_v^2]^{-1}. \tag{11}$$

The ambiguity of sign can be resolved in a particular case.

Since $G=G(u, v)$ can be obtained from this equation, (10) and (11) yield $p=p(u, v)$ and $q=q(u, v)$. Therefore the reflector R in (8) is given as a function of u and v alone. In some simple problems, it is possible to eliminate the parameters u and v to obtain the reflector surface as $G=G(p, q)$.

As an example of the preceding analysis, let the wave front $X(u, v)$ be that produced by a source along the z axis whose phase variation is such as to yield the wave front surface $y^2=[(r^2-z^2)^{\frac{1}{2}}-a]^2-x^2$. In this case $y=F$, $x=u$, $z=v$.

In order to use (11), it is first determined that

$$y_x^2+y_z^2=(x^2+z^2T^2)/y^2$$

where

$$T^2=(x^2+y^2)/(r^2-z^2).$$

Then, from (11) one component of R is

$$G=y+\frac{y(y-C)[y\pm rT]}{x^2+z^2T^2}=y(1+D).$$

When this value is substituted into (10) the other two components of R become

$$p=x(1+D),$$
$$q=z(1+DT).$$

Points on the reflector surface are obtained by computing G, p, and q for appropriate values of x, y, z. If z is set equal to zero, the reflecting curve is one of two parabolas, due to the ambiguity of sign. The correct reflector corresponds to the negative sign of the radical in (11).

As a check of the method, it might be noted that setting $a=0$ yields a spherical wave front, such that $T=1$ and $D=(C-y)/(r+y)$. Upon elimination of y from the components of R, there results

$$p^2+q^2=-(C+r)[2G-(C+r)]$$

which is the expected paraboloid surface.

The Effect of an Obstacle in the Fresnel Field on the Distant Field of a Linear Radiator

G. A. WOONTON
Department of Physics, McGill University, Montreal, Quebec, Canada
(Received October 19, 1949)

At radio wave-lengths the use of mirrors and lenses in the measurement of radiators, by methods which are customary in physical optics, is possible only if errors, due to incidental diffraction from the relatively small apertures of such apparatus, can be corrected by calculation. Theory is developed in this paper from which these calculations can be derived for linear radiators. A new relation which expresses the Fresnel field in terms of the distant field is fundamental to the method. Satisfactory agreement has been obtained between the predicted and measured distant fields of several electromagnetic horns whose near fields were obstructed; the dispersion between measured and predicted values is given as under one-half decibel but the details of the experiment are not reported.

INTRODUCTION

At radio wave-lengths, the information from optical measurements often is obscured by incidental diffraction from the apertures of the component lenses, mirrors, and slits of the optical system. Incidental diffraction, although present in optical systems for visible light, can usually be neglected, but in the radio case, even for the shortest microwaves, the ratio of aperture dimension to wave-lengths is such that these effects, always, must be considered; practical limitations on physical dimensions and weight make it impossible to scale radio-optical devices in proportion to wave-length so that the ratio of aperture diameter to wave-length in the radio case is different by a factor of at least 10^{-5} from the ratio used in apparatus for measurements with visible light. It is for this reason that the application of optical techniques to radio measurements depends on the ability of the experimenter to calculate instrument errors and to use the calculations to plan the location of apertures so as to minimize the disturbance that they cause.

A problem of this nature, which is fundamental to many radio measurements, can be stated in specific terms; the radiation field from a linear radiator, for example a sectoral electromagnetic horn, is obstructed by a second aperture placed a short distance in front of it and at an arbitrary angle to its normal;[1] find the distant field produced by the combination. The analysis which follows is a general solution of this problem, and is capable of quantitative application to particular systems.

OPTICAL THEORY

An experimental investigation reported by Woonton, Hay, and Vogan[2] has shown that Kirchhoff's scalar formulation of Huygen's principle[3] is adequate to describe the distant diffraction field of a rectangular aperture whose dimensions are as small as 10 wave-lengths to a side and to describe the near field of the same aperture at a distance no greater than 10 or 20 wave-lengths from its opening. In the same investigation it was verified, also, that as in the optics of visible light, the complete fields can be calculated as the product of two independent, one-dimensional fields due separately to the electric distribution along the X axis of the aperture and along the Y axis. For these reasons, the solution which follows is based on the Kirchhoff formula and assumptions, and expresses the fields in terms of one coordinate only.

A system of Cartesian coordinates is chosen so that the origin lies at the intersection of the diagonals of a plane, rectangular, radiating aperture which will be called S_1; for first consideration S_1 is not rotated and lies wholly in the XY plane. The distribution of electric intensity along its X axis is given in both phase and amplitude by $F_1(x)$. At a distant point in the XZ plane, $P_1(R_1\theta_1)$ (where R_1 is the radius vector from the origin to P_1 and θ_1 is the angle between R_1 and the Z axis), the distant field (subject to the usual approximations, which include the requirements that θ_1 is not too great) is:

$$\varphi_1\left(R_1, \frac{\sin\theta_1}{\lambda}\right) = Re\frac{(\cos\theta_1+1)}{R_1}\exp(j[\omega t - kR_1])$$

$$\times Y\left(\frac{j}{2\lambda}\right)^{\frac{1}{2}}\int_{-\infty}^{\infty} F_1(x)\exp(-j2\pi x\gamma_1)dx, \quad (1)$$

in which λ = wave-length of the radiation, $k=2\pi/\lambda$, ω = angular velocity of the field, $j=(-1)^{\frac{1}{2}}$, Y = a factor which remains constant as long as P is confined to the XZ plane and which is an integral of the same form as that which appears in (1) but is related to aperture distribution in the Y direction, $\gamma_1=-(\sin\theta_1)/\lambda$.

Equation (1) represents a circular wave, expanding from the origin, whose front at radius R_1, in the XZ plane, is modified in phase and amplitude by the integral factor:

$$G_2(\gamma_1)=\int_{-\infty}^{\infty} F_1(x)\exp(-j2\pi x\gamma_1)dx. \quad (2)$$

[1] Woonton, Borts, and Carruthers, J. App. Phys. **21**, 428 (1950).

[3] J. S. Slater and N. H. Frank, *Electromagnetism* (McGraw-Hill Book Company, Inc., New York, 1947), p. 167.

(The use of the negative sign in the definition will be clear later.)

The distribution $F_1(x)$ produces a Fresnel distribution of electric intensity in front of the radiator, as well as the field at a great distance. At $z=b$ define an auxiliary set of (ξ, η) coordinates in which the ξ- and η-axes are parallel to those of X and Y and take the new origin at $(0, 0, b)$. The distribution produced along the ξ-axis by $F_1(x)$ is $F_2(b, \xi)$, which for convenience will be described as $F_2(\xi)$. At a distant point $P_2(R_2\theta_2)$ (where R_2 is the radius vector from $z=b$ to P_2, and θ_2 is measured at $(0, 0, b)$ the distribution $F_2(\xi)$ may be thought of as producing the field instead of $F_1(x)$. This field is given by:

$$\varphi_2\left(b, R_2, \frac{\sin\theta_2}{\lambda}\right) = Re\frac{(\cos\theta_2+1)}{R_2}\exp(j[\omega t - kR_2])$$

$$\times Y''\left(\frac{j}{2\lambda}\right)^{\frac{1}{2}}\int_{-\infty}^{\infty} F_2(\xi)\exp(-j2\pi\xi\gamma_2)d\xi \quad (3)$$

where

$$\gamma_2 = -(\sin\theta_2)/\lambda.$$

Equation (3) describes a circular wave expanding from $(0, 0, b)$ whose front at radius R_2 (measured from $z=b$) is modified in amplitude and phase by the integral factor

$$G_2(\gamma_2) = \int_{-\infty}^{\infty} F_2(\xi)\exp(-j2\pi\xi\gamma_2)d\xi. \quad (4)$$

The relation between the integral factors (2) and (4) which appear in Eqs. (1) and (3) can be found by comparison of (1) and (3) after (1) has been modified to express the field along the circular wave front marked out by P_2 as θ_2 varies. Let $R_1=(R_2+b)$ so that Eqs. (1) and (3) express the same field at $\theta_1=\theta_2=0$. Choose R_1 and R_2 both very large compared to b, so that in the amplitude factors of the two equations R_1 can be interchanged with R_2 and so that a single angle θ can be used to represent the θ-coordinate of corresponding points on the two circular wave fronts instead of separate angles θ_1 and θ_2. Because Eqs. (1) and (3) both express distant fields, one can reason that at any angle θ the two equations differ only in phase and this difference can be traced to two causes: the translation of the origin directly and the separation of the perimeters of the two circles which the translation of the origin causes. The first phase difference is constant and can be written by substitution:

$$\exp(-jkR_1) = \exp(-jk[R_2+b]) = \exp(-jkR_2)\exp(-jkb). \quad (5)$$

The second phase difference arises because Eq. (1) describes the field along a circle of radius (R_2+b) with center at the origin while Eq. (3) describes the field along a circle of radius R_2 with center at $(0, 0, b)$. At any angle, θ, the perimeters of the two circles are separated by a distance, δ, which can be written to an approximation that improves with the magnitude of R_1 and R_2 as:

$$\delta \doteqdot b(1-\cos\theta) \doteqdot b(\sin^2\theta)/2. \quad (6)$$

Equation (1) will describe the field along the circle marked out by R_2 only if its phase is corrected by the constant factor (5) and advanced by a variable factor proportional to the distance, δ, namely:

$$\exp(jkb\sin^2\theta/2) = \exp(j\pi b\lambda[\sin\theta/\lambda]^2). \quad (7)$$

Equate the modified Eq. (1) to Eq. (3) and cancel the common factors:

$$Y\exp(-jkb)\exp\left(j\pi b\lambda\left[\frac{\sin\theta}{\lambda}\right]^2\right) \times \int_{-\infty}^{\infty} F_1(x)\exp(-j2\pi x\gamma)dx = Y'\int_{-\infty}^{\infty} F_2(\xi)\exp(-j2\pi\xi\gamma)d\xi. \quad (8)$$

Define

$$G_3(\gamma) = \exp\left(j\pi b\lambda\left[\frac{(\sin\theta)}{\lambda}\right]^2\right);$$

then in the abbreviated notation:

$$Y\exp(-jkb)G_3(\gamma)G_1(\gamma) = Y'G_2(\gamma). \quad (9)$$

Because relative, rather than absolute amplitudes and phases are important in experimental work, in the discussion of the next section the constant factors in Eq. (9) will be dropped, for convenience, and the relation taken to be:

$$G_3(\gamma)G_1(\gamma) = G_2(\gamma). \quad (9a)$$

Figure 1 illustrates the relations between the aperture field, the Fresnel field, and the distant fields.

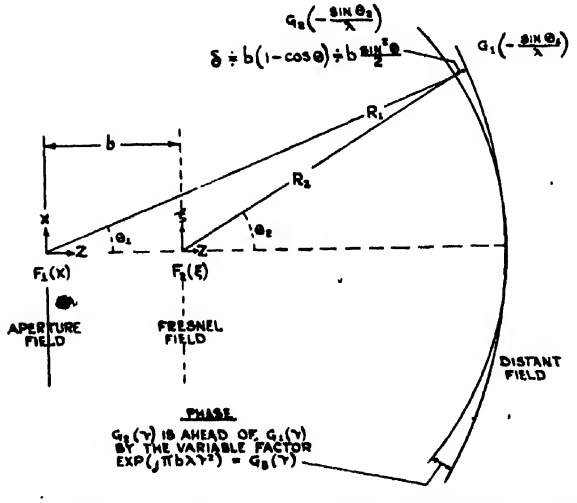

FIG. 1. Relations between the aperture field, Fresnel field and the distant field.

FOURIER TRANSFORM THEORY AND THE SOLUTION

For convenience in using tables[4] and to agree with Ramsay,[5] the definition has been made:

$$\gamma = -(\sin\theta)/\lambda$$

so that Eq. (2) has been written

$$G_1(\gamma) = \int_{-\infty}^{\infty} F_1(x) \exp(-j2\pi\gamma x)dx.$$

Michelson[6] in the field of optics of visible light and Spencer[7,8] and Ramsay[5] in connection with radiators have discussed the reciprocal relation of the Fourier transform pair that holds between an intensity distribution and the diffraction, or antenna pattern that it causes. These authors justify the use of the process inverse to that described in (2):

$$F_1(x) = \int_{-\infty}^{\infty} G_1(\gamma) \exp(j2\pi\gamma x)d\gamma. \tag{2a}$$

To abbreviate the analysis, transformation symbols are now introduced as has been done in the work of the writers,[5,7,8] who have been mentioned. Equations (2) and (2a) are written:

$$F_1(x) \leftrightarrow G_1(\gamma), \tag{10}$$

and in the same way:

$$F_2(\xi) \leftrightarrow G_2(\gamma), \tag{11}$$

$$F_3(\xi) \leftrightarrow G_3(\gamma) = \exp(j\pi b\lambda\gamma^2). \tag{12}$$

Since $G_2(\gamma) = G_1(\gamma)G_3(\gamma)$ it appears that on making use of the convolution theorem:

$$F_2(\xi) = \int_{-\infty}^{\infty} F_1(t)F_3(\xi - t)dt \leftrightarrow G_1(\gamma) \times G_3(\gamma). \tag{13}$$

$F_2(\xi)$ is the variable factor in the expression for the Fresnel field at $z = b$; Eq. (13) can be put into explicit form by first finding the transform of $F_3(\xi - t)$ from that of $F_3(\xi)$:

$$F_3(\xi - t) \leftrightarrow \exp(-j2\pi\gamma t)G_3(\gamma) = \exp(-j2\pi\gamma t) \exp(j\pi b\lambda\gamma^2) \tag{14}$$

and, by then writing out the integral implied by the transformation symbol:

$$F_3(\xi - t) = \int_{-\infty}^{\infty} \exp(j\pi b\lambda\beta^2) \times \exp(-j2\pi\beta t) \exp(j2\pi\beta\xi)d\beta \tag{15}$$

where the dummy label, β, has been introduced in place of, γ, to avoid confusion. Substitute (15) in (13):

$$F_2(\xi) = \int_{-\infty}^{\infty} F_1(t) \int_{-\infty}^{\infty} \exp(j\pi b\lambda\beta^2) \times \exp(-j2\pi\beta t) \exp(j2\pi\beta\xi)d\beta dt. \tag{16}$$

Equation (13) expresses the Fresnel field as a Fourier transform of the distant field and Eq. (16) expresses the Fresnel field in terms of the aperture field. Equation (9) and the reasoning that leads to it can be verified by evaluating the inner integral of Eq. (16) which then becomes:

$$F_2(\xi) = \left(\frac{j}{b\lambda}\right)^{\frac{1}{2}} \int_{-\infty}^{\infty} F_1(t) \exp\left(-j\frac{\pi}{b\lambda}[\xi - t]^2\right)dt. \tag{16a}$$

Equation (16a) will be recognized as the variable part of the Fresnel field expressed in the conventional manner by a Fresnel's integral and, in fact, (16a) can be made to agree completely with the conventional expression if the constant factors, which were dropped between Eqs. (9) and (9a), are reintroduced.

Up to this point there has been no suggestion of an obstruction in front of the aperture. Let a large screen be erected in the (ξ, η) plane at a distance, b, in front of S_1 and cut in it a rectangular opening, S_2, which extends along the ξ-axis from $-c/2$ to $+c/2$. Follow Kirchhoff in the assumption that in the opening S_2, $F_2(\xi)$ has its uninterrupted value, and that the intensity on the front surface of S_2 is zero everywhere else. $F_2(\xi)$ then must be given the mutilated form expressed by:

$$\begin{aligned} &F_2(\xi) = 0, && c/2 \leq |\xi| \leq \infty, \\ &F_2(\xi) \text{ is unchanged}, && -c/2 \leq \xi \leq c/2. \end{aligned} \tag{17}$$

The distant pattern will be modified from $G_2(\gamma)$ to a new function $G_{2m}(\gamma)$ by the mutilation of $F_2(\xi)$ which is caused by the screen. This can be written as the transform of $F_2(\xi)$ when expressed as in Eq. (16).

$$G_{2m}(\gamma) = \int_{-c/2}^{c/2} F_2(\xi) \exp(-j2\pi\xi\gamma)d\xi. \tag{18}$$

Reverse the order of integration so as to integrate first with respect to ξ, then with respect to t.

$G_{2m}(\gamma)$ is then found to be given by:

$$G_{2m}(\gamma) = c\int_{-\infty}^{\infty} G_1(\beta) \frac{\sin[\pi c(\beta - \gamma)]}{\pi c(\beta - \gamma)} \times \exp(j\pi b\lambda\beta^2)d\beta. \tag{19}$$

To convert $G_{2m}(\gamma)$ to $G_{1m}(\gamma)$, which is expressed as a wave diverging from S_1 (the original aperture), divide

[8] R. C. Spencer, Radiation Lab. Report 762-2 (March, 1946).

by $G_3(\gamma)$ as indicated by Eq. (9a):

$$G_{1m}(\gamma)=c\int_{-\infty}^{\infty}G_1(\beta)\frac{\sin[\pi c(\beta-\gamma)]}{\pi c(\beta-\gamma)}\times\exp(j\pi b\lambda[\beta^2-\gamma^2])d\beta. \quad (20)$$

Equation (20) when substituted in Eq. (1) gives the distant field of S_1 as modified by S_2 at $z=b$ when S_1 is not rotated and lies in the XY plane; the solution is in terms of the unmutilated pattern $G_1(\beta)$, the width, c, of S_2, the distance, b, between the two screens, and the wave-length, λ, of the radiation.

The effect of rotating S_1 out of the XY plane by an angle, α, measured between the normal to S_1 and the Z axis can be found as follows: If α is not too great, and b not too small, the effect of rotation is to introduce a linear phase shift into the original $F_1(x)$ distribution. This is expressed by:

$$F_{1\alpha}(x)=F_1(x)\exp[-j2\pi x(\sin\alpha)/\lambda] \quad (21)$$

which leads to the transformation:

$$F_1(x)\exp[-j2\pi x(\sin\alpha)/\lambda]\leftrightarrow G_1[\beta+(\sin\alpha)/\lambda]. \quad (22)$$

On substituting $G_1[\beta+(\sin\alpha)/\lambda]$ for $G_1(\beta)$ in Eq. (20) the complete solution of the problem is obtained:

$$G_{1\alpha m}(\gamma)=c\int_{-\infty}^{\infty}G_1\left[\beta+\frac{(\sin\alpha)}{\lambda}\right]\times\frac{\sin[\pi c(\beta-\gamma)]}{\pi c(\beta-\gamma)}\exp(j\pi b\lambda[\beta^2-\gamma^2])d\beta. \quad (23)$$

Equation (23) can be verified by reducing it to known forms. Put $\alpha=0$ and $b=0$ so that the second aperture S_2 lies on S_1 and limits $F_1(x)$ to the range $|x|\leq c/2$. Equation (23) becomes:

$$G_{1\alpha m}(\gamma)=c\int_{-\infty}^{\infty}G_1(\beta)\frac{\sin[\pi c(\beta-\gamma)]}{\pi c(\beta-\gamma)}d\beta, \quad (24)$$

which is a result obtained by Ramsay.[9]

If in Eq. (23) $c\to\infty$, then the screen S_2 no longer obstructs the near field. Since:

$$Lt_{c\to\infty}\frac{\sin[\pi c(\beta-\gamma)]}{\pi c(\beta-\gamma)}\frac{1}{c}=S_0(\beta-\gamma), \quad (25)$$

where $S_0(\beta-\gamma)$ is a unit impulse at $\beta=\gamma$, Eq. (23) reduces to the unmutilated distant field, $G_1[\beta+(\sin\alpha)/\lambda]$, when S_2 is removed from the near field.

[9] J. F. Ramsay, Marconi Rev. X, 90 (1947).

EXPERIMENTAL METHODS AND RESULTS

The amplitude of the electric field, in the aperture of an electromagnetic horn, in the E-plane, can be expressed to a good approximation by:

$$F_1(x)=F_A\exp[-j(\pi x^2/\lambda l)]$$

where

$$F_A=0 \text{ if } (a/2)<|x|, \qquad F_A=A \text{ if } |x|<a/2 \quad (26)$$

in which l = distance from the vertex to the aperture plane of the horn, a = width of the horn aperture in the E-plane. The E-plane aperture distribution function, for an electromagnetic horn, which may be rotated out of the XY plane as in Eq. (21) is therefore:

$$F_1(x)=F_A\exp\left(-j\left[\frac{\pi x^2}{\lambda l}+\frac{2\pi x\sin\alpha}{\lambda}\right]\right) \quad (27)$$

with F_A restricted as in (26).

Elliot and Rigby* have shown that on substitution of Eq. (27) in Eq. (18) it is possible to integrate Eq. (18) twice, then expand the resulting integral into an asymptotic series. They have estimated that when the constants of the expansion have the values $c=110$ cm, $b=100$ cm, $a=32$ cm, $\lambda=3.2$ cm, the first two terms of the series give the relative amplitudes of $G_{2\alpha m}(\gamma)$ to a precision of not worse than 1 db in the angular interval $-20°\leq\alpha\leq 20°$.

The E-plane amplitudes of $G_{2\alpha m}(\gamma)$ have been calculated at $\alpha=0$, 5, 10, 15, and 20 degrees for two horns, radiating 3.2-cm waves, through a mutilating aperture, 110 cm wide in the E-plane by 22 cm high in the H-plane, placed 100 cm in front of the horn aperture. The aperture of both horns was taken to be square, 32 cm to the side, and the lengths of the horns were taken as 100 and 50 cm, respectively. Patterns measured at a wave-length of 3.2 cm both with and without the mutilating aperture, for two horns of these dimensions are reported in Figs. 4 and 5 of a companion paper.[1] Comparison of the measured and calculated points, between $\pm 20°$ indicate that the probable error in the calculation, for the horn of length 100 cm is ± 0.25 db, and for the 50-cm horn, is ± 0.34 db.

ACKNOWLEDGMENT

The experimental work associated with this research was made possible by a grant for equipment from the Defence Research Board of the Department of National Defence, Ottawa, Canada. The writer wishes to thank Dr. H. A. Elliot and Miss E. C. Rigby, both of McGill University, for permission to refer to their unpublished expansion of Eq. (18).

Second-Order Transition Temperatures and Related Properties of Polystyrene. I. Influence of Molecular Weight*

THOMAS G. FOX, JR., AND PAUL J. FLORY
Department of Chemistry, Cornell University, Ithaca, New York
(Received November 17, 1949)

Dilatometric and viscometric data on fractionated polystyrenes containing diethylbenzene end groups are presented over wide temperature ranges. The second-order transition temperature, viscosity-temperature coefficient, and specific volume all change rapidly with increasing molecular weight toward asymptotic limits which are practically reached at $M \simeq 30{,}000$. Empirical expressions are presented relating these properties to molecular weight and temperature. In each case the dependence on molecular weight is expressed as a simple function of $\bar{M}_n^{-1}$. These observations are interpreted and correlated on the basis of the hypothesis that the local configurational order in a liquid polymer is disturbed by the introduction of end groups to a degree that is proportional to their number. The second-order transition does not represent an isoviscous state. The internal local configurational structure appears to be equivalent, and independent of temperature, in all polystyrenes below their second-order transition temperatures.

INTRODUCTION

A LIQUID which may be cooled without incidence of crystallization solidifies to a glass over a fairly narrow temperature range which is characteristic of the substance.[1,2] This is true not only of hydrocarbons, polar and hydrogen-bonding liquids, inorganic glasses, etc., but also of amorphous polymers (including semi-crystalline, or semi-amorphous polymers) regardless of their composition or structural pattern (i.e., non-linear network polymers as well as linear ones). The temperature about which this transformation takes place is usually referred to as the "glass" temperature T_g, or the "second-order transition temperature"; for polymers it is often designated as the "brittle temperature," inasmuch as the polymer changes from a highly viscous liquid, or rubbery solid, to a brittle substance which will not tolerate appreciable deformation without fracture at all lower temperatures.

It is well established that this so-called "second-order transition" is not an equilibrium transition in the thermodynamic sense, but that it originates from kinetic limitations on the rates of the internal adjustments occasioned by changes in temperature (or by mechanical stress). At temperatures below T_g, the internal mobility is insufficient for maintenance of the equilibrium internal configuration and, hence, of the equilibrium volume. No discontinuity is observed in the first-order properties, volume and internal energy, but the second-order properties, thermal expansion coefficient and heat capacity, exhibit abrupt changes by means of which the "transition" is easily located.

The macroscopic viscosity often is employed as an inverse measure of internal mobility in monomeric substances, and it has been pointed out that the second-order transition generally occurs at a viscosity of about 10^{12} poises. The macroscopic viscosity of a polymer, however, depends not only on the mobility of each segment but also on an intersegment cooperation factor which increases rapidly with molecular weight.[3,4] If the second-order transition in polymers depends only on the local segment mobility and not on the interactions between all of the segments of a given molecule, then the magnitude of the macroscopic viscosity should not afford a universal measure of the approach to the second order transition; viscosities well above 10^{12} poises at T_g should be expected if the molecular weight is large. On the basis of the same postulate, the second-order transition might be expected to be independent of the molecular weight of the polymer except insofar as it affects the liquid configuration of the polymer.

Considerations such as these point to the desirability of securing reliable information on the dependence of the volume (as an index of liquid configuration) and of the viscosity of polymers on their molecular weights and temperatures, and on the dependence of T_g on molecular weight. Asymptotic increases of T_g's for polystyrenes,[5] polyisobutylenes,[6] and poly-(ethylacrylates)[7] with their "molecular weights" have been indicated by previous work on polymers of unknown degrees of heterogeneity. In a recent paper we have reported a qualitatively similar asymptotic increase in the viscosity-temperature coefficient with the molecular weights M of polystyrene fractions.[4] The rapid increase of both T_g and the viscosity-temperature coefficient toward their limiting values with increase in M contrasts sharply with the sustained increase in viscosity with increasing M even to the highest values investigated.[4]

TABLE I. The polystyrenes used for fractionation.

Polymer	Molar ratio styrene/diethylbenzene	Reaction temperature	Reaction time, hours	Extent of reaction (percent)	$\bar{M}_v$	Initial conc. for fractionation g/100 ml
A	1	150°	2	27	120,000	2.0
B	0.093	150°	9	72	9560	2.0
C	0.051	150°	17	90	4870	1.5

In the present investigation the specific volumes of polystyrene fractions have been investigated as functions of temperature and molecular weight. Second-order transition temperatures have been secured in the customary fashion from the discontinuity in the thermal expansion coefficient. The results have been correlated with the viscosity-temperature coefficient and its observed dependence on M. Polystyrene has been chosen as a model non-polar polymer for this investigation on account of the convenient location of its second-order transition temperature, the simplicity of its structure, and the comparative abundance of information concerning its various properties.

EXPERIMENTAL

Preparation and Fractionation

Three polymers of styrene of varying molecular weights (Table I) were prepared by thermal polymerization in diethylbenzene *in the absence of added catalyst.* The concentrations of styrene employed and other details pertinent to these polymerizations are summarized in Table I. The polymers were separated by precipitation in an excess of vigorously stirred methanol and were dried in vacuum at 60°.

These polymers were fractionated by the single precipitation technique described in a previous paper.[4] The initial concentrations of the solutions employed are shown in the last column of Table I. Each of the two polymers of lower molecular weight was separated into nine fractions by fractionating from acetone solution at 30° using as the precipitant a mixture consisting of equal volumes of water and methanol. Each individual fraction employed here represented from 5 to 17 percent of the whole polymer (Table II). The polystyrene of higher molecular weight (120,000) was separated into three fractions employing methyl ethyl ketone-methyl alcohol as the solvent-precipitant combination. Only the middle fraction, $M=85{,}000$, representing 38 percent of the whole polymer was retained for subsequent experiments.

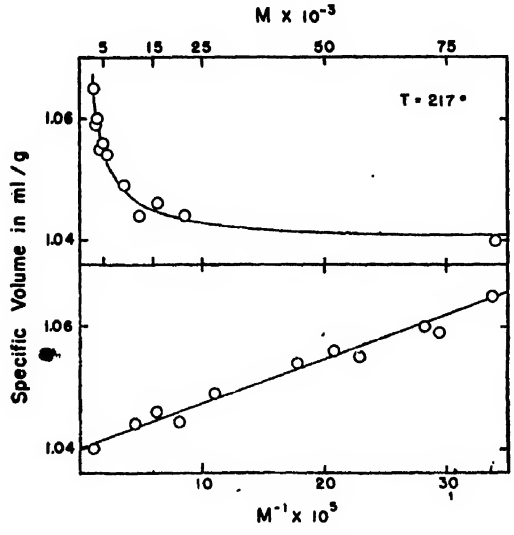

FIG. 1. Specific volume at 217° for polystyrene fractions *vs.* molecular weight (upper curve) and *vs.* M^{-1} (lower curve).

Molecular Weight Determination

Molecular weights of the polystyrene fractions have been calculated from their intrinsic viscosities, $[\eta]$, in freshly distilled benzene, using the relationship of Ewart[8]

$$\log\bar{M}_v=(\log[\eta]+4.013)/0.74,$$

where $\bar{M}_v$ is the viscosity average molecular weight. The solution viscosities were measured at 30.00±0.01° using a Ubbelohde No. 1 viscometer the calibration of which included the kinetic energy term.[9] In each case the intrinsic viscosity has been calculated from the relative viscosity, η_r, of a single solution by means of the viscosity-concentration relationship reported by Tingey.[10]

$$\ln\eta_r/c=[\eta]-0.125[\eta]^2c,$$

where c is expressed in g/100 ml.

Molecular weights determined in this way are generally reproducible to ±2 percent.

Determination of Specific Volumes

The pycnometers and the technique employed were similar to those described in a previous publication.[3] Densities were determined at 217° by filling a weighed pipette of known volume (from 1 to 2 ml) with the liquid polymer at this temperature, and subsequently weighing at room temperature. The reproducibility of the data was generally within ±0.1 percent.

Dilatometric Measurements

The dilatometers and techniques employed resemble those described by Bekkedahl.[11] A weighed quantity (generally about two grams) of bubble-free polymer, previously dried under vacuum at 217°, was placed in the bulb of a glass dilatometer and the bulb was sealed, with precautions to avoid heating the polymer. Mercury was introduced under vacuum (0.005 mm Hg).

The amount of mercury in the dilatometer was determined by weighing. The volume of polymer plus mercury was calculated at the calibration temperature, 217°, where the density of the polymer was known from the absolute specific volume measurements. The position of the mercury in the capillary tube was noted at 217° and then at lower temperatures usually at intervals of 10°. The measurements were made in a constant temperature bath regulated within ±0.1° and the relative densities generally were accurate to ±0.03 percent. At all temperatures except those in the vicinity of T_g, volume equilibrium was quickly established and in trial experiments no further change could be observed over a period of 24 hr. Hence before recording the volume the sample was held for a period of 10 to 60 min. at each temperature 10° or more above T_g and from 6 to 12 hr. at all lower temperatures.

Melt Viscosities

Melt viscosities in the range of 10 to 10^6 poises were determined by observing the rate of flow into uniform bore capillary viscometers under a measured pressure differential. The calibration and use of these viscometers have been described.[4] For measurement of viscosities from 0.1 to 10 poises, pipette type viscometers were employed. These consisted in each case of a Pyrex capillary tube of 1-mm bore with a small bulb (capacity 0.2 to 1.0 ml) about 12 to 15 cm from the lower end of the capillary. Absolute viscosities in poises were calculated in this case from $\eta = klp$, where t is the measured time required to fill the viscometer bulb under a predetermined pressure differential p, and k is a constant determined from the tp product for an oil the viscosity of which was accurately determined with the capillary viscometers mentioned above. Temperature control was provided by means of vapor baths (±0.3°) above 100° and by thermostated oil baths (±0.1°) at lower temperatures. The viscosity values usually were reproducible to ±3 percent.

High Temperature Stability

It was reported previously[4] that phenyl β-naphthylamine greatly retards the degradation of polystyrene at high temperatures, and that 0.5 percent of this substance assures adequate stability to permit measurement of viscosities up to 217°. The experiments on which this conclusion was based were conducted on polymers of high molecular weight, the assumption being made that the lower polymers would be at least

[a] Interpolated.

as stable. Subsequent experiments revealed, however, that phenyl β-naphthylamine fails to inhibit degradative reactions in the lower polystyrenes included in the previous investigation. These low polymers were prepared with the aid of benzoyl peroxide initiation, and a connection between the observed instability and the presence of benzoate end groups in the polystyrene molecules[12] was indicated by the sublimation of a quantity of pure benzoic acid when these polymers were heated at 217° under reduced pressure. The low molecular weight polystyrenes prepared as described above *without the use of catalyst* (Table I) were relatively stable. When heated for an hour at 217° in an inert atmosphere (pure nitrogen) they discolored only slightly and exhibited no change in intrinsic viscosity even in the absence of inhibitor.

RESULTS

Specific Volumes at 217° *vs.* Molecular Weight for Polystyrene Fractions

The specific volumes of eleven polystyrene fractions ranging in molecular weight from 2970 to 85,000 were determined at 217° by the constant volume pipette method. The specific volume at 217°, v_{217}, decreases with increasing molecular weight in the lower range and is relatively constant for molecular weights above 25,000 (upper curve of Fig. 1). When the specific volume is plotted against $1/M$ as in the lower portion of Fig. 1, the data are well represented by the straight line, the equation of which is

$$v_{217}=1.040+72/M. \qquad (1)$$

The units employed for the specific volume throughout this paper are ml/g.

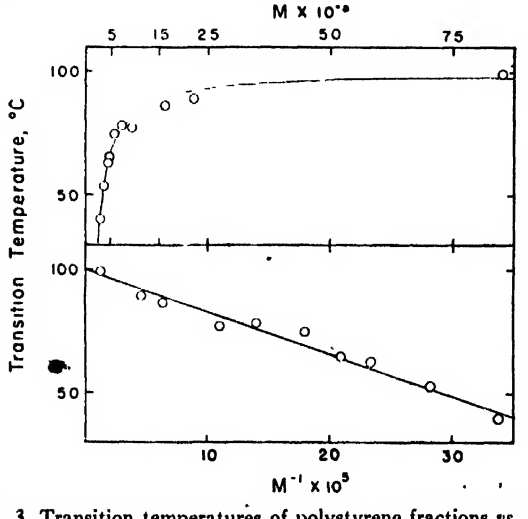

FIG. 3. Transition temperatures of polystyrene fractions *vs.* molecular weight (upper curve) and *vs.* M^{-1} (lower curve).

[12] P. D. Bartlett and S. G. Cohen, J. Am. Chem. Soc. 65, 543 (1943).

Dilatometric Data on Polystyrene Fractions

Specific volumes were measured by the dilatometric method as a function of temperature on ten polystyrene fractions ranging from 2970 to 85,000 in molecular weight. As illustrated in Fig. 2, the volume-temperature curve up to 160° for each polymer may be represented by two intersecting straight lines. The temperature at which these lines intersect is taken as the second-order transition temperature, T_g. In the vicinity of 160°, the volume-temperature coefficient (i.e., the slope) exhibits a further increase with increasing temperature. The results in this range may again be approximated, for simplicity, by two intersecting straight lines, the temperature at the intersection being about 160°. Hence, each polymer may be characterized by five quantities: T_g, the volume v_g at T_g, and three volume-temperature coefficients, $(dv/dT)_1$ above 160°, $(dv/dT)_2$ between 160° and T_g, and $(dv/dT)_3$ below T_g. The values of these parameters, as obtained from a series of experiments, details for which are not included here, are presented in Table II.

The transition temperature T_g becomes almost independent of molecular weight above 25,000 but decreases rapidly with decreasing molecular weight below this value (upper curve of Fig. 3). In analogy with the dependence of specific volume on M^{-1}, T_g is likewise a linear function of M^{-1}, as is shown in the lower curve of Fig. 3. The equation of the straight line is

$$T_g=100-1.7\times10^5/M \qquad (2)$$

from which the upper curve of Fig. 3 has been calculated.

Although at T_g the abrupt change in slope and the accompanying increase in the time needed for equilibration justify the use of a function with a discontinuity in its slope at this temperature, the use of two straight lines intersecting at 160° to represent the data above T_g is arbitrary. The change of slope at 160° is much smaller than that observed at T_g, and a line with curvature over a wide range about 160° would represent the data equally well.

The specific volume-temperature coefficients $(dv/dT)_2$ and $(dv/dT)_3$ (Table II) appear to be independent of molecular weight within the admittedly large experimental error involved in their evaluation over limited temperature ranges. Average values are 5.5 and 2.5 $\times 10^{-4}$, respectively. The value of $(dv/dT)_1$ is about 7×10^{-4} with an indication of an increase at very low molecular weight.

The portion of the volume-temperature curve between T_g and 160° may be represented by the equation

$$v = A + 5.5\times 10^{-4}T + 53/M, \quad 160 \geq T \geq T_g, \qquad (3)$$

where A is a constant equal to 0.913 and T is in degrees centigrade. Combining this with Eq. (2), we obtain

$$v_g = 0.943 + 2.4\times 10^{-4}T_g. \qquad (4)$$

Values of v_g calculated by this equation agree within experimental error with the observed values, as shown in Table II. In view of the non-dependence of $(dv/dT)_3$ on molecular weight, the specific volume below T_g is given by

$$v = v_g - 2.5\times 10^{-4}(T_g - T), \quad T \leq T_g$$

and combining this with Eq. (4), ignoring the slight difference between the two temperature coefficients, we obtain

$$v = 0.943 + 2.5\times 10^{-4}T, \quad T \leq T_g. \qquad (5)$$

This equation illustrates the important observation that the specific volume below the transition temperature is substantially independent of the molecular weight.

Volume-Time Relationships

The effect of temperature on the rate of volume relaxation was determined for several polystyrene fractions exhibiting values of T_g from 60 to 100°. In each case a dilatometer containing the polymer (and mercury) was quickly transferred from a bath at temperature T_1, generally about 30° above T_g, to a second constant temperature bath at a lower temperature T_2. The volume was then observed as a function of time. Subsequently the polymer was again heated to T_1 and the procedure repeated at a different temperature T_2. At temperatures T_2 exceeding T_g by about 10°, temperature and volume equilibria appeared to be attained simultaneously. At lower temperatures the volume was observed to decrease approximately linearly with the logarithm of time, at least for periods up to 24 hr. The magnitude of the rate of volume relaxation, which was too high to measure about 10° above T_g, had a value of about 30 to 50×10^{-4} at T_g, as measured by the slope of the v *vs.* log$t$ curve (t in min.), and decreased rapidly with decreasing temperature, becoming practically constant at a temperature generally about 10° below T_g. This limiting value of $-dv/d\log t$ was about 8×10^{-4} for all polystyrenes studied.

These results emphasize the fact that although the value of T_g depends on the observation time employed, the marked temperature dependence of the rate of volume relaxation in the vicinity of T_g makes it impossible, using reasonable periods of time, to appreciably alter the value of T_g; it would, for example, be increased by only 5 or 10° on decreasing the time scale of the experiment from 24 hr. to 5 min.

It has been reported[13] that high molecular weight polystyrene previously kept at 20° for two years can be heated from 20 to 140° without undergoing a second-order transition and, further, that the annealing times for this polymer at 20 to 30° below the usual value of T_g are measured in hours or at most in a few days. This reported observation cannot be reconciled with the present results which indicate that the annealing time in this range would consist of many centuries at the least. It is therefore doubtful whether an equilibrium volume-temperature curve for polystyrene has been obtained in the indicated range.[14]

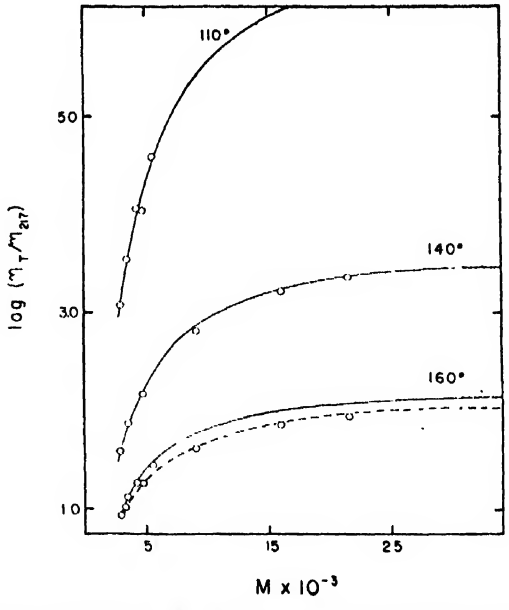

FIG. 4. Log(η_T/η_{217}) *vs.* M for polystyrene fractions at several temperatures. The solid curves are calculated by Eq. (7). The dotted line is calculated by Eq. (6) using the value of $F(T)$ at 160° obtained from Fig. 5.

[13] R. S. Spencer and R. F. Boyer, J. App. Phys. 17, 398 (1946).
[14] Close scrutiny indicates that the reproducibility of the data of reference 13 is poor. In at least one of the two experiments the

Viscosity-Temperature-Molecular Weight Relationships for Polystyrene Fractions

Viscosities were measured at 217° and at lower temperatures for twelve polystyrene fractions of molecular weight from 2970 to 85,000 (Table III). The viscosities at 217° (η_{217}) for the fractions of higher molecular weight are in good agreement with the viscosities previously reported,[4] while those for the fractions of lower molecular weight are generally about 10 percent higher. This discrepancy almost certainly arises from the susceptibility to decomposition of the lower polystyrenes previously used as pointed out in the Experimental section. The relation between $\log(\eta_T/\eta_{217})$ and $1/T$ (in °K) is non-linear and its dependence on molecular weight is qualitatively similar to that previously reported.[4,15]

The dependence of the viscosity-temperature coefficient on molecular weight is illustrated in Fig. 4 where values of $\log(\eta_T/\eta_{217})$ at 160, 140, and 110° are plotted *vs.* the molecular weight. At a given temperature T the quantity $\log(\eta_T/\eta_{217})$ increases with increasing molecular weight up to about 25,000 beyond which it is relatively constant. Its dependence on M is similar for different temperatures, which suggests that $\log(\eta_T/\eta_{217})$ may be expressed as the product of two factors, one of which depends only on T and the other only on M. In further support of this supposition, and in analogy with the dependence of the specific volume and the second-order transition temperature on M, plots (Fig. 5) of $\log\log(\eta_T/\eta_{217})$ *vs.* $1/M$ from 90 to 190° are represented by a set of parallel straight lines. The indicated relationship may be written

$$\log(\eta_T/\eta_{217}) = F(T)e^{-2530/M} \qquad (6)$$

where $F(T)$ is a function of the absolute temperature only. This equation offers a satisfactory limiting form at both very low and very high molecular weights.[16]

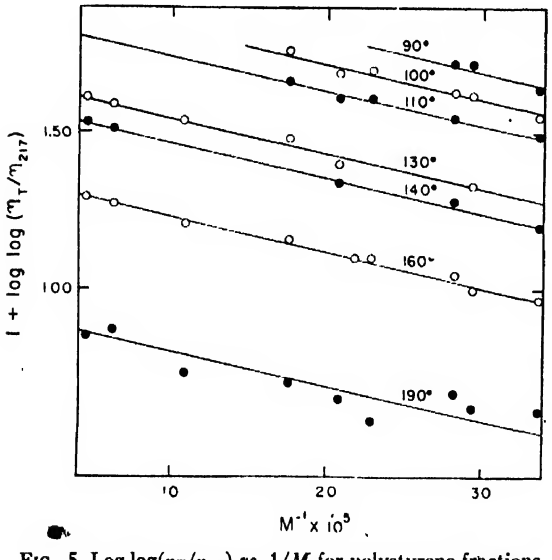

FIG. 5. Log $\log(\eta_T/\eta_{217})$ *vs.* $1/M$ for polystyrene fractions at various temperatures.

In the quest for a suitable empirical expression for $F(T)$, the viscosity-temperature function at $M=\infty$, it has been found (Fig. 6) that the values of $F(T)$ obtained from the intercepts at $1/M=0$ in Fig. 5 are linear functions of $1/T^6$, where T is in °K.[17] Hence the empirical relationship

$$\log(\eta_T/\eta_{217}) = 2.92\times10^{15}(1/T^6 - 1/\langle 490\rangle^6)e^{-2530/M} \qquad (7)$$

expresses the dependence of the temperature coefficient of viscosity on both temperature and molecular weight. Differentiating we obtain the expression for E_T, a quantity which we have called the "apparent energy of activation for viscous flow."[4]

$$Rd\ln(\eta_T/\eta_{217})/d(1/T) = E_T = (8.1\times10^{17}/T^5)e^{-2530/M} \qquad (8)$$

where the units for E_T are cal./mole.

The extent to which the data of Table III conform to Eq. (7) is illustrated in Fig. 4. The solid curves are calculated by Eq. (7) and the circles represent the experimental points. At 110 and 140° the agreement is good, while at 160° the calculated ratio (solid line) is too high. This failure is due to the inadequacy of the form of the temperature dependence rather than to the exponential dependence on the molecular weight, as is indicated by the agreement between the dotted line of Fig. 6 and the experimental points at 160°. The latter line was calculated using the value of $F(T)$ obtained from the extrapolation of the data at 160° to $M=\infty$ (Fig. 5) rather than from Eq. (7). [The values of $F(T)$ at 140 and 100° obtained from the intercepts of Fig. 5 are in agreement with the respective values calculated for $M=\infty$ by Eq. (7).]

In general the discrepancy between viscosities calculated by Eq. (7) and the observed values is less than 20 percent. It is possible that the higher discrepancies which occur are due to a slight degradation of the polymer during the viscosity determinations. On the other hand, Eqs. (7) and (8) are presented merely as approximate empirical representations of the data, which may not necessarily be significant theoretically. They are included primarily for their value in interpolating and extrapolating the experimental measurements.

data could be represented as having a second-order transition at 90°. It may be significant that the values of the "equilibrium" expansion coefficients were about 25 to 30 percent lower than that corresponding to the value of $(dv/dT)_2$ reported here.

[15] The viscosity-temperature coefficients for the high molecular weight polystyrene fractions are identical with those reported in reference 4, but they decrease less rapidly with decreasing molecular weight. These differences probably are due to the occurrence of decomposition in the previous unstable fractions.

[16] Over the molecular weight range investigated, $\log(\eta_T/\eta_{217})$ may alternately be represented as decreasing linearly with $1/M$. However, this relationship must fail at low molecular weights when the quantity $(1-\text{const.}/M)$ becomes small or negative (const.$\cong$1600).

[17] The use of the sixth power of the temperature affords a better approximation to the data than either the fifth or the seventh powers. No attempt was made to employ a fractional power of T.

The use of these equations is illustrated in Table IV where values of $\log\eta$ and E_T have been calculated for polystyrenes of various molecular weights at their transition temperatures. Here T_g has been calculated in each case from the molecular weight by Eq. (2); $\log\eta_T$ at T_g has been calculated from Eq. (7) together with the viscosity-molecular weight relationship at 217°,[4] and E_T has been calculated by Eq. (8). The viscosities of polystyrene fractions at their transition temperatures are not identical but on the contrary vary considerably with molecular weight. The calculated values of E_T at T_g for the various polystyrene fractions, however, are all within 2 kcal. of 110 kcal. per mole. The second-order transition temperatures for a series of polystyrenes do *not* occur at an isoviscous state but *the viscosity-temperature coefficient at the transition temperature is independent of molecular weight.*

The approximate constancy of E_T at T_g may be deduced alternately from Eq. (8). If we require the temperature T at which a polystyrene of molecular weight M has the same value of E_T as that for polystyrene of $M=\infty$ at the transition temperature of the latter ($T_{g,\infty}$), then from Eq. (8)

$$\frac{8.1\times10^{17}}{T^5_{g,\infty}}=\frac{8.1\times10^{17}}{T^5}\,e^{-2530/M}$$

or solving for T and using the first two terms of the series expansion of the exponential term

$$T=T_{g,\infty}(1-506/M). \qquad (9)$$

Inserting the value of 373°K for $T_{g,\infty}$, and converting to °C

$$T=100-1.9\times10^5/M \qquad (10)$$

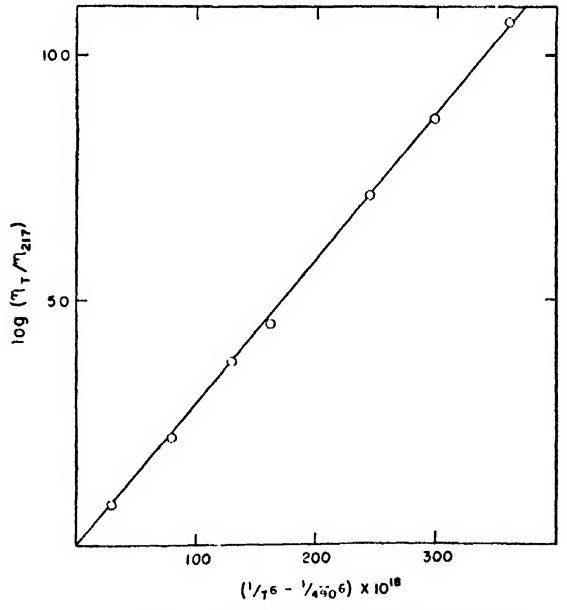

FIG. 6. Log (η_T/η_{217}) for polystyrene of infinite molecular weight *vs.* ($1/T^6-1/(490)^6$).

Mixtures of Polystyrene Fractions

Equations (1), (3), (2), and (7) relating the specific volume, the transition temperature, and the viscosity-temperature coefficient to the molecular weight M have been established from measurements on polystyrene fractions which, for the purpose of the experiments described, may be considered to be essentially homogeneous in molecular weight. In order to establish the particular average (if any) on which these properties depend, three mixtures of polystyrene fractions were prepared having the compositions given in Table V. The values of $\bar{M}_n$ and $\bar{M}_w$ calculated by the usual equations

$$\bar{M}_n=\sum_i w_i/\sum_i(w_i/M_i) \qquad (11)$$

$$\bar{M}_w=\sum_i w_i M_i/\sum_i w_i \qquad (12)$$

where w_i is the weight fraction of the species of molecular weight M_i are also listed in Table V. In each case a benzene solution containing the indicated proportions of the two fractions of widely separated molecular weights was evaporated to dryness in order to assure intimate mixing of the constituents. Measured specific volumes, transition temperatures, and viscosity-temperature coefficients are compared in Table V with the values computed from Eqs. (1), (2) and (7), using the number and the weight average molecular weights of each mixture. In every case the observed value of the given property agrees more nearly with that calculated for a fraction possessing a molecular weight which matches the number rather than the weight average molecular weight of the mixture. Agreement with the calculations based on the number average molecular weight is in all cases within the experimental error. Hence, for a heterogeneous polystyrene the specific volume, transition temperature, and the viscosity-temperature coefficient[18] depend explicitly on the number average molecular weight of the polymer, in accordance with Eqs. (1), (2), (3), (7), and (8).

The volume-temperature coefficients observed for the

[18] The dependence of the viscosity-temperature coefficient for a heterogeneous polystyrene on $\bar{M}_n$ was reported in reference 4.

DISCUSSION

According to current concepts,[19] the equilibrium configuration of a liquid changes continuously with temperature in a manner such that the density of packing of the molecules, or of the chain segments in the case of a polymer, increases with decreasing temperature. The degree of order also increases as the temperature is lowered, and the character of the spatial arrangement, as expressed for spherical molecules by the average coordination number, may change as well.

The linear increases in the specific volume v of polystyrene with $1/\bar{M}_n$ may be interpreted as an influence of the end groups which is proportional to their concentration. Since the end groups, i.e., the $C_2H_5—C_6H_4—\overset{CH_3}{\underset{|}{CH}}—$ groups, occurring in the polystyrenes used here and the styrene structural unit should possess similar net densities, we are led to suggest that the observed dependence of specific volume on molecular weight reflects changes in average density of packing with the concentration of end groups. Thus, the end groups act like a foreign substance in disrupting the local configurational order of the styrene units, and this is manifested by an increase in the specific volume v which is proportional to the concentration of end groups, or to $1/\bar{M}_n$. It follows also that the specific volume affords a convenient index of the average internal configuration or of the average density of packing irrespective of M.

The specific volume-temperature relationships for polystyrene are summarized in Fig. 7. Three parallel straight lines represent the equilibrium v-T relationships for polystyrenes of different molecular weights. The broken line intersecting these v-T lines represents the barrier imposed by the second-order transition. The dotted extensions of the v-T lines into the region below the second-order transition are essentially unrealizable experimentally. All polystyrenes whose *equilibrium* v-T lines would place them in this forbidden region exhibit the *same specific volume-temperature relationship*, as given by the broken line, *independent of molecular weight*. The position of the broken line representing the glassy state depends somewhat on the rate at which observations are made, but, as has been pointed out above, this rate must be altered by several orders of magnitude before it is shifted appreciably.

The internal changes in liquid configuration which must occur on lowering of the temperature obviously involve the motion of segments relative to their nearest neighbors from one configurational arrangement to another. When the temperature is altered well above T_g this motion of the segments relative to their neighbors in the relatively "loose" or "open" structure is rapid and volume equilibration is practically instantaneous. As the temperature approaches T_g however, the configurational structure becomes more and more compact and hence the rate of volume equilibration diminishes rapidly. Finally, at T_g the segments are so densely packed that the internal mobility is negligibly small and consequently, the liquid structure is "frozen-in," and therefore *remains the same for all temperatures below* T_g. The identity of the specific volumes for polystyrenes of different molecular weight at all temperatures below this second-order transition leads at once to the conclusion that *below* T_g *the local configurational arrangement of the polymer segments is independent of both* M *and* T. Furthermore, it is clear that since the presence of end groups in the liquid polymer at a given temperature decreases the density of the configurational structure in proportion to $1/\bar{M}_n$ and since lowering the temperature increases this density of packing in proportion to T, the temperature at which this critical

[19] J. D. Bernal, Trans. Faraday Soc. 33, 27 (1937).

structure of low mobility is reached (T_g) must decrease in a linear fashion with $1/\bar{M}_n$.

Although the configurational structure remains unchanged as T is lowered below T_g, there remains a small linear decrease in volume with temperature associated with the crystal-like "contraction of the lattice" due to decreased amplitudes of oscillation of the segments about mean fixed positions. Obviously the equilibration rate for this process should be very rapid and should be essentially independent of the structural details mentioned above.

If a model for the liquid is chosen in which the chain segments are represented as hard, inelastic bodies, in accordance with certain approximate theories of the liquid state,[20,21] the above conclusions translate to the statement that the "free volume" (or volume of "holes" between the segments) in polystyrene below its transition temperature is a constant independent of both molecular weight and temperature. This follows from the separation of the specific volume into the sum of the free volume v_f and the occupied volume v_0, the latter being given by

$$v_0 = A_0 + (dv/dT)_3 T, \tag{13}$$

where A_0 is the hypothetical volume of the solid (glass) at $T=0$°C. Subtracting this expression from Eq. (3) for the temperature range from T_g to 160° we obtain

$$v_f = A_f + [(dv/dT)_2 - (dv/dT)_3]T + 53/M, \tag{14}$$

where $A_f = A - A_0$. Imposing the requirement that the equilibrium free volume of a polystyrene of molecular weight M at its transition temperature T_g be equal to that of one for which $M=\infty$ at its transition temperature $T_{g,\infty}$, then

$$T_g = T_{g,\infty} - 53/[(dv/dT)_2 - (dv/dT)_3]M. \tag{15}$$

Substituting the values of the parameters given above,

$$T_g = 100 - 1.8\times 10^5/M, \tag{16}$$

which is identical within the limits of experimental accuracy with Eq. (2). Hence, the second-order transition for polystyrene represents a state of "*iso-free volume*," and this same free volume is retained at all temperatures below T_g.

The above considerations suggest that the internal relaxation rate (mobility) is determined almost entirely by the configurational arrangement of the segments (or by the free volume associated with the given configuration) and that it is otherwise very nearly independent of both temperature and molecular weight. A corresponding dominant role of the volume in determining the internal mobility of simple non-polar liquids is illustrated by the fact that their fluidities depend primarily on the specific volume, i.e., the viscosity-temperature coefficient at constant volume is nearly zero.[22] As the temperature is lowered (for any liquid substance) toward T_g, the free volume shrinks to a small value and below T_g remains constant for all lower temperatures. Inasmuch as the volume decreases about linearly with temperature, the *percentage* change in free volume per degree increases rapidly as the temperature is lowered near T_g. Both the observed precipitous decrease of $-dv/d\log t$ for polystyrene near T_g and the approximate constancy of this coefficient below T_g follow as consequences of these considerations.

These concepts may be re-stated in mathematical form. The observations cited[22] on the fluidities of simple liquids suggest that the viscosity of such a substance may be expressed as the product of two functions as follows:

$$\eta = f(v_f)g(T) \tag{17}$$

where $f(v_f)$ is a function only of the free volume (and hence implicitly of the specific volume), or of the liquid configuration, and $g(T)$ is a function of temperature only. For non-polar liquids at least, the value of the latter function changes relatively slowly with T, hence the viscosity is determined primarily by the free volume. Since the internal mobility is also determined by the free volume, the manifestation of the second-order transition as an isoviscous state in *substances of low molecular weight* is consistent with Eq. (17).

The macroscopic viscosity of a polymer depends not only on the free volume and temperature but also on the length of the polymer chain, Z.[3,4] Equation (17) must be replaced therefore by a relationship of the form

$$\eta = f(v_f)g(T)h(Z), \tag{18}$$

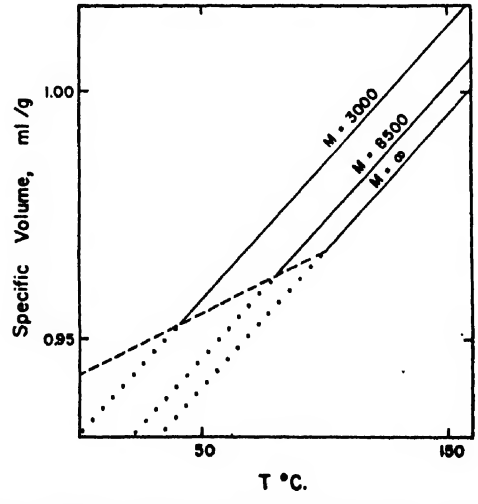

FIG. 7. Specific volume-temperature relations for polystyrene. The parallel lines represent the equilibrium curves, the dotted portions being non-realizable. The dashed line is the v-T curve for polystyrenes in the glassy state.

[20] H. Eyring, J. Chem. Phys. 4, 283 (1936).
[21] Alfrey, Goldfinger, and Mark, J. App. Phys. 14, 700 (1943).
[22] A. J. Batschinsky, Zeits. f. physik. Chemie 84, 643 (1913). D. B. MacLeod, Trans. Faraday Soc. 19, 6 (1923); 21, 151 (1925). W. R. Van Wijk and W. A. Seeder, Physica 4, 1073 (1937); 6, 129 (1939).

where $h(Z)$ is the statistical factor expressing the required coordination of the motions of *all* segments of the polymer molecule. Since the internal mobility depends only on the first two factors (i.e., the rearrangement of local configurational structure does not require long range cooperation of the segments of a given molecule), it is clear that the macroscopic viscosity for a polymer at its second-order transition will vary with M. This is not true of the viscosity-temperature coefficient. If Eq. (18) is rewritten in the form

$$\ln\eta = F(v_f) + G(T) + H(Z) \tag{19}$$

and differentiated with respect to $1/T$, there is obtained

$$\begin{aligned} E_T &= Rd\ln\eta/d(1/T) \\ &= R[(dF(v_f)/dv_f)(dv_f/d(1/T)) + dG(T)/d(1/T) \\ &\quad + (dH(Z)/dZ)(dZ/d(1/T))]. \end{aligned} \tag{20}$$

For non-polar polymers the last two terms on the right should be very small, and presumably may be neglected for the purpose of the present discussion. The quantity $dv_f/d(1/T)$ is independent of M and is not sensitive to temperature [see Eq. (14)]. Hence, E_T depends predominantly on $dF(v_f)/dv_f$, which is a function of the free volume only, and the dependence of E_T on M must be related primarily to the dependence of v_f on M. The constancy of v_f below T_g requires that the first term on the right of Eq. (20) shall be zero below T_g. Hence, the viscosity of polystyrene below T_g will vary only as a result of the contributions of the second and third terms of Eq. (20). To the approximation that these terms may be neglected, the viscosity of a given polystyrene should remain constant at all temperatures below T_g.

No experimental data are available with which to test this latter prediction with regard to polystyrene. Viscosity measurements of silicate glasses, however, have been extended below their second-order transition temperatures. While the temperature coefficient does not fall to zero, it passes through a pronounced maximum at T_g.[23] This behavior is indeed to be expected, when, as in glass, the intermolecular forces between elementary units are large. The second term in Eq. (20) is then appreciable—perhaps comparable in magnitude with the first. The third term must be small or zero.[24] In other words, viscous flow involves a considerable activation, and the resulting temperature dependence persists below T_g notwithstanding the disappearance of the first term in Eq. (20).

Unpublished measurements that we have made of the specific volumes of polyisobutylene fractions at 217° and at lower temperatures indicate that the "free volume" of this polymer is given by

$$v_f = A_f + BT + 32/M \tag{21}$$

which is the analog of Eq. (14) for polystyrene. Here B, the change in the volume-temperature coefficient at T_g, is estimated as $4.5(\pm1)\times10^{-4}$ from the data of Ferry and Parks.[25] If we assume that the second-order transition occurs at a characteristic free volume, then

$$T_g = T_{g,\infty} - 6.9\times10^4/M. \tag{22}$$

Values of T_g calculated from this equation are approximately equal to the corresponding literature values[6,25] provided $T_{g,\infty}$ is taken as $-63°$. This suggests that the correlations observed here for polystyrene may have general validity.

The second-order transition temperature (100°) that we have observed for high molecular weight polystyrene is somewhat higher than values reported elsewhere (Table VI). It is possible that those previously reported may have been vitiated by the presence in the polymer samples of low molecular weight impurities such as unpolymerized monomer, residual solvent, or degradation products formed from the polymer itself.

The volume-temperature coefficients reported here just above and below T_g correspond to values of the expansion coefficient (α) of 6.0 and 2.7×10^{-4}, respectively. These are in good agreement with most of the previously reported values of these coefficients (Table VI). The slightly lower values obtained by some workers for α below T_g may be due to their use of shorter observation times. The lower values obtained in a few cases for α above T_g are unexplained unless, as has been suggested elsewhere,[26] they are due to the presence of impurities. It should be emphasized that the present values were reproducible (within ±10 percent) over wide ranges in temperature for polymers differing widely in molecular weight.

Since the configuration of complex liquids and their volume-temperature dependence are imperfectly understood, we prefer not to hazard an explanation for the non-linearity of the v-T curves above T_g at this time.

SUMMARY

1. The specific volumes of polystyrene fractions ranging in molecular weight from 2970 to 85,000, and of various mixtures of these fractions, have been measured at 217°. The specific volume at a fixed temperature increases linearly with $1/\bar{M}_n$.

2. Measured values of the specific volume-temperature coefficients for these polystyrenes are 7.0, 5.5, and 2.5×10^{-4} above 160°, between the second-order transition temperature (T_g) and 160°, and below T_g, respectively. The last two coefficients appear to be independent of M; the first increases with decreasing M at low molecular weights. Alternately, the results above T_g may be represented by a line with curvature over a wide range in the neighborhood of 160°.

3. The second-order transition temperature is 100 ±2° for high molecular weight polystyrene, and it decreases linearly with $1/\bar{M}_n$.

[23] H. R. Lillie, J. Am. Ceram. Soc. **16**, 619 (1933).
[24] R. W. Douglas, J. Soc. Glass. Tech. **31**, 74 (1947).
[25] J. D. Ferry and G. S. Parks, J. Chem. Phys. **4**, 70 (1936).
[26] F. E. Wiley, Ind. Eng. Chem. **34**, 1052 (1942).

4. At temperatures 10° or more above T_g volume equilibrium appears to coincide with the attainment of temperature equilibrium. In the vicinity of T_g the specific volume decreases approximately linearly with the logarithm of time. In this range the rate of volume relaxation (as measured by $-dv/d\log t$) decreases rapidly with decreasing volume, attaining a low limiting value about 10° below T_g. This limiting value is independent of molecular weight. The rate of internal relaxation (mobility) appears to depend primarily on the internal configurational structure (and on the associated free volume) and to be otherwise independent of T and M.

5. It has been observed that *the specific volumes of polystyrenes below their transition temperatures are independent of the molecular weight.* Hence, it appears that the same "frozen-in" internal configuration prevails in the glassy state independent of molecular weight as well as temperature. The observed dependence of T_g on M can be deduced as a consequence of this conclusion.

6. Bulk viscosities (η) of the same polystyrene samples have been measured from 217 to 75°. The quantity $\log(\eta_T/\eta_{217})$ may be expressed as the product of two factors, one of which depends only on the absolute temperature (as T^{-6}) and the other on $\bar{M}_n$. This ratio at a fixed temperature decreases exponentially with $1/\bar{M}_n$.

7. Generalized relationships for the viscosity of liquids are suggested which indicate that the second-order transition for simple liquids may represent an isoviscous state but that this concept should fail (as it did here) for polymers differing in M. The molecular weight dependence of the viscosity-temperature coefficient for polystyrene above T_g is related logically to its specific volume-molecular weight relationship; the observed non-dependence of this coefficient on M for polystyrenes at their second-order transition temperatures is shown to be a consequence of the non-dependence on M of the specific volumes of these polymers at (or below) their second-order transition temperatures.

8. It is predicted that the viscosity of polystyrene should become relatively independent of T below T_g. The maximum observed in the viscosity-temperature coefficient for a soda-lime-silica glass is explained on the basis of the above relationships.

9. A relationship between T_g and M for polyisobutylene has been suggested.

Electrical Breakdown in CSF_8

RONALD GEBALLE AND FRED S. LINN
Department of Physics, University of Washington, Seattle, Washington
(Received December 27, 1949)

The breakdown potential of a new gas, CSF_8, has been measured over the range from $p\delta=4$ to 200 mm×cm under conditions approximating plane-parallel geometry. A comparison of breakdown in air Freon-12 and CSF_8 in the same apparatus indicates the ratio of the strengths of these gases to be approximately 1:2:3, respectively. CSF_8 decomposes rapidly during breakdown into CF_4 and SF_4 with a consequent doubling of pressure and appreciable increase in breakdown potential.

INTRODUCTION

THE insulating properties of certain gaseous compounds of carbon or sulfur and the halogens, notably Freon-12 (CCl_2F_2) and sulfur hexafluoride (SF_6) have been discussed recently by several investigators.[1–5] The two substances named above are found to have breakdown strengths of about 2 to 2.5 times that of air under comparable conditions. It is believed that the high breakdown strengths of such compounds result from the large number of electronegative atoms contained in each molecule, together with the existence of many degrees of freedom capable of absorbing energy from electrons in inelastic collisions. The above two compounds are particularly useful as insulators because they possess, in addition to notable breakdown potentials, the rather large vapor pressures of 5.5 and 22 atmospheres at room temperature, respectively. Recently, in connection with certain syntheses of fluorine-containing compounds, a substance with the empirical formula CSF_8 was isolated by Mr. Gene A. Silvey of the Department of Chemistry. This compound is colorless, and chemically inert. It possesses a boiling point of $-20°C$ at atmospheric pressure and a saturation vapor pressure of 4.3 atmospheres at 20°C. Its structure is believed to be F_3C-SF_5. A detailed description of its synthesis and chemical behavior will be discussed elsewhere.[6] In view of the large number of fluorine atoms per molecule and the high vapor pressure of CSF_8 a survey of its insulating properties was felt to be of considerable interest and was undertaken by the present authors. Measurements of the breakdown strength of this gas were made in the range from $p\delta=4$ to 200 mm×cm under conditions closely approximating plane-parallel geometry. A comparison of its strength with those of air and Freon-12 was made under the same conditions. It was found that air, Freon-12, and CSF_8 possess strengths in the approximate ratio 1:2:3 in this range of $p\delta$. It was also found that CSF_8 decomposes in an unusual manner in the course of electrical breakdown. The breakdown products could be separated in relatively pure states and their identity verified.

APPARATUS

The breakdown voltage was measured in a Pyrex discharge vessel containing two plane Monel disks of 7.65 cm diameter and spaced 1.5 cm apart. Because of the limited supply of CSF_8 the volume of the envelope was deliberately made small, about 0.8 liter. To localize discharges on the axis of the electrode system under this condition a hemispherical boss of 1.6 mm radius was mounted at the center of the anode. The small field distortion thus introduced was responsible, in certain cases, as will be seen, for the production of streamer pulses preceding breakdown. The distortion was sufficiently small, however, that no serious alteration in breakdown potential was noticed in standard gases in the range of $p\delta$ under investigation. In computing $p\delta$, the electrode separation, neglecting the boss, was used.

The pumping system consisted of a mercury diffusion pump backed by a mechanical pump. Pressures were determined by the use of appropriate McLeod gauges or a mercury manometer. Traps surrounded by liquid nitrogen were used to eliminate contamination by mercury vapor except during short intervals when pressure measurements were being made.

Direct voltage up to 40 kv was supplied by a half-wave rectifier with sufficient filtering to reduce ripple to 0.1 percent. Small increments in voltage were made possible by the use of a small transformer in series with the high voltage one, each with its own variable input. The voltage was read with the aid of a calibrated multiplier and a potentiometer. The over-all error in voltage readings, due primarily to line voltage fluctuation, amounted to about one percent. A two-megohm resistor was in series with the high voltage to prevent excessive current upon breakdown.

To insure an adequate supply of initiating electrons a radium-containing sample was placed near the discharge chamber.

PROCEDURE

The electrodes were polished and cleaned before assembly of the system performed in an atmosphere of nitrogen. The tube was annealed in hydrogen and baked

out at 400°C while at a pressure of 10^{-5} mm of mercury. Between runs in different gases the tube was well pumped out. In one case, after the run in Freon-12, the system was completely dismantled and cleaned before proceeding.

The air used in this investigation was withdrawn slowly from the room and passed through a trap surrounded by liquid nitrogen. For all the measurements in this gas, except the last, the vapor pressure of oxygen at the temperature of the trap exceeded the total pressure in the apparatus; hence the composition of the air was not appreciably altered. In any case, the breakdown potentials of air and nitrogen are very closely the same in this range of $p\delta$.[3] The more readily condensed gases were admitted from traps after careful drying by redistillation. Hydrogen, used to test the geometry, was obtained from a commercial cylinder, passed through a catalytic purifier and then through a trap immersed in liquid nitrogen.

Breakdown voltages were found by slowly increasing the applied potential in increments of a few volts, with suitable delay between each step in an attempt to eliminate errors due to statistical factors. In general the onset of a visible discharge was taken as the breakdown potential. In certain cases, as described below, observations were made with an oscilliscope connected across a series resistor.

EXPERIMENTAL RESULTS

1. Hydrogen

The breakdown potential of hydrogen was investigated in order to determine the properties of the particular geometrical arrangement employed. The oscilliscope showed small pulses, increasing in size with increased voltage, which suddenly assumed the character of breakdown streamer pulses.[7] A few volts above this the discharge became visible, first pulsating and then steady to the eye. These events took place at well-defined potentials, reproducible within the accuracy of the apparatus. In Fig. 1 the streamer onset voltage thus found is compared with the curve compiled by Druyvesteyn and Penning[8] for breakdown between plane electrodes. All pressures have been reduced to standard conditions. It can be seen that the advent of the large pulses coincided rather closely with the breakdown voltage found under conditions of strictly uniform field.

2. Freon-12

Commercial Freon-12 was used after vapor density measurements indicated its purity was better than 99.5 percent. The oscilliscope gave no hint of impending breakdown in this gas, but merely exhibited preliminary burst pulses as reported by Mohr and Weissler.[9] In contrast to these workers no hysteresis was noted. There were, however, large fluctuations in delay between the time of application of voltage and breakdown when the voltage was applied by closing a switch. The average of these fluctuations is a function of the applied voltage. It decreases, for example, from 30 sec. at 29,700 volts to 2 sec. at 30,900 volts for $p\delta = 275$ mm×cm. Figure 1 shows the breakdown potentials associated with a maximum delay of 1 min. For comparison the curves of Trump, Safford, and Cloud[2] as well as Hochberg and Sandberg[4] are shown. The decomposition products of Freon-12 were found to be exceedingly corrosive, attacking glass, electrodes, and mercury.

3. Air

The breakdown potential of air was determined for use as a reference. The appearance of visible discharge was regarded as breakdown. There was no noticeable fluctuation in delay times and voltages were easily reproducible. No study of the pre-breakdown pulses was made. The data obtained are compared in Fig. 1 with the curve compiled by Whitehead[10] for plane geometry. They agree with the results of Fisher[11] in the range where comparison is possible.

4. CSF_8

No streamer pulses were observed in this gas. The small burst pulses, which in many gases precede streamers, increased in size and frequency until a spark occurred, persisting until the high voltage switch was

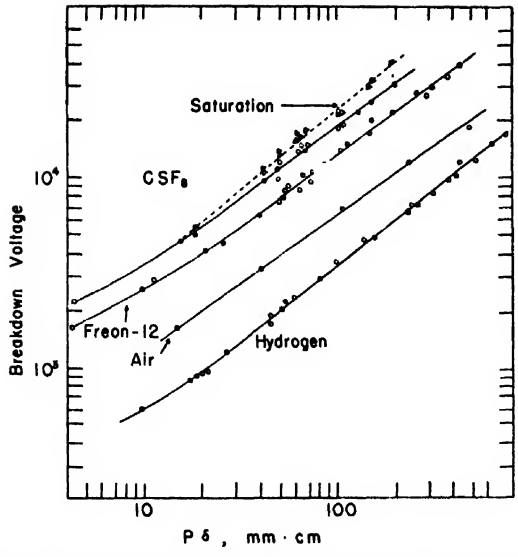

FIG. 2. Comparison of breakdown voltages of CSF_8 with other gases. Curves are drawn through the experimental points. Dashed curve is the saturation voltage discussed in the text. All data reduced to 0°C.

opened. On closing the switch again, the potential remaining constant, breakdown did not recur. When the voltage was increased to a new level it could be reapplied several times to produce sparking. The time lapse between the closing of the switch and the spark increased for each of these breakdowns from an initial value of less than a second to more than five minutes and eventually it was apparent that no more sparks were possible at this level. At higher levels the sequence of events was similar except that the total number of breakdowns at each voltage increased. In addition, the time lag increased less rapidly with the number of breakdowns at a given level. At a level about ten percent above the initial breakdown potential a saturation voltage was attained after which sparking took place with small time lags which fluctuated between zero and about three seconds without steady increase.

It was believed that an investigation of the decomposition products would provide the explanation of these observations. To obtain the products in sufficient quantity for analysis, a continuous discharge of 2 ma was permitted to pass through CSF_8 for 15 min. and the gases collected over liquid nitrogen. This process was repeated several times. During the course of these runs measurements of the pressure indicated an increase to twice the initial value, after which no further change occurred. Analysis of the products by Mr. Silvey provided the following information:

(1) When condensed, the products formed two immiscible phases.

(2) One of the phases was definitely identified through its vapor density and freezing point as CF_4.

(3) The other constituent, because its odor, melting and boiling points agreed closely with those reported by Fischer and Jaenchner,[12] was tentatively identified as SF_4, a compound of hitherto dubious existence.[5]

(4) The average vapor density of the products was correct assuming the above are the sole products.

It appears then that during the course of electrical discharge the CSF_8 is split rapidly into two products, CF_4 and SF_4. The consequent rise in pressure accounts for the behavior of the breakdown potential in the following manner: When the first breakdown took place some of the CSF_8 was decomposed, the pressure rose and no further breakdown was possible at this voltage. When the voltage was increased and reapplied, breakdown occurred immediately, producing further decomposition. At a constant pressure the breakdown potential of the products is considerably less than that of the CSF_8. Hence, because of the slow diffusion rate of the heavy molecules involved, the mixture of gases between the electrodes broke down when the same voltage was again applied, even though the pressure had increased to some extent. With successive applications of voltage the decomposition continued, the mixture of gases became more nearly homogeneous until the pressure increased to such an extent that no further breakdown could take place at this potential. At higher voltages the process was similar. Because the percentage of CSF_8 continually diminished, the lag introduced by diffusion became less pronounced until with complete decomposition the saturation voltage was attained. It should be noted that the lags after reaching saturation were not dependent on voltage in the pronounced manner of Freon-12. To verify the nature of the decomposition products an additional sample of CSF_8 was subjected to discharge. Again the doubling of pressure and rise in breakdown potential were noted. Separation of the two phases and analysis for sulfur and fluorine by Mr. Silvey indicated without doubt that one of the products was SF_4.

The breakdown potential of CSF_8 as well as the saturation voltage characteristic of the completely decomposed gas under conditions of constant volume are shown in Fig. 2 with pressures reduced to 0°C. For comparison, the results obtained under Sections 1–3 are given. It can be seen that in the range of the present investigation the strengths of air, Freon-12, and CSF_8 are in the approximate ratio 1:2:3.

At the conclusion of the discharges in CSF_8 a thin whitish layer, identified as sulfur, coated the glass. The Monel electrodes used in the first set of measurements showed no evidence of corrosion. The vessel used to decompose the gas in the second set contained stainless steel, which became markedly corroded. These effects are probably due to further decomposition during the passage of the current. When allowed to stand for a day or so, the mixture of CF_4 and SF_4 exhibited a constant pressure and breakdown potential.

It is a pleasure to thank Professor George H. Cady and Mr. Silvey of the Department of Chemistry for supplying the CSF_8 and to acknowledge the aid rendered by the latter in performing the various analyses.

The Effect of Cold-Work Distortion on X-Ray Patterns*

B. E. Warren and B. L. Averbach
Massachusetts Institute of Technology, Cambridge, Massachusetts
(Received January 9, 1950)

With modern experimental technique, it is possible to measure a peak shape with sufficient accuracy to justify an interpretation based on the precise shape of the reflection. The corrected shape is represented by a cosine Fourier series and a set of A_n coefficients determined. A plot of the A_n coefficients *vs.* n will distinguish between distortion and particle size broadening. From the A_n coefficients, root mean square values of strain averaged over lengths na_3 are obtained. The decrease in these values for increasing length na_3 is a direct indication of the non-uniform nature of the strains in cold-worked metal. By measuring several orders of a given plane, it is theoretically possible to obtain a distribution function of the strains directly from a Fourier transform of the A_n coefficients.

I. INTRODUCTION

COLD-WORK distortion produces a broadening of powder pattern reflections. Most of the previous work in this field has involved measurements of cold-work broadening as a function of λ and θ, and the use of these breadth measurements to distinguish between various assumed theories of the nature of cold-work distortion.

With modern experimental technique, using focusing curved crystal monochromators and Geiger counter spectrometers, it is possible to measure the shape of a powder pattern line with sufficient accuracy to justify an interpretation based on the precise shape of the line, rather than using just the line breadth.[1] By making full use of the shape of the line, it is possible to get a great deal of information about the nature of cold-work distortion without making any *a priori* assumptions. The theoretical treatment must be carried through for a completely general distortion, so that what we get in the end is given uniquely by the x-ray measurements and is not partly the result of assumptions concerning the nature of the distortion which have been inserted during the treatment.

II. EFFECT OF A GENERAL DISTORTION

We start with the same formulation used by Stokes and Wilson.[2] Only cubic crystals are considered for which it is always possible to adopt a set of orthogonal axes so as to make any reflection of the form $(00l)$. The position of any cell $m_1m_2m_3$ is given by the vector

$$R_m = m_1a_1 + m_2a_2 + m_3a_3 + \delta_{m_1m_2m_3},$$

where δ is an arbitrary displacement, in general different for every cell. Expressed in electron units the intensity from one crystal is

$$I = F^2 \sum_{m_1} \sum \sum \sum \sum \sum_{m_3'} \exp[2\pi i/\lambda (s - s_0)\cdot(R_m - R_{m'})],$$

where s_0 and s are unit vectors giving the directions of the primary and diffracted beams. Let

$$s - s_0 = \lambda(h_1b_1 + h_2b_2 + h_3b_3),$$

where $b_1b_2b_3$ are the reciprocal vectors, and $h_1h_2h_3$ are continuous variables. The intensity per crystal is

$$I(h_1h_2h_3) = F^2 \sum \sum \sum \sum \sum \sum_{m_3'} \exp\Big[2\pi i \; h_1(m_1 - m_1') + h_2(m_2 - m_2') + h_3(m_3 - m_3') + \left(\frac{s - s_0}{\lambda}\right)\cdot(\delta_m - \delta_{m'}) \Big\} \Big]. \quad (1)$$

For a powder pattern, the total diffracted power in a reflection is given by an integration throughout a sufficient volume in the reciprocal lattice to include everything contributing to the reflection.

$$P = \frac{MjR^2\lambda^3}{4v_a} \int\int\int \frac{I(h_1h_2h_3)}{\sin\theta} dh_1dh_2dh_3, \quad (2)$$

where M is the number of crystals in the sample, j is the hkl multiplicity, R is the sample to film distance, and v_a is the volume of the unit cell. The distribution of power with angle is expressed by $P_{2\theta}$ where

$$P = \int P_{2\theta} d(2\theta). \quad (3)$$

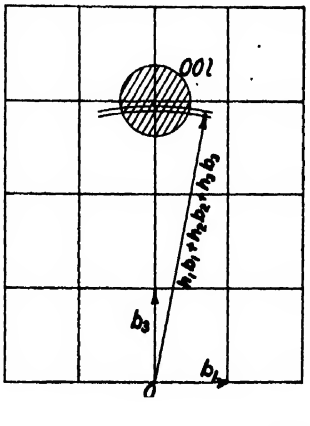

FIG. 1. Approximation of a spherical surface by a tangent plane involved in the integration about 00*l*.

* Research sponsored by the ONR under Contract N5 ori-07832.
[1] B. L. Averbach and B. E. Warren, J. App. Phys. **20**, 885 (1949).
[2] A. R. Stokes and A. J. C. Wilson, Proc. Camb. Phil. Soc., **38**, 313 (1942); Proc. Phys. Soc. **56**, 174 (1949).

In carrying out the integration about the point $00l$ in Fig. 1, it is assumed that the spreading out of the point due to distortion is small compared to its distance from the origin, so that a spherical layer can be approximated by a horizontal layer

$$|s-s_0| = 2\sin\theta = \lambda|h_1b_1+h_2b_2+h_3b_3| \rightarrow \lambda|b_3|h_3$$

$$dh_3 = \frac{\cos\theta d(2\theta)}{\lambda|b_3|}.$$

The integration with respect to dh_3 in (2) can be expressed in terms of $d(2\theta)$ and from (3) we get $P_{2\theta}$ by leaving out this integration.

$$P_{2\theta} = \frac{MjR^2\lambda^2}{4v_a|b_3|\tan\theta}\int\int I(h_1h_2h_3)dh_1dh_2. \qquad (4)$$

Experimentally we measure the distribution of power per unit length of diffraction line

$$P_{2\theta}' = \frac{P_{2\theta}}{2\pi R\sin 2\theta}.$$

Let

$$K = -\frac{MjR\lambda^2F^2}{16\pi v_a|b_3|\sin^2\theta}.$$

The distribution of power is then

$$P_{2\theta}' = K\int\int \sum_{m_1}\sum\sum\sum\sum\sum_{m_3'} \exp\left[2\pi i\left\{h_1(m_1-m_1') + h_2(m_2-m_2') + h_3(m_3-m_3') + \left(\frac{s-s_0}{\lambda}\right)\cdot(\delta_m-\delta_{m'})\right\}\right]dh_1dh_2. \qquad (5)$$

Represent the displacement δ_m by

$$\delta_m = X_ma_1 + Y_ma_2 + Z_ma_3 \quad (m = m_1, m_2, m_3)$$

and for computing the scalar product $(s-s_0)\cdot(\delta_m-\delta_m')$ use the average position of the vector $(s-s_0)$, $\langle s-s_0\rangle_{Av} = \lambda h_3b_3$

$$\frac{2\pi i}{\lambda}(s-s_0)\cdot(\delta_m-\delta_{m'}) = 2\pi i h_3(Z_m-Z_{m'}).$$

It is only the component of displacement perpendicular to the reflecting planes that is involved. To include everything belonging to point $00l$ we carry out the integration with respect to dh_1 and dh_2 from $-\frac{1}{2}$ to $+\frac{1}{2}$.

$$P_{2\theta}' = K\sum_{m_1}\sum\sum\sum\sum\sum\sum_{m_3'} \frac{\sin\pi(m_1-m_1')}{\pi(m_1-m_1')} \times \frac{\sin\pi(m_2-m_2')}{\pi(m_2-m_2')} \exp[2\pi i h_3\{(m_3-m_3') + (Z_m-Z_{m'})\}]. \qquad (6)$$

The sine functions are zero except for $m_1=m_1'$ and $m_2=m_2'$. This means that we should think of the crystal in terms of columns of unit cells, the columns being parallel to a_3 or perpendicular to the reflecting planes $00l$. The summation with respect to m_3 and m_3' is carried out for all pairs of cells in a given column, and the summation with respect to m_1 and m_2 means summation of the contributions from each column.

Let

$$n = m_3 - m_3' \quad Z_n = Z_{m3} - Z_{m3}'.$$

Assuming that the number of cells in a column N_3 is large compared to the value of n at which a summation with respect to n will converge

$$\sum_{m_3}\sum_{m_3'} \rightarrow N_3\sum_{n=-\infty}^{+\infty}$$

$$P_{2\theta}' = K\sum_c N_3\sum_{n=-\infty}^{+\infty}\langle\exp[2\pi i h_3(n+Z_n)]\rangle_{Av}, \qquad (7)$$

where $\sum_c$ means summation over the columns, and the average is an average over-all pairs of cells $m_1m_2m_3$ and $m_1'm_2'm_3'$ with $m_1=m_1'$, $m_2=m_2'$ and $m_3-m_3'=n$. Let the total number of cells in the crystal be $N=\sum_c N_3$. Since $Z_{-n}=-Z_n$

$$P_{2\theta}' = KN\sum_{n=-\infty}^{+\infty}\langle\cos 2\pi h_3(n+Z_n)\rangle_{Av}$$

$$P_{2\theta}' = KN\sum_{n=-\infty}^{+\infty}(A_n\cos 2\pi nh_3 + B_n\sin 2\pi nh_3), \qquad (8)$$

where $A_n = \langle\cos 2\pi h_3Z_n\rangle_{Av}$ and $B_n = -\langle\sin 2\pi h_3Z_n\rangle_{Av}$.

The coefficients of the sin terms will vanish if positive and the negative values of Z_n are equally probable for a given n. If they do not vanish their effect is to displace the center of the $P_{2\theta}'$ peak from the position for an undistorted material. This is just another way of recognizing that cold-work distortion may produce an average expansion or contraction of the lattice. Measurements on cold-worked metals to which the theory has been applied so far, show no appreciable shift in peak position, and hence we will confine our attention to the restricted case where the sin terms are negligible.

$$P_{2\theta}' = KN\sum_{n=-\infty}^{+\infty}A_n\cos 2\pi nh_3, \qquad (9)$$

where

$$h_3 = 2a_3(\sin\theta)/\lambda$$
$$A_n = \langle\cos 2\pi lZ_n\rangle_{Av}.$$

In the expression for A_n we have replaced h_3 by its peak value l. From (9) the corrected shape of the peak is represented by a cosine Fourier series, and the coefficients A_n depend only on relative displacements perpendicular to the reflecting planes. By definition a_3Z_n is the change in length of a column of original length na_3.

III. EXPERIMENTAL DETERMINATION OF FOURIER COEFFICIENTS

The coefficients A_n are determined from carefully measured peak shapes from a cold-worked sample and from an annealed sample. The second peak is used to correct the first for all sources of broadening other than that due to cold-work distortion. The correction is carried out by the method of Stokes[3] using the Lipson-Beevers strips. This method delivers directly the desired A_n coefficients. The Fourier analysis is done over the range h_3' from $-\frac{1}{2}$ to $+\frac{1}{2}$ where $h_3'=h_3-l$. Fictitious values of l and a_3 are used where necessary to make the range of the Lipson-Beevers strips cover efficiently the range of 2θ-values in the measured peak.

IV. EFFECT OF PARTICLE SIZE BROADENING

Particle size broadening is represented by a cosine Fourier series similar to that developed for distortion broadening and hence the Fourier coefficients A_n give a very general method of handling either effect. The particle size broadening follows the same treatment used for distortion broadening up to Eq. (6) except that δ and hence Z_m and $Z_{m'}$ are zero.

$$P_{2\theta}'=K\sum_{m_1}\sum\sum\sum\sum\sum_{m_3'}\frac{\sin\pi(m_1-m_1')}{\pi(m_1-m_1')}\times\frac{\sin\pi(m_2-m_2')}{\pi(m_2-m_2')}\exp[2\pi i h_3(m_3-m_3')].$$

Consider the crystal in terms of columns of unit cells perpendicular to the reflecting planes. Let n_i be the number of columns of length i cells, so that

$$N=\sum_{i=1}^{\infty} in_i$$

is the total number of cells in the sample.

$$P_{2\theta}'=KN\sum_{n=-\infty}^{+\infty}A_n\cos2\pi nh_3, \tag{10}$$

where

$$A_n=\frac{1}{N}\sum_{i=|n|+1}^{\infty}(i-|n|)n_i.$$

Introduce a distribution function $p(i)$ such that $p(i)di$ is the number of columns of length between i and $i+di$ cells.

$$\int_1^{\infty}p(i)di=N_c \qquad \int_1^{\infty}ip(i)di=N,$$

where N_c is the number of columns and N is the number of cells. In terms of the distribution function

$$A_n=\frac{1}{N}\int_{i=|n|+1}^{\infty}(i-|n|)p(i)di.$$

[3] A. R. Stokes, Proc. Phys. Soc. **61**, 382 (1948).

For both distortion and particle size broadening the coefficients A_n have been defined so that A_0 is unity.

$$\frac{dA_n}{dn}=-\frac{1}{N}\int_{i=|n|+1}^{\infty}p(i)di.$$

The initial slope of the A_n *vs.* n curve is

$$(dA_n/dn)_{n=0}=-N_c/N=-1/\bar{N}_3, \tag{11}$$

where $\bar{N}_3a_3$ is the average column length and hence an average particle size in the direction a_3.

$$(d^2A_n)/(dn^2)=(1/N)p(n). \tag{12}$$

If the measurements of particle size broadening are expressed in terms of a plot of the Fourier coefficients A_n *vs.* n the initial slope of the curve gives directly the average column length and the second derivative gives the column length distribution. This important result has already been obtained by M. F. Bertaut[4] by essentially the same method. The treatment given here is one developed by the authors before they were aware of Bertaut's work and it has been included here so as to present the particle size theory in the same notation used for distortion broadening.

V. REPRESENTATION BY FOURIER COEFFICIENTS

The representation of measured peak shapes by a plot of the Fourier coefficients A_n *vs.* n gives a very general and powerful method for representing many different effects in the sample. Three different examples are shown in Fig. 2. For a distortion such as that of cold-work the coefficients are given by

$$A_n=\langle\cos2\pi lZ_n\rangle_{Av}.$$

For small n, we expect the values of $\langle Z_n^2\rangle_{Av}$[4] to be small and proportional to n and hence A_n *vs.* n should start with the shape of an error curve. The effect of small particle size is to give a finite initial slope whose value is determined by the average particle size. This

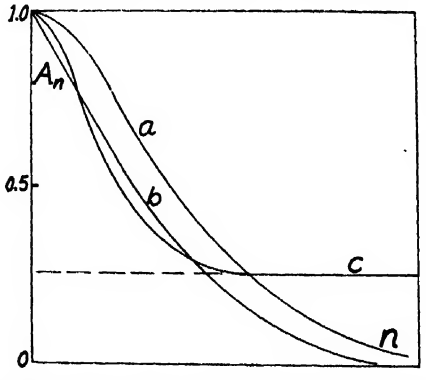

FIG. 2. Difference in shape of the A_n *vs.* n curves. (a) Cold-work distortion. (b) Particle size broadening. (c) Temperature effect.

[4] M. F. Bertaut, Comptes Rendus **228**, 492 (1949).

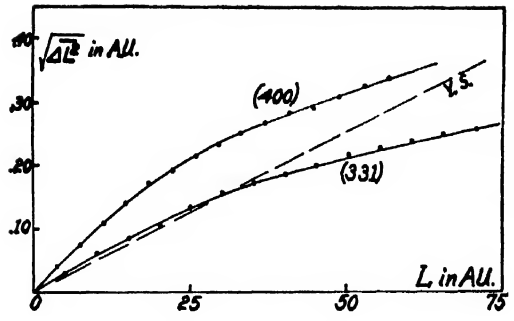

FIG. 3. Relative displacements for cold-worked 70–30 α-brass. ΔL is the change in length of a column of length L, both expressed in angstrom units.

expected difference in the shape of the A_n *vs.* n curves has been confirmed by the experimental measurements which have been made. From precise measurements of the shape of a *single reflection* it is possible to distinguish between particle size and distortion broadening.

The effect of temperature vibration is represented schematically by curve c. For large n, the value of $\langle Z_n^2\rangle_{Av}^{\frac{1}{2}}$ becomes independent of n, and A_n approaches a constant value. If each A_n value is split into the part above and below the horizontal line of curve c, the complete set of values below the line represents the sharp reflection unaffected in breadth but cut down in height, while that part of the coefficients above the line represents a diffuse scattering which peaks at the position of the reflection.

The integral breadth β of a reflection is given by

$$\beta=\frac{1}{(P_{2\theta}')_{\max}}\int P_{2\theta}'d(2\theta)$$

$$\beta=\frac{1}{\sum_{-\infty}^{+\infty}A_n}\int_{-\frac{1}{2}}^{+\frac{1}{2}}\sum A_n\cos(2\pi nh_3)\frac{\lambda}{a_3\cos\theta}dh_3$$

$$\beta=\frac{\lambda}{a_3\cos\theta}\frac{1}{\sum_{-\infty}^{+\infty}A_n}. \qquad (13)$$

From a measurement of a peak breadth β we get only the sum of the Fourier coefficients $\sum A_n$, and hence not nearly as much information as is available in a knowledge of the value of each coefficient.

VI. INTERPRETATION OF MEASUREMENTS ON COLD-WORKED METAL

From the experimental peak shape we determine a set of coefficients A_n which involve the relative displacements Z_n. If the values of Z_n are sufficiently small, or if they follow a Gaussian distribution $p(Z_n)=C\times\exp -\alpha^2Z_n^2$, the average of the cosine can be expressed as an exponential.

$$A_n=\langle\cos 2\pi lZ_n\rangle_{Av}\rightarrow\exp[-2\pi^2l^2\langle Z_n^2\rangle_{Av}]. \qquad (14)$$

From each coefficient A_n we compute a root mean square relative displacement $\langle Z_n^2\rangle_{Av}^{\frac{1}{2}}$.

Figure 3 shows a set of measurements on cold-worked 70–30 α-brass filings. To avoid the confusion resulting from the fictitious a_3 values used in the Fourier analysis, the Z_n values computed by (14) have been changed to distances in angstrom units.† L is a column length and ΔL is the change in length of the column due to cold-work

$$L=na_3 \quad \Delta L=a_3Z_n.$$

The slope of a line from the origin to any point on a curve represents a root mean square strain averaged over columns of length $L=na_3$ perpendicular to the reflecting planes. The initial slopes represent the true root mean square strains for the respective directions. The initial slopes are roughly in the inverse ratio to the values of Young's modulus for the corresponding directions, in agreement with previous studies involving measurements of peak width only.[5,6] For the cold-work involved in preparing filings, the initial slopes are of the same order as the yield strain computed from the yield stress and an average value of Young's modulus.

If strains were constant over appreciable distances in the material, as is usually assumed in the micro stress theory of cold-work broadening, the curves of Fig. 3 should be straight lines. To the extent that the approximation in (14) is justified, the noticeable drooping of these curves at distances as small as 20A is evidence for the non-uniform and localized nature of the strains in cold-worked metal.

The curves of Fig. 3 depend on the approximation that the Z_n values are either small or represented by a Gaussian distribution function $p(Z_n)=C\exp[-\alpha^2Z_n^2]$. In principle it is possible to obtain the distribution function directly from the x-ray data rather than assuming it. By using different wave-lengths it is possible to throw several orders of a particular set of planes into the high angle region. By measuring the A_n coefficients for several values of l and making use of the fact that $A_n=1.0$ for $l=0$, and vanishes for large l, we determine $A_n(l)$ approximately as a function of the variable l. In terms of the distribution function

$$A_n(l)=\langle\cos 2\pi lZ_n\rangle_{Av}=\int_0^\infty p(Z_n)\cos 2\pi lZ_ndZ_n.$$

The distribution function is given directly as the

† In a previous presentation of similar curves (reference 1) the scale of ordinates for the 331 and 222 curves involved fictitious a_3 values different from the cube edge a and the slopes are not comparable.

[5] C. S. Smith and E. E. Stickley, Phys. Rev. **64**, 191 (1943).

[6] Stokes, Pascoe, and Lipson, Nature **151**, 137 (1943).

Fourier transform of the measured $A_n(l)$ values.

$$p(Z_n)=4\int_0^\infty A_n(l)\cos 2\pi Z_n l dl. \qquad (15)$$

In principle we can determine an average strain distribution function for each n and plane (hkl). The plane (hkl) selects a direction in the crystal perpendicular to the planes, the index n selects a distance $L=na_3$ along this direction, and $p(Z_n)$ gives the distribution of strain magnitudes averaged over such lengths na_3. This probably represents as much information about the nature of cold-work deformation in a metal as can be obtained directly from the x-ray broadening data, with no assumptions about the nature of the strains being introduced.

A Quantized Theory of Strain Hardening as Applied to the Cutting of Metals

MILTON C. SHAW
Massachusetts Institute of Technology, Cambridge, Massachusetts
(Received January 18, 1950)

A theory of strain hardening is presented which utilizes the fact that metals deform blockwise rather than continuously. A metal is assumed to possess an orderly array of weak spots through which slip planes pass. The slip displacement which occurs upon a single plane is related to the spacing of weak points and the slip plane inclination. Use of a linear relation between shear plane displacement and resisting shear stress, enables the mean shear stress to be computed.

In the two examples considered it is seen that the influence of normal stress on the shear plane is less important in cutting than has been generally believed. Strain hardening and the short range inhomogeneity of metals is seen to account for most of the dynamic increase in shear strength during cutting, including the increase in shear energy per unit volume with decreased depth of cut. This size effect is akin to the increase in tensile strength with decreased specimen diameter, both phenomena involving strain hardening as influenced by inhomogeneity. The quantity Aa^2 which represents in a single number the strain hardening and short range inhomogeneity characteristics of a metal should prove particularly valuable in analyzing the cutting characteristics of metals which strain harden extensively.

INTRODUCTION

FUNDAMENTAL studies in the field of solid state physics have revealed that, in general, metals do not strain uniformly. When a single metal crystal is loaded, it will first deform elastically and then plastically. The plastic deformation is observed to occur by a process of slip as one section of the crystal slides over another. The direction of this shear deformation in a single crystal is along those planes containing the greatest number of atoms per unit area. Slip planes are clearly evident under the microscope on a polished and etched single crystal that has been plastically deformed. The presence of slip planes of a fairly regular spacing attests the fact that the metal has not been strained uniformly throughout but rather that the deformation is confined to well-defined planes that are many atomic layers apart. It is further found that polycrystalline metals also strain blockwise rather than uniformly.

Energy considerations show that slip does not involve the motion of one layer of uniformly spaced atoms over another en masse. Present theory rather suggests that slip occurs due to the motion of certain types of lattice imperfections called dislocations through a crystal. Dislocations are generally associated with highly localized stress gradients in a metal which may arise from any one of a number of causes (small internal cracks or holes, the mutual interference of adjacent grains at grain boundaries or small inclusions of foreign matter). While the exact physical nature of dislocations is not exactly clear, the properties of dislocations explain a number of characteristics of metals that are not as conveniently explained in other ways. For the purpose of the present discussion the dislocation sources may be considered as weak spots which are present in a piece of metal that has been processed in a particular way. The planes along which slip occurs are those which pass through one or more of these weak spots, the metal between adjacent planes being undeformed.

FIG. 1. Photomicrograph of a partially formed chip. Magnification 100×.

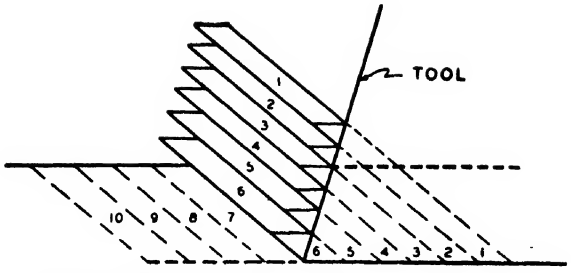

FIG. 2. Schematic representation of cutting process.

Despite the foregoing inhomogeneous picture of plastic deformation, it has been customary to treat the metal as a continuum in quantitative calculations of strain. Consideration of the well-known phenomenon of strain hardening makes it evident that a quantized treatment of strain should be used in place of a treatment involving uniformly distributed strain. The metal cutting process is a convenient one for illustrating the need for adopting such a discontinuous picture of the straining process.

THE METAL CUTTING PROCESS

When metal is cut by a two-dimensional single point cutting tool the material removed is plastically deformed to a considerable extent. Photomicrographs of the chip-tool interface of a partially formed chip, such as that shown in Fig. 1, show that metal is removed in a cutting operation by a process of shear. A distinct line of demarcation in structure (AB) is generally evident in such photomicrographs, below which metal is undeformed plastically and above which it has a deformed structure. The angle which AB, the shear line, makes with the direction of cut is called the shear angle, ϕ.

Piispanen[1] first likened the metal cutting process to the successive displacement of a series of cards as shown in Fig. 2. In this figure portions of the chip numbered 1, 2, 3 etc. originally occupied the similarly numbered positions on the workpiece. In practice the thickness of the individual "cards" is quite small, corresponding to the spacing of the aforementioned weak spots in a piece of metal. The mechanism of cutting shown exaggerated in Fig. 2 forms the basis for the theory of metal cutting that is presented here.

Previous attempts to formulate a quantitative theory of metal cutting have ignored the important tendency of a metal to strain harden. Piispanen[1] has mentioned that metals strain harden and that this factor should be included in a complete analysis of the cutting process. Merchant[2] has also mentioned that strain hardening may occur in cutting but concludes that it plays an insignificant role. Drucker[3] has more recently discussed the possibility of strain hardening in metal cutting and concludes that metal behaves as an ideal plastic when cut, strain hardening not being among the items of interest.

To prove conclusively that strain hardening can play a very significant role in metal cutting, one need only attempt to machine a specimen of austenitic stainless steel. Herbert[4] has presented data for such materials which clearly show the importance of strain hardening when they are machined. The source of the conclusion that strain hardening plays an insignificant role in metal cutting arises from the classical view that strain in a plastically deformed metal is uniformly distributed rather than being confined to certain planes. This matter will be considered in greater detail in the following discussion.

PRESENT THEORY OF METAL CUTTING

Before discussing the manner in which strain hardening may be introduced into cutting calculations, it may be well to review briefly the present theory of metal cutting that has been developed for the most part by Piispanen and Merchant. This theory is for cutting operations which produce a continuous chip with no built-up edge. The forces acting at the point of a two-dimensional cutting tool are shown in Fig. 3. If the chip above the shear plane (shown heavy) is taken as a free body, then forces R and R' must be equal if the negligible inertia force due to the change in velocity of the metal as it flows across the shear plane is ignored. Force R' is shown resolved into two sets of force components F_H and F_V, those which are normally measured with a cutting dynamometer; and F_S and N_S, those along and perpendicular to the shear plane. Force R is shown resolved into the friction and normal components on the tool face, F and N. Attention is drawn to angles α

[3] D. C. Drucker, J. App. Phys. 20, 1013–1021 (1949).
[4] E. G. Herbert, "Work Hardening Properties of Metals," Trans. ASME 48, 705–748 (1926).

(the rake angle), ϕ (the shear angle), and μ (the friction angle) which are defined in the figure. A velocity triangle is also shown in Fig. 3 where V_H is the absolute velocity of the tool, V_S is the velocity of the chip along the shear plane relative to the stationary work piece, and V_C is the velocity of the chip up the face of the tool.

For purposes of analysis, the shear and normal stresses may be considered constant across the shear plane although actually it is evident that this cannot be the case.[5] We may also ignore the fact that plastic deformation in the vicinity of the tool point may not be along the main shear plane but at a much greater angle of shear as is evident in Fig. 1.

Piispanen[1] and Merchant[2] have suggested that the shear stress to cause slip along the shear plane is influenced by the normal stress on the shear plane and given to a good approximation by the expression

$$\tau = \tau_0 + B\sigma \tag{1}$$

where τ_0 is the critical shear stress to cause slip in the absence of normal stress, σ is the normal stress on the shear plane, and B is a constant. Under certain conditions a dependence of critical shear stress or normal stress has been observed experimentally by Bridgman[6] for polycrystalline metals.

Both Piispanen[1] and Merchant[2] have applied the principle of minimum energy to the cutting process in order to relate the shear angle to other known variables. From the geometry of Fig. 3, it is evident that for a cut of unit width

$$F_H V_H = \tau d V_H \frac{\cos(\mu-\alpha)}{\sin\phi\cos(\phi+\mu-\alpha)} \tag{2}$$

where $F_H V_H$ is the rate at which work is expended in the cutting process. Equation (1) may be written

$$\tau = \tau_0 + B\tau\tan(\phi+\mu-\alpha) \tag{3}$$

and by combining Eqs. (2) and (3)

$$F_H V_H = \tau_0 d V_H \cdot \times \frac{\cos(\mu-\alpha)}{\sin\phi\cos(\phi+\tau-\alpha) - B\sin\phi\cos(\phi+\tau-\alpha)}. \tag{4}$$

Applying the principle of minimum energy by differentiating with respect to ϕ (considering μ constant[7]) and equating to zero gives

$$\cot(2\phi+\mu-\alpha) = B. \tag{5}$$

[5] In order that the shear plane correspond to a plane of maximum shear stress, it is necessary that at each point along the shear plane a compressive stress exist that is directed parallel to the shear plane and which is equal to the compressive stress acting normal to the shear plane. The compressive stress parallel to the shear plane will be zero at the free surface of the chip and have its maximum value at the end of the shear plane adjacent to the tool point.

[6] P. W. Bridgman, J. App. Phys. 14, 273–283 (1943).

[7] Drucker (see reference 3) has pointed out that in this step μ has been considered independent of ϕ but it is not at all clear that this is so.

This equation which relates the shear, friction, and rake angles to the slope of the shear stress-normal stress curve (B) will be discussed later.

STRAIN HARDENING

As already mentioned when metal is cut at a temperature sufficiently below its melting point, it shears in blocks rather than uniformly. Under ordinary conditions, the shear planes will be very closely spaced corresponding to the closeness of spacing of the weak spots in the metal. It may be assumed that slip planes are so spaced that a single weak spot is present on each plane. Drucker[3] has recently employed a random array of weak points to qualitatively demonstrate the increase in unit cutting energy with decrease in depth of cut. However, inasmuch as the spacing of weak

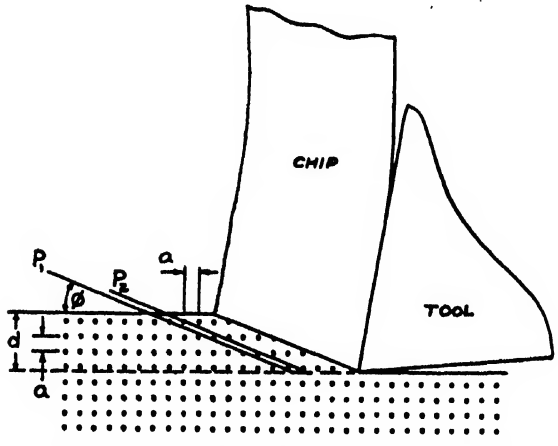

FIG. 4. Specimen with uniform array of weak spots.

points is very small compared with usual depths of cut, an orderly array of weak spots seems justified. The dots shown in Fig. 4 represent such an orderly arrangement of weak points to an exaggerated scale. These points have a uniform spacing of a units in each direction.

Let P_1 and P_2 be two shear planes making an angle ϕ with the direction of cut and passing through adjacent points in the first row below the surface. If the depth of cut is d, then d/a planes may be placed between those at P_1 and P_2 such that a single plane passes through each weak spot in the layer in the process of being cut. The number of planes per inch in a direction perpendicular to the shear plane will be

$$n = \frac{d}{a(a\sin\phi)} \tag{6}$$

or the spacing of successive planes is

$$y = \frac{a^2\sin\phi}{d}. \tag{7}$$

The total slip on a given shear plane will be

$$x=\frac{a^2\sin\phi}{d}\gamma \tag{8}$$

where γ is the unit uniform strain which from Figs. 1 and 3 may be shown to be

$$\gamma=\cot\phi+\tan(\phi-\alpha). \tag{9}$$

Need now exists for data concerning the manner in which shear stress is related to shear strain. As a guide to the nature of a relation which might be assumed the so-called true stress-strain curves for metals tested in direct tension may be considered. A representative curve of this type is shown in Fig. 5. Such curves are characterized by a linear elastic region from 0 to P_1 and a less steep nearly linear plastic region extending from P_2 to the breaking point P_3. For purposes of analysis involving large strains (as in metal cutting), the curve shown dotted may be substituted for the actual diagram. Thus, according to this approximation, a critical stress σ_0 exists below which there is no plastic flow, and the stress required to produce a given strain increases linearly with the strain. The slope of this curve represents the best known measure of the tendency of a metal to strain harden.

A diagram similar to that of Fig. 5 is obtained if shear stress is plotted against shear strain. Such a diagram is shown in Fig. 6 with total shear strain x as the abscissa rather than unit strain. The critical shear stress to initiate slip is τ_0' while the slope of the curve is represented by the symbol A in the following discussion. Point P_3 is the point at which slip on a given plane ceases. Following Piispanen and Merchant we may assume that τ_0' is influenced linearly by normal stress as follows

$$\tau_0'=\tau_0+B\sigma. \tag{10}$$

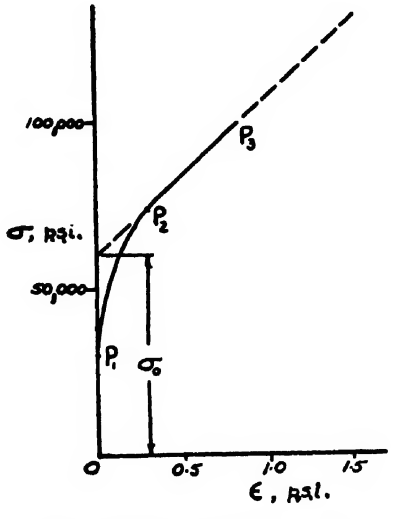

FIG. 5. True stress-strain diagram.

It is then evident that the mean shear stress during slip is

$$\tau=\tau_0+B\sigma+(Ax/2) \tag{11}$$

or from Eqs. (8) and (9)

$$\tau=\tau_0+B\sigma+\frac{Aa^2\sin\phi}{2d}[\cot\phi+\tan(\phi-\alpha)]. \tag{12}$$

This equation differs from that employed by Piispanen and Merchant by the inclusion of the last term on the right which introduces the effect of strain hardening and the inhomogeneity of the metal cut. It is interesting to note that the slope of the stress-strain curve (A) and the spacing of weak points (a) appear in the equation only in the form of the product Aa^2. This product may thus be considered a new constant of the material which measures its tendency to strain harden during shear flow. For a given material the strain hardening effect is seen to increase linearly with the unit uniform strain γ which the chip undergoes (the quantity in brackets in Eq. (12)), and inversely with the first power of the depth of cut d.

The most convenient method of evaluating the constants τ_0, Aa^2, and B for a given metal is from cutting data obtained by use of a tool dynamometer. While theoretically the data from but three different cuts would be sufficient to enable these constants to be determined, actually it is advisable to use from 10 to 20 points so that probability may tend to neutralize the effect of the natural scatter in the data due to long range in homogeneity of metal cut and other causes.

FIRST EXAMPLE

In order to illustrate the method of evaluating the three constants from cutting tests, some data previously published by Merchant[2] will be considered. In these tests a particular specimen of NE9445 steel having a Brinell hardness of 187 was cut with a carbide tool. The workpiece was in the form of a tube so as to give a simple two-dimensional cut when the tool was fed axially against the end of the tube. The chips produced were in the form of a continuous ribbon, the condition on which the foregoing analysis is based. The data obtained for a range of cutting speed, depth of cut and rake angle are summarized in Table I. Merchant plotted these data in accordance with Eq. (1) to obtain Fig. 7. The values of τ and B obtained from this plot were 58,000 lb./in.^{2} and 0.23 respectively, corresponding to the solid line.

These same data may be replotted in accordance with Eq. (12) developed here. For this purpose it is convenient to rearrange the equation as follows

$$\tau-B\sigma=Aa^2[\cot\phi+\tan(\phi-\alpha)]\frac{\sin\phi}{2d}+\tau_0$$

$$=Aa^2\left(\frac{\gamma\sin\phi}{2d}\right)+\tau_0, \tag{13}$$

where it is evident that a straight line of slope Aa^2 and intercept τ_0 will be obtained when the quantity $(\tau - B\sigma)$ is plotted against $(\gamma \sin\phi)/2d$. Such a plot could be readily obtained from the data of Table I if B were known. A procedure which may be followed in the absence of this value is to assume successive values of B and obtain a series of plots. The line best fitting the data points corresponds to the value of B to be adopted. A series of plots obtained in this manner is shown in Fig. 8 for values of B of 0, 0.05, 0.1, 0.2 and Merchant's value of 0.23 which of course should be a horizontal line. The foregoing procedure of plotting a series of curves involves less work than it might appear at first glance due to the ease of obtaining successive curves from the one first plotted.

It would appear from Fig. 8 that the curve best fitting the data points corresponds to a B of 0.05 and the corresponding equation for shear stress may be written

$$\tau = 80{,}000 + 0.05\sigma + 29\frac{\gamma \sin\phi}{2d}, \text{ p.s.i.} \qquad (14)$$

In considering which value of B best fits the data points, special attention should be given those points corresponding to high and low depths of cut. Data corresponding to a greater range of depth of cut will enable a more decisive choice of the correct value of B. The value of B in Eq. (14) is seen to be far less than that in Merchant's analysis and in better agreement with the value of 0.125 directly observed by Bridgman[6] for drill rod. It would thus appear that much of the effect which Merchant has attributed to normal stress on the shear plane is actually due to strain hardening and the inhomogeneity of the metal cut.

Merchant[2] has plotted directly measured values of ϕ against the quantity $(\mu - \alpha)$ from Eq. (5) in which B is taken equal to 0.23. This plot corresponds to the solid line in Fig. 9. If Eq. (12) including the effect of strain hardening is substituted for Eq. (1) in the derivation leading to Eq. (5) it is found that for minimum energy

3.70	400	−10	16.5	3.9	0.64	153	89	342
3.70	637	−10	19.0	3.5	0.58	152	90	311
3.70	1160	−10	22.0	3.1	0.51	154	94	289
1.09	542	10	19.0	3.1	1.12	164	103	308
2.34	542	10	18.5	3.1	1.08	140	92	287
3.70	542	10	21.5	2.7	0.96	131	91	248
7.88	542	10	25.0	2.4	0.76	116	89	214
1.09	542	−10	12.5	5.0	0.78	179	103	523
2.34	542	−10	16.0	4.0	0.70	172	96	385
3.70	542	−10	19.0	3.5	0.60	164	94	306
7.88	542	−10	22.5	3.1	0.46	138	90	270

(again considering μ to be independent of ϕ)

$$\cot[\cot^{-1}(B) - \phi - \mu + \alpha] = \cot\phi - \frac{\tan(\phi-\alpha)\tan\phi\sin(2\phi-\alpha)}{\cos\alpha\left(1+\frac{2d\tau_0}{Aa^2}\right)}. \qquad (15)$$

This is seen to reduce to Eq. (5) if strain hardening is ignored (i.e., when $Aa^2 = 0$). For most applications the last term on the right side of Eq. (15) is negligible and Eq. (15) reduces to Eq. (5). The strain hardening term will be important only when the quantity $(d\tau_0)/(Aa^2)$ is small, i.e., if Aa^2 is large, the depth of cut is very small as in grinding, or the material has a low critical shear stress τ_0.

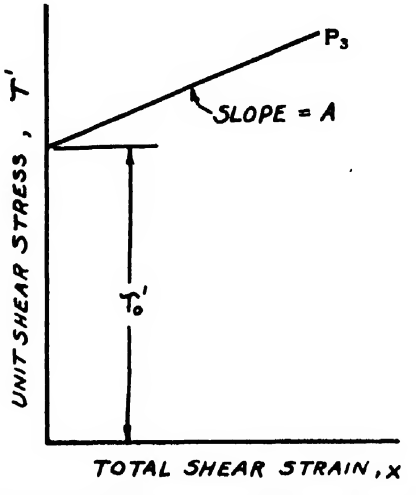

FIG. 6. Unit shear stress-total shear strain diagram.

Equation (15) has been used to obtain the dotted curve shown in Fig. 9. In this instance the second term

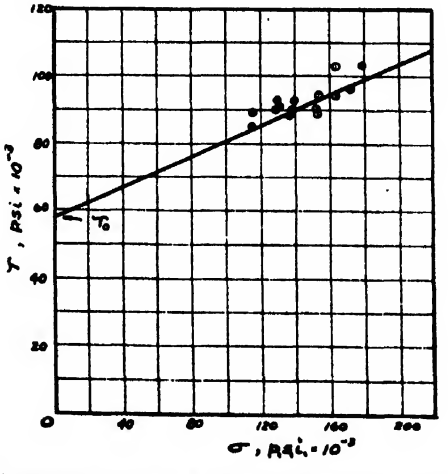

FIG. 7. Relation between shear strength and normal stress for cutting data of Table I.

on the right is negligible. It is evident that the dotted curve does not fit the data as well as the solid curve but this observation is not thought very significant in view of the following approximations of the theory leading to Eqs. (5) and (15).

1. The influence of temperature upon τ_0 has been ignored. This effect is apt to be quite significant since in practice the mean temperature along the shear plane is quite high. The effect of temperature is to cause a decrease in the value of ϕ obtained from Eqs. (5) or (15). The inclusion of the temperature effect would thus tend to lower both curves of Fig. 9, bringing the dotted line into better agreement with the experimental points but the solid line into poorer agreement.

2. The coefficient of friction has been considered independent of the shear angle in the foregoing analysis. It is not known how significant this approximation is but it may be observed that a decrease in the coefficient of friction that accompanies the use of an effective cutting fluid causes an appreciable increase in the angle ϕ. Conversely, it is to be expected that a change in ϕ will be accompanied by a change in μ. This point

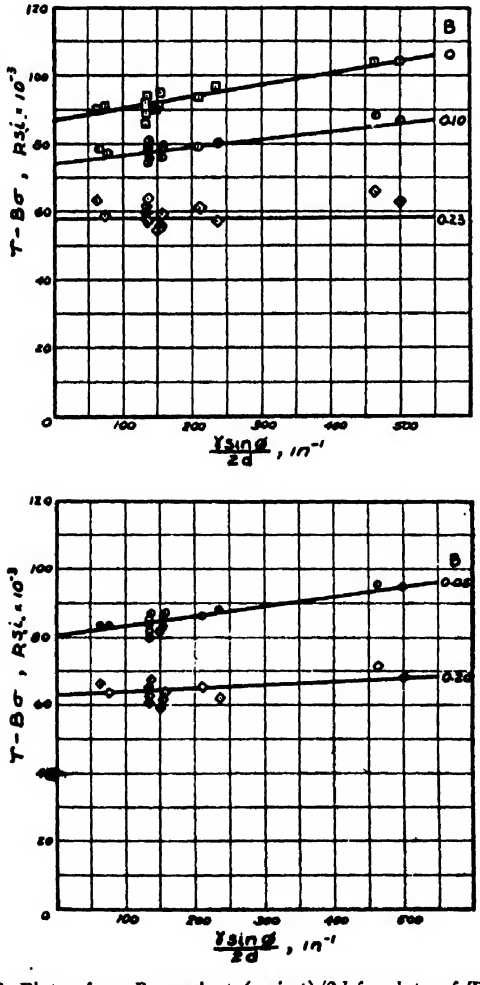

FIG. 8. Plots of $\tau - B\sigma$ against $(\gamma \sin\phi)/2d$ for data of Table I.

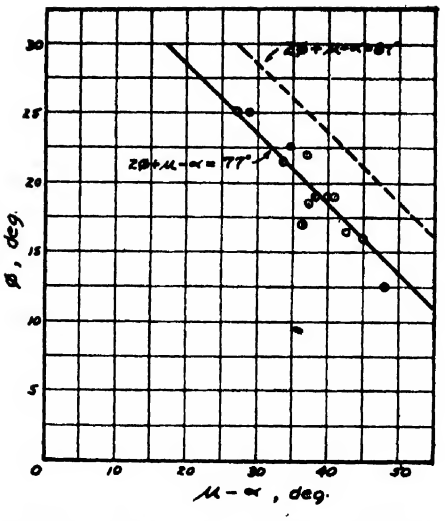

FIG. 9. Plot of ϕ against $\mu - \alpha$ for data of Table I.

places the portion of the analysis leading to Eqs. (5) and (15) in question.

3. The effect upon τ_0 of the change in the rate of strain with ϕ has been ignored in the derivation of Eqs. (5) and (15). If this effect were included, it would also cause the dotted and solid curves of Fig. 9 to be lower. However, it is unlikely that this effect would be significant inasmuch as the rate of strain is always at a very high level in metal cutting. As is evident in Fig. 1, the metal goes from an essentially unstrained condition to the fully strained condition in the very short time it takes to traverse the shear plane. Theoretically this would correspond to an infinite rate of strain were the shear plane a truly mathematical surface of zero thickness.

The position of the solid curve in Fig. 9 is significantly influenced by the choice of curve in Fig. 7. In this instance it would appear that the points in Fig. 7 call for a line of considerably less slope which would tend to shift the solid line of Fig. 9 in the direction of the dotted line.

SECOND EXAMPLE

Results of a series of tests were recently published[8] in which seamless tubing of 6 inch diameter and 0.475 inch wall thickness was cut using two-dimensional high speed steel tools having rake angles ranging from 25 to 45°. The steel was cut under conditions to prevent the formation of a built-up edge at a speed of 90 feet per minute. It is interesting to examine these data which are summarized in Table II from the point of view of the foregoing theory.

In accordance with Merchant's theory, the relation of shear strength to normal stress is first considered (Fig. 10). In this instance it is quite difficult to know

[8] Lapsley, Grassi, and Thomsen, "Correlation of Plastic Deformation during Metal Cutting with Tensile Properties of the Work Material, ASME Preprint No. 49-A-121 (December, 1949).

just where to draw the line, there being apparently two possibilities—the line shown solid and that shown dotted. The data are next shown plotted in Fig. 11 in accordance with the strain hardening theory presented here. Only the curve corresponding to $B=0$ is shown inasmuch as other values of B investigated gave points which fitted a straight line less closely than that for $B=0$. The solid line shown corresponds to the equation

$$\tau = 52{,}000 + 153(\gamma \sin\phi)/2d, \text{ p.s.i.} \qquad (16)$$

In the third figure of this series (Fig. 12) the observed values of ϕ are shown plotted against the quantity $(\mu-\alpha)$. Equation (15) again reduces to Eq. (5) since the strain hardening term is negligible. The relation based on strain hardening theory is given by the dash line in Fig. 12 while the relation predicted by Merchant's theory (corresponding to the solid line in Fig. 10) is shown solid. If the dotted line in Fig. 10 is used, the dotted line of Fig. 12 is obtained. The line in Fig. 12 corresponding to strain hardening theory is seen to be in good agreement with the data for tools of high rake angle, but the data for the 25° rake angle tool lies below the curve as in the example of the previous section and probably for the same reasons

DISCUSSION

Drucker[3] has considered the fact that essentially all of the strain which occurs in the cutting process takes place as the material crosses the shear plane at approximately a constant shear stress to be a paradoxical result. He concludes that this can only mean that the metal behaves as an ideal plastic which strains without strain hardening ($A=0$). This is a natural conclusion when viewed from the classical point of view where the metal is considered to strain uniformly. However, while there is no appreciable spatial change in shear stress in the vicinity of the shear plane, there is a significant temporal

* See reference 8.

change. The shear stress on the shear plane is not constant with time but increases as slip proceeds due to strain hardening. This variation in shear stress would give rise to a variable shearing force which could be detected with a very sensitive dynamometer of high frequency response were it not for the fact that the process of slip is in varying phases of completion at different points across the chip. This may be seen by examining the back surface of a chip where the edges of certain slip planes are evident as wavy rather than straight lines extending across the chip in a direction perpendicular to the direction of cut. The slip process is thus not quite as simple as the sliding of cards one over the other, but the actual process appears to involve the propagation of screw type as well as edge type dislocations.

The stress concentration associated with a sharp tool point is largely responsible for the fact that strain occurs essentially on only one plane at a time. In this

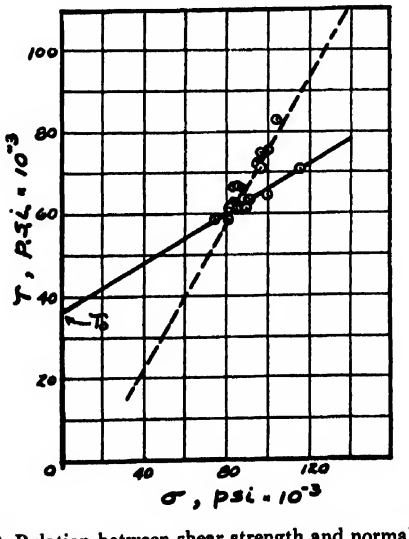

FIG. 10. Relation between shear strength and normal stress for cutting data of Table II.

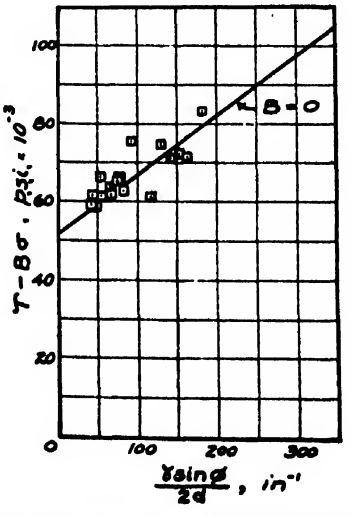

FIG. 11. Plot of $\tau - B\sigma$ against $(\gamma \sin\phi)/2d$ for data of Table II.

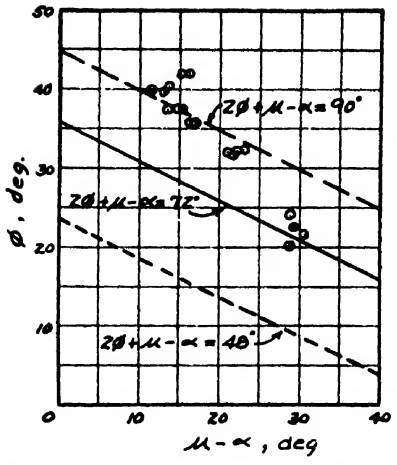

FIG. 12. Plot of ϕ against $\mu-\alpha$ for data of Table II.

respect the cutting process differs from all others in the field of plastic flow. For example, in the ordinary tensile test, strain occurs simultaneously upon many planes as the load is progressively increased. The concept of a homogeneous strain is not so serious in such applications as in the case of the cutting process. However, it would appear that even in such problems it is advantageous to adopt the quantized picture of strain which will enable a size effect to be included in the quantitative theory just as the effect of the depth of cut was included in the foregoing theory of metal cutting.

In Table II it is evident that the shear work to remove a cubic inch of metal increases with decreased depth of cut. This is particularly true for the data obtained with the 25° rake angle tool. The strain hardening theory explains this observation. The shear work for this metal may be obtained by use of Eq. (16) as follows

$$W_S = \tau\gamma = 52{,}000\gamma + 153(\gamma^2 \sin\phi)/2d, \text{ in.-lb./in.}^3. \quad (17)$$

From this expression it is evident that the specific shear work is increased with an increase of shear strain γ or a decrease of depth of cut d. The experimental values of W_S given in Table II are in agreement not only with the observation concerning the influence of depth of cut but also shear strain. The specific work is seen to increase as the rake angle α is decreased, the main reason for this being the increase in strain associated with the decrease in rake angle.

CONCLUSIONS

As the basic metal cutting process becomes better understood, the gap between our well-known materials tests and the metal cutting operation is narrowed. The simple two dimensional machining operation is seen to provide means for conducting materials tests that are now carried out only with considerable difficulty. Specifically the cutting test offers a very convenient method for determining the dynamic shear strength of metals since the inherent feature of this process is to allow shear on approximately one plane at a time thus naturally providing very high rates of strain. Correspondingly high rates of strain are obtained in the ordinary tensile test only with considerable difficulty and uncertainty due to inertia effects. Furthermore the characteristics of the cutting process enable tests to be carried to strains that are considerably higher than those in the usual tensile test. The simplicity of the test apparatus and the fact that a specially shaped specimen need not be prepared are additional factors of interest. While the tensile test has a superficial appearance of simplicity, a little study will reveal that this process may even at present be less completely understood than the cutting process. It would therefore not be surprising to one day find the simple two-dimensional cutting process in use in materials laboratories engaged not alone in machinability studies but also in use in evaluating the basic physical properties of metals.

Mechanical and Electrical Properties of Plasticized Vinyl Chloride Compositions*

LAWRENCE E. NIELSEN, ROLF BUCHDAHL, AND RITA LEVREAULT
Plastics Division, Monsanto Chemical Company, Springfield, Massachusetts

(Received January 24, 1950)

The temperature dependence of the dynamic mechanical and a.c. electrical properties of a given polyvinyl chloride plasticizer composition can be characterized by two quantities: (a) the transition temperature which is defined as the temperature of maximum dissipation factor and (b) the half-widths of the loss factor-temperature curve. A simple relationship exists between the transition temperature determined mechanically or electrically and the volume fraction of a compatible plasticizer. The modification of this relationship for non-compatible plasticizer has been indicated. The half-width is a function of the volume fraction of the plasticizer, although this relationship is not as simple as the one obtained for the transition temperature. A simple correlation exists between the electrical and mechanical half-width. The compliance measured in tensile creep has been found to be a function of the applied load and the compliance-load relationship varies depending on the region in which the material finds itself. The shape of the creep curve at different temperatures has been correlated with the dissipation factor-temperature curve. The shape of the stress-strain curve has been related to the modulus-temperature curve and a correlation between the initial Young's modulus and the ultimate elongation and breaking strength has been established. It has been shown that the relaxation theory is not sufficient to explain certain features of the modulus (or dissipation factor) temperature relationship. The limited significance of the μ-value and of the viscosity of plasticizers with respect to plasticizer efficiency has been demonstrated.

INTRODUCTION

THE mechanical properties of plasticizer-polymer systems in the solid state have been the subject of several investigations.[1–4] As a result of such work, it has been possible to draw the following conclusions concerning the effect of plasticizer concentration and type of plasticizer on these properties: (1) the addition of plasticizer always lowers and broadens the transition or softening region compared to the unplasticized resin; (2) plasticizers differ in their effectiveness to lower and broaden the transition region.** Several attempts have been made to interpret these data in terms of other physical quantities. For example, Jones[5] tried to show that the viscosity and the viscosity temperature coefficient of the plasticizer are significant quantities determining plasticizer efficiency, or the transition range of plasticizer-polymer systems. On the other hand, Boyer and Spencer[6] have derived an expression for the flex or second-order transition temperature as a function of polymer concentration, assuming that this temperature corresponds to an isoelastic or isoviscous state of this system, and second, making use of the Flory equation of viscous flow. The same authors have also suggested[6] that the reason for the difference in kind of plasticizers might be due to the difference in μ-value for different plasticizers in various polymers. The importance of plasticizer-resin interaction has also been pointed out by Aiken[4] in interpreting the very different creep curves which one obtains for polyvinyl chloride-plasticizer systems. Alfrey[7] has tried to show that the creep data support in general his relaxation theory of viscoelastic deformations of linear high polymers. However, the experimental data available until now are neither extensive nor precise enough to permit a proper evaluation of the proposed mechanism of plasticizer action. It was, therefore, one of the major objectives of this work to undertake a systematic study of various mechanical properties, such as the dynamic modulus and dissipation factor, stress-strain relationships and creep, over a wide temperature range as a function of plasticizer concentration and type of plasticizer, in order to obtain more definite information concerning the dependence of these properties on the above-stated variables. In Table I are shown the various plasticizers used, and it will be noted that all of them, with the exception of di-lauryl phthalate, are commonly referred to as solvent-type plasticizers; such generalizations, which will be permissible on the basis of the results obtained, apply, therefore, primarily to this type of plasticizer, although some characteristic effects of non-solvent type plasticizers will be considered. In order to study the significance of the μ-value on plasticizer action, without changing the functional groups of the molecule, five different phthalate plasticizers were chosen, covering a μ-value range in polyvinyl chloride from -0.1 to $+1.4$.[8]

The a.c. electrical properties of plasticizer-polymer systems have been studied by several investigators;[9–11]

the work of Fuoss,[11] in particular, has given us extensive data concerning the dependence of the dielectric constant and the power factor on temperature, on plasticizer concentration and type of plasticizer. However, the theoretical interpretation of such data on the basis of a simple relaxation mechanism has not been too successful.[12] It was hoped, therefore, that a simultaneous investigation of the electrical and mechanical properties *on identical samples* might aid in the clarification of the plasticizer mechanism in general, particularly as a close qualitative correlation between the electrical and mechanical properties of plasticizer systems had been suggested in the past.[13]

EXPERIMENTAL DETAILS

Preparation and Composition of Specimens

A polyvinyl chloride of fine particle size, having an intrinsic viscosity of about one in cyclohexanol, was used in the preparation of all specimens. The volume and mole fractions of all the compositions used and the density of the resin and the plasticizers are given in Table I, columns 3, 4, and 5, respectively. The preparation of all test specimens was carried out according to the following procedure. The resin, the plasticizer, and a small amount of tribase stabilizer (two percent based on the amount of the resin used) were weighed out separately and mixed together by hand. The mix was then transferred to a two-roll mill and was milled for not longer than 10 min. at a temperature varying between 265° and 280°F. The mix was taken off the mill, cut into small pieces, and specimens of various thickness were compression-molded to the required dimensions using, as much as possible, the same molding cycle throughout.

Instruments and Testing Procedures

The dynamic mechanical properties were measured using a torsion pendulum, with the exception of a few measurements on unplasticized polyvinyl chloride, which were carried out with a vibrating reed-type instrument.[14] The rectangular test strip ($2\times\frac{3}{8}\times0.025$ in.) is part of the pendulum, see Fig. 1. The dynamic modulus is calculated from the frequency of the free vibration and the dimensions of the specimens, and the damping is determined from the logarithmic decrement of the vibration. Actually, the frequency and the damping are measured as a function of the load attached to the lower end of the specimen and all data given are extrapolated to zero load. The temperature of the instrument is controlled by an air bath, having a temperature variation of about ±0.5°C. The frequency of the vibration can be varied by a factor of 10, using different disks giving the system different moments of inertia. The precision of the shear modulus and logarithmic decrement values is ±5 and ±10 percent, respectively, provided the damping is not too high; as the damping increases the precision of the measurement decreases.

The tensile creep was measured by clamping both ends of the strip, applying a fixed load to the lower clamp and following the separation of two inked lines on the sample with a cathetometer as a function of time. The sample, but not the load, was surrounded by an air bath, controlled within ±0.5°C. A difference of 0.005 cm in length could be measured with the cathetometer. In general, the creep data could be reproduced within ±5 percent, except in the transition region, provided a new sample was used in the repeat run. It was found that the previous history definitely affected the absolute value of the creep and the shape of the creep

curves; however, no systematic study was made of this phenomenon.

The stress-strain properties were measured on an Instron machine† at 25°C and 50 percent relative humidity. For each composition five separate runs were made; the variations in Young's modulus, determined graphically from the initial slope of the stress-strain curve, and the tensile strength are less than 10 percent, but the variations in elongation at break were at times as much as 100 percent for the same composition.

A 5-sec. modulus was measured with a torsional instrument, first described by Clash and Berg.[15] The specimen, which consists of a narrow strip immersed in a liquid bath of constant temperature, is held rigidly at the lower end, whereas the upper end is attached to a rod to which a known torque can be applied. The angular deflection after 5 sec. is noticed and Young's modulus is calculated knowing the torque, the angle of twist, and the dimension of the specimen, using a Poisson ratio of 0.5 to convert from shear to Young's modulus. Shore hardness was measured by the indentation and/or the penetration of a needle-type point under usually variable load into the surface of the plastic composition. The viscosity of the plasticizers was measured with a capillary viscosimeter of the Ostwald-Fenske type. The viscosimeters were immersed in a liquid bath controlled to ±1°C.

The dielectric constant and power factor were measured for all compositions at 1000 c.p.s. as a function of temperature. The measurements were made with a General Radio capacitance bridge using circular specimens, and the surfaces of each specimen was painted with a du Pont silver electrode paint. For a few compositions measurements were also made at 500 and 10,000 c.p.s. The d.c. resistance was measured with a General Radio resistance bridge using General Electric type electrodes. The precision of these measurements was at best ±15 percent, but in many cases it was much poorer because of the high resistance of the samples, which approached frequently the upper limit of sensitivity of the instrument. For all electrical measurements the samples were immersed in an air bath controlled to ±0.5°C.

RESULTS

Figures 2 and 3 show some typical log modulus and dissipation factor data as a function of temperature for various plasticized compositions. Within a certain temperature range the modulus is high, of the order of magnitude of 10^{10} dynes/cm^2, whereas in the higher temperature range the modulus is low, of the order of magnitude of 5×10^7 dynes/cm^2. These two regions, the hard and the rubbery one, are joined by a third one where the modulus changes strongly in a relatively narrow temperature range and this range can be called the transition region. The dissipation factor, or damping,‡ also changes with temperature in a characteristic manner; the damping is low and fairly insensitive to temperature in the hard and the rubbery region, and goes through a definite maximum in the transition region. In the hard and rubbery region the modulus and the damping factor approach a constant value which is fairly independent of plasticizer and plasticizer concentration. It is clear, therefore, that these curves can be characterized quite satisfactorily by two constants, the transition temperature and the half-width.[16] The transition temperature is defined as the temperature where the dissipation factor has its maximum, or where the log modulus-temperature curve goes through an inflection point. The use of transition temperature, as defined above, to characterize the transition region is to be preferred to other temperatures (flex temperature, brittleness, etc.) for the following reasons: (a) it is not an arbitrarily defined quantity, as many of the other temperature values; (b) it is independent of the half-width, and (c) it leads to a simpler relationship with the amount of plasticizer than do the other quantities. The half-width is defined as the temperature difference in degrees centigrade where the dissipation factor has reached half its maximum value. Columns 5

and 7 of Table I give the transition temperature and the half-width of all compositions. In a few cases it was not possible to determine the half-width with any degree of reliability, because the absolute value of the maximum could not be determined. In these cases the half-width given is the best estimate possible. Figure 4 shows the dielectric constant and loss factor as a function of temperature for various plasticized compositions. Here again it is possible to characterize these curves by two constants, namely the transition temperature and the half-width. Columns 6 and 8 of Table I show these two quantities for all compositions.

The dependence of the mechanical and electrical transition temperature on plasticizer concentration turns out to be a very simple one, as can be seen from Figs. 5 and 6. For all the plasticizers investigated, with the exception of dilauryl phthalate, which will be discussed later, the transition temperature is a linear function of the volume fraction (c_v) of the plasticizer. For four members of the phthalate homologous series the slope of the $T_t - c_v$ curve is the same, whereas the slope is different for tricresyl phosphate and dibutyl sebacate. The concentration dependence of T_t is independent of frequency, but the absolute value of T_t is dependent on frequency. Finally, it should be pointed out that the transition temperature as a function of the mole fraction of the plasticizer yields a non-linear relationship between these two quantities and also different curves for each plasticizer.

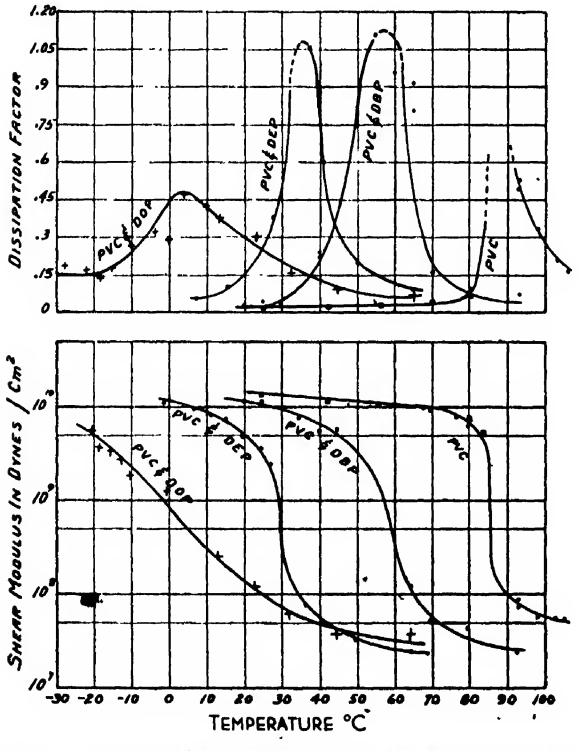

FIG. 2. Dynamic shear modulus and dissipation factor as a function of temperature. 0.158 DBP+PVC; 0.254 DEP+PVC; 0.402 DOP+PVC; PVC without plasticizer (number gives volume fraction).

The dependence of the half-width of the electrical power factor-temperature curve on plasticizer and plasticizer concentration is shown in Fig. 7. The half-width first increases with plasticizer concentration, goes through a maximum at about 0.5 c_v, and then appears to decrease again. For a given plasticizer concentration the half-width increases with increasing chain lengths of the mechanical dissipation factor. It was not possible to determine the relationship between the mechanical half-width and plasticizer concentration with the same accuracy as in the electrical case. However, a correlation between the electrical and mechanical dissipation factors shown in Fig. 8 suggests very strongly that the same conclusions arrived at in the electrical case also hold for the mechanical dissipation factor. It should also be noted that the mechanical dissipation factor is always smaller than the corresponding electrical dissipation factor.

The most interesting feature of stress-strain curves of plasticized polyvinyl chloride compositions (Fig. 9) is the wide difference in the shape of the stress-strain curve as a function of plasticizer and plasticizer concentration. Some stress-strain curves show a definite yield point; in other cases the stress increases rapidly and then remains almost constant over a considerable elongation range before the sample breaks. A more careful analysis of the data shows that the shape of the curves is closely related to the region in which the sample finds itself: in the hard region the slope of the stress-strain curve is very steep and frequently followed by a yield value before break; in the transition region the stress-strain curve slopes strongly, followed by a very flat region with an indefinite yield point, whereas in the rubbery region the stress-strain curve has a small slope which changes little over a very wide range of elongation. The relationship between initial Young's modulus and (a) elongation at break and (b) the tensile strength is shown in Fig. 10. Figure 11 shows the ultimate elongation as a function of the volume fraction of plasticizer; although a slight difference seems to exist for various plasticizers, the number of tests and the precision of the elongation measurement do not justify putting too much emphasis on these differences, and, to a first approximation, one can conclude that the ultimate elongation is very small up to a critical plasticizer concentration at a given temperature and then increases linearly with concentration, irrespective of the type of plasticizer employed. Column 9, Table I gives the ratio of the initial Young's modulus, obtained from the stress-strain curve, to the corresponding dynamic shear modulus obtained with the torsion pendulum, both measured at 25°C.

In studying the creep properties of the various compositions listed in Table I, it was found (a) that repeated creep and recovery runs on the same sample

changed the creep properties of the specimen[17] and (b) that the compliance is a function of the applied stress.[4] As a matter of fact, the relationship between load and compliance appears to show significant differences depending on the region in which the material finds itself. In the hard region an increase in the load shifts the compliance-log time curve along the compliance axis toward higher values. In the transition region the slope of the compliance-log time curve decreases with increasing load and in the rubbery range the reverse appears to be true. For these reasons, it seemed more reasonable to study the creep at small and similar elongations by varying the load correspondingly. Some typical results obtained in this manner are shown in Figs. 12 and 13. In the rubbery region the initial elongation is very large, and then changes only slightly with time.§ As one approaches the transition region, the initial elongation becomes less and the change in elongation with time is quite pronounced. In the hard region the change of elongation with time becomes very small, although very few reliable experiments were carried out in this range. In other words, "the curvature" of the elongation-time curve increases as the material proceeds from the rubbery to the transition range and then decreases again going from the transition to the hard region and does not seem to depend very much on the type or amount of plasticizer. Therefore, if one plots the difference in delayed and instantaneous creep as a function of temperature, which was first suggested by Conant and Liska,[18] one obtains a curve very similar to the dissipation factor-temperature curve shown previously and the temperatures of the maxima of both curves are identical. It is believed that the similarity of these two sets of data is more than a coincidence.

The d.c. resistance of the plasticized compositions and of some of the plasticizers was measured as a function of temperature. Over a rather limited temperature range the dependence of the resistance on temperature can be represented by the usual exponential relationships and the slopes of the $\log R - 1/T$ curves which can be represented as an energy of activation, are given in column 10 of Table I. It will be noticed that this quantity increases in all cases with plasticizer concentration, and shows wide variations for different plasticizers at about equal concentration. It should be pointed out, however, that the experimental precision of these measurements was not good enough to establish whether or not the resistance changed in a similar manner as the modulus with changing temperature.

Clash-Berg data and Shore hardness values were

obtained as a function of temperature. The shape of the static 5-sec. modulus temperature curve is the same as that for the dynamic modulus temperature curve and the $T_t - c_v$ curves are identical with those shown in Fig. 5, but the absolute values differ by a constant factor. The correlation between Shore hardness and moduli data is not very satisfactory. This is in agreement with previous work on similar compounds[19] and shows the limited usefulness of Shore hardness data to determine moduli of plasticized compositions.

DISCUSSION

During the last few years, several suggestions have been made concerning the mechanism of plasticization; in most cases, these considerations have been concerned with plasticizer efficiency as measured, for example, by the transition temperature, whereas the half-width, or range of plasticization, has not been considered to any great extent. It is the purpose of this section to consider these theoretical attempts in the light of the data presented above.

It has been suggested that the viscosity[5] and the temperature coefficient of the viscosity of plasticizers are of major importance with respect to plasticizer efficiency. However, if the plasticizer efficiency is measured in terms of the transition temperature, then the data given above certainly do not support this contention; see also column 11, Table I. Furthermore, no significant correlation could be established between the temperature coefficient of the viscosity and the temperature dependence of the modulus (or the half-width of the damping curve) in the transition region. Other investigators[6] have tried to show a correlation between the compatibility and plasticizer efficiency; they suggest that the efficiency goes through a maximum as a function of the thermodynamic μ-value. However, it has been shown here that, at least for the first eight members of the homologous phthalate series, the transition temperature is completely independent of the μ-value of the different plasticizers. Furthermore, it is not possible to establish a satisfactory correlation between the μ-value and the slope of the transition temperature-volume fraction curve, not only for the plasticizers studied in this investigation but also for other plasticizer-resin systems reported by other investigators. Nevertheless, the deviation of dilauryl phthalate from the $T_t - c_v$ relationship for all other phthalate plasticizers suggests that the compabitility has some bearing on the transition temperature. Recent investigations[20,21] have brought out rather clearly the relationship between compatibility and plasticizer efficiency: to the extent that the plasticizer is compatible

with the resin, the dependence of the transition temperature on the volume fraction of the plasticizer is within the same range as the data given above. Beyond, what might be called a critical concentration, the transition temperature then remains essentially unchanged as more of the incompatible plasticizer is added to the resin. In other words, as the plasticizer becomes incompatible with the resin it has only a negligible effect on lowering the transition temperature, that is the plasticizer efficiency approaches zero.|| Neither does there exist a close correlation between the half-widths, at equal volume concentration, and the μ-value; it rather appears, on the basis of the data shown in Fig. 7 that the half-width increases with increasing chain length of plasticizers belonging to a homologous series.

Based on the analogy between the a.c. electrical properties and the dynamic mechanical properties, it has been suggested at various times that the mechanical properties of plasticized polymeric systems can be interpreted on the basis of a simple relaxation theory. Assuming such a mechanism, Alfrey[22] has derived an

expression for the compliance as a function of time (or frequency) and molecular weight. If one now considers the transition temperature as an indication of an isoelastic state, one can then derive an expression for the transition temperature as a function of plasticizer concentration, with the result that the reciprocal of the absolute transition temperature must be proportional to the square root of the weight average molecular weight of the mixture. The same relationship has been obtained by Boyer and Spencer,[6] without using Alfrey's compliance equation, by applying Flory's equation of viscous flow of liquid polymers[23] to the transition region in the solid state. A plot of the reciprocal of the absolute transition temperature as a function of the square root of the weight fraction (w_f)** shows that the relationship is more or less linear, although the value for the unplasticized resin does not fall on the linear portion of

the curve. The square root dependence is due, in both cases, to the use of Flory's equation which, as a result of recent investigations on polystyrene and polyisobutylene, will require some modification.††

Figure 14 shows the transition temperature as a function of the frequency in c.p.s. for several plasticized compositions; the transition temperature changes slowly with frequency, as would be expected on the basis of the relaxation theory. The shape of the curve suggests a very broad relaxation spectrum which has been found to exist for rubber compounds,[24] when investigated over a wide frequency range. However, the frequency dependence of T_t is smaller in the mechanical case than in the electrical.

By and large then, these data could be used to argue in favor of the validity of a relaxation theory were it not for another very important experimental fact, which is the very strong temperature dependence of the modulus or the loss factor in the transition region. It will be recalled that the modulus changes by a factor of 500 to 1000 over a temperature range of 20° to 30°C. This would correspond to an activation energy of the order of 100 kcal. or more, and it is very difficult, if

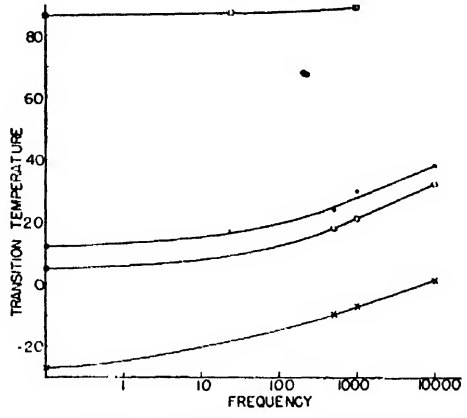

FIG. 14. Transition temperature as a function of frequency. □ unplasticized PVC; ● 0.443 TCP; ○ 0.403 DOP; ⊙ 0.458 DBS.

not altogether impossible, to explain such a high activation energy in terms of a relaxation mechanism. In this connection it seems worth while to point out that the half-width, which is a measure of the temperature dependence in the transition region, is always larger in the electrical case than in the mechanical and on the basis of a relaxation theory one would, at first hand, expect the reverse to be true.

Recently, experimental evidence has been presented in support of the existence of crystalline structure in polyvinyl chloride compositions.[25] One might, therefore, interpret the transition temperature as a melt temperature, and we have tried to fit our data to the equations given by Flory concerning the melting point of polymers.[23] The agreement is not too good using the simplified equation and becomes worse when the more exact equations are being used.‡‡ Furthermore, the existence of a similar transition temperature in completely amorphous polymers, such as polystyrene requires an explanation which is independent of the presence or absence of detectable crystallites. Nevertheless, it seems inescapable to assume some sort of a transition, if for no other reason than to explain the high temperature coefficient of the modulus and loss factor. The nature of this transition is not yet well understood, but it seems to be peculiar to any polymeric or network system.

†† Some years ago, Fuoss (see reference 11) suggested that the product of the mole fraction and a characteristic length of the plasticizer molecule would be a useful quantity to characterize the efficiency of a given plasticizer. When the data given above are treated in this manner, one finds that the transition temperatures of most of the phthalate plasticizers fall on a single curve, but the transition temperature for tricresyl phosphate and dibutyl sebacate fall on a different curve, unless an arbitrary factor is being used to change the length of the plasticizer molecule. This treatment of the data is, therefore, not more advantageous than the treatment given above on the basis of volume fraction.

X-Ray Tube Producing a Beam of X-Rays Convergent to a Point

C. H. Bachman and S. J. Silverman
Department of Physics, Syracuse University, Syracuse, New York
February 9, 1950

A TUBE has been developed which produces a convergent beam of X-radiation in the form of a hollow cone, the apex of which forms a crossover point in space for the radiation. The radiation density at this crossover point is much greater than at any region in space before or after it.

Figure 1 shows the basic idea of operation of the tube. A filament C is arranged coaxial with target T which is in the shape of a truncated cone. Electrons from the cathode are drawn outward radially to strike the interior face of the cone. X-radiation is emitted in all directions. Much of it is cut off by the shape of the tube. In cross section, that which escapes the tube from the right side is shown as D', that from the left side is D''. Region A is more intense since it has overlapping contributions. No radiation appears at B.

The point F is the region of interest. This point, the apex of the projected conical target, contains like the rest of region A, contributions from all portions of the target area. However, a collimating block may be so placed as to remove all radiation from A and consequently D' and D'' except for a sheath of radiation of controlled thickness. This sheath, a hollow cone of radiation, passes through F, crosses over and diverges beyond.

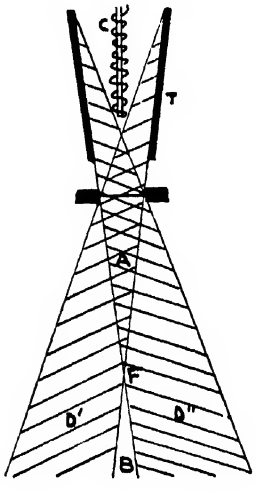

Fig. 1. Schematic ray diagram.

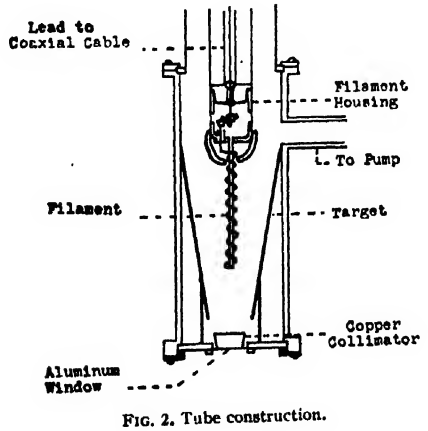

Fig. 2. Tube construction.

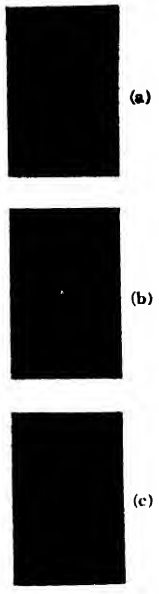

Fig. 3. Beam cross sections. Distance from window: (a) 2.5 cm (before crossover); (b) 7.5 cm (near crossover); (c) 11 cm (after crossover).

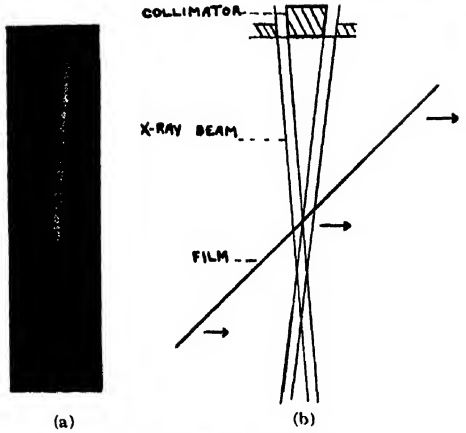

Fig. 4. Crossover presentation.

Figure 2 shows the design features of such a tube and Fig. 3 shows pictures of the beam cross section at several distances from the window. The clover leaf pattern in the scattered outer radiation is due to three radial spacing pins which cross the collimating gap.

Figure 4 was taken by placing a film at 45° to the beam axis and drawing it through the beam. The increased beam density in the crossover region is easily apparent in the negative.

It will be noted that in the tube design no electron focusing problem is encountered; all electrons contribute regardless of where they hit the cone. The very large target area eliminates the customary anode cooling problem or stated conversely, tremendous energy may be used in the tube without being limited by the cooling problem. Also the power rating and x-ray output may be increased by extending the axial length of the conical target since all target areas contribute to the crossover point.

Present efforts are toward explaining some unpredicted radial distribution effects and determining the radiation density distribution in the vicinity of the beam before and after crossover. Other target geometric and methods of utilizing them are also being investigated. More complete results will be published in a future paper.

On Turbulent Jet Mixing in Two-Dimensional Supersonic Flow

D. Bershader and S. I. Pai
Institute for Fluid Dynamics and Applied Mathematics, University of Maryland, College Park, Maryland
February 16, 1950

At the present time techniques for the measurement of turbulent fluctuations in a supersonic stream are still in the developmental stage and our knowledge of turbulent supersonic flow is correspondingly meager. This note reports a preliminary attempt to investigate the problem by comparing a phenomenological theory of turbulence, extended to the supersonic regime, with some experimental results on the density distribution in such flows. Both the phenomenological type of approach and the measurements in this case deal with the mean properties of the turbulent supersonic flow and lead to some information on the general characteristics of supersonic turbulent flow such as the value of the coefficient of eddy kinematic viscosity and the divergence of jets.

Distributions of mean density in several sections of the mixing region of a rectangular, uniform, fully expanded jet of Mach number 1.7,[1] discharging into the atmosphere, have been calculated from measurements made with the Mach-Zehnder interferometer.* The results thus obtained have been compared with predicted density distributions, calculated by use of a theory developed by the second author in reference 2, which makes use of Reichardt's theory of free turbulence.[2]

In the theory, the coefficient of eddy kinematic viscosity ϵ is assumed to be constant over each cross section of the zone of mixing. Its dependence on X, the distance along the axis of the jet, is found by dimensional analysis to be

$$\epsilon = \epsilon_0 X/L \qquad (1)$$

where ϵ_0 is a proportionality constant having the same dimensions as ϵ, and L is a reference length.

The theory further predicts that the density ρ, in terms of the free stream density ρ_1, i.e., ρ/ρ_1 is a function of y/X, y being the coordinate normal to the flow axis. Hence if we plot ρ/ρ_1 *vs.* $\sigma y/X$, the experimental results for all sections must lie on one curve. σ is an experimentally determined scale factor whose value depends on the divergence or spreading of the mixing region. The larger the value of σ, the smaller the divergence of the jet. Comparison with the theory shows that

$$\sigma = (U_1 L/2\epsilon_0)^{\frac{1}{2}} \qquad (2)$$

where U_1 is the free stream velocity. Other conditions remaining the same, the divergence of the jet decreases with increasing stream velocity.

Figure 1 is a plot of the experimental results for four sections at distances 2, 3, 5, and 7 mm, respectively from the exit of a nozzle approximately 1 by 2 cm in cross section. Superimposed on this is the theoretical curve corresponding to (2). In comparing the experimental data with theory, the following points arise.

(1) Width of the boundary layer at the orifice. The theory assumes zero width of the mixing region at the orifice. In the experiments there exists a 1-mm boundary layer at this point, so extrapolation was employed to obtain the "virtual orifice." This was found to be 10 mm upstream of the actual nozzle exit so that the four test sections were then at X 12, 13, 15, and 17 mm, respectively.

(2) Choice of X axis. Due to the finite dimensions of the nozzle, one would expect a shift of the mixing zone density profile toward the side of the air at rest with increasing X. This is in contrast with a semi-infinite free stream for which a line through the starting point of the jet and parallel to the main flow is an axis of symmetry for the mixing zone and in the present theory corresponds to a density value $\rho/\rho_1 = 0.75$. In the present case, the line $\rho/\rho_1 = 0.75$, chosen as X axis, was found to make an angle θ with the direction of the free stream given by $\theta = 1° 28'$. Gooderum, Wood, and Brevoort,[3] in a similar type of experiment on a jet of Mach number 1.6 found that $\theta = 1\frac{1}{4}°$.

(3) Scale factor. A value of scale factor $\sigma = 17$ was found to give best agreement between theory and experiment. The value of σ in low speed subsonic flow is about 12,[4] showing the smaller divergence of the jet in the present case. (Gooderum *et al.* find $\sigma = 15$.)

From Fig. 1 we see that the experimental points show fairly good agreement with the general shape of the theoretical curve, the deviations becoming more pronounced at the outer edge of the mixing region, which is explained by the fact that in all probability the turbulence is less developed in this region, a phenomenon also found in the case of low subsonic flow.[5]

The calculation of ϵ_0 from the data gives $\epsilon_0 = 7.92$ cm²/sec. To calculate a typical value of ϵ, we find at $X = 17$ mm and $L = 1$ mm that $\epsilon = 134.7$ cm²/sec. which is 1950 times larger than typical values obtained for the laminar coefficient of kinematic viscosity. This is of the same order of magnitude as the ratio of eddy kinematic viscosity to laminar kinematic viscosity for the case of an incompressible fluid.

Use of Brightness Temperatures in Richardson Plots

Henry F. Ivey
Westinghouse Electric Corporation, Bloomfield, New Jersey
February 27, 1950

Quite frequently in experimental investigations it is desired to study the thermionic emission from a material whose spectral emissivity is unknown. In this case the brightness temperature, as determined with an optical pyrometer, cannot be corrected to give true temperature values. It is therefore of interest to investigate the errors in the values of work function, ϕ, and emission constant, A, which result from using brightness

temperatures in making a Richardson plot. The writer is not aware of a published discussion of this kind.

An indication of the magnitude of the effect considered was obtained in the following manner. The emission to be expected from tungsten was calculated at 100° intervals in the temperature range 1200–2800°K, using the constants $\phi=4.52$ volts and $A=60$ amp./cm^2 deg.^{2}. The brightness temperatures corresponding to these points were then determined from the known temperature scale for tungsten.[1] A Richardson plot constructed from these data for emission as a function of brightness temperature showed negligible curvature and yielded values of the constants, as determined by the usual least-squares method, of $\phi'=4.57$ volts and $A'=698$ amp./cm^2 deg.^{2}. It is seen that the apparent work function differs from the true value by only a small amount but the apparent value for the emission constant has been increased by an order of magnitude.

The effect on the emission constants can be predicted theoretically as follows. The brightness temperature, T_B, and true temperature, T, are related by the expression

$$(1/T)-(1/T_B)=(\lambda\log e_\lambda)/c_2=p\log e_\lambda, \tag{1}$$

where e_λ is the spectral emissivity at the wave-length λ used in the pyrometers and natural logarithms are used. The value of the constant p is 4.553×10^{-6} deg.$^{-1}$ for $c_2=1.4385$ cm-deg. and $\lambda=6550$A. When relation (1) is substituted in the Richardson emission equation,

$$J=AT^2e^{-b/T}, \tag{2}$$

the result is

$$J=\frac{AT_B^2e_\lambda^{-bp}}{(1+T_Bp\log e_\lambda)^2}e^{-b/T_B}. \tag{3}$$

It is desired to find the constants b' and A' in the Richardson equation in terms of brightness temperature,

$$J=A'T_B^2e^{-b'/T_B}. \tag{4}$$

The constant b' is given by the relation

$$b'=-\frac{d[\log(J/T_B^2)]}{d(1/T_B)}=T_B^2\frac{d}{dT_B}\log(J/T_B^2), \tag{5}$$

or

$$b'=b-2T_B\left[\frac{T_Bp\log e_\lambda}{1+T_Bp\log e_\lambda}\right]-\frac{T_B^2p}{e_\lambda}\left[b+\frac{2T_B}{1+T_Bp\log e_\lambda}\right]\frac{de_\lambda}{dT_B}. \tag{6}$$

The constant A' can be expressed in terms of b' by elimination between Eqs. (3) and (4).

$$A'=\frac{Ae_\lambda^{-bp}}{(1+T_Bp\log e_\lambda)^2}e^{-(b'-b)/T_B}. \tag{7}$$

In Eqs. (6) and (7), T_B is to be interpreted as the mean of the temperature range over which the measurements are made.[2]

When it is recalled that $e_\lambda<1$, it is seen that the result of the first bracketed term in Eq. (6) is to make the apparent work function ($\phi'=b'/11{,}606$) slightly greater than the true value. The effect of the second term will depend on the sign of de_λ/dT_B and will further increase ϕ' if this quantity is negative (as is the case for tungsten). The effect of the de_λ/dT_B term will be greater the greater the work function. The magnitude of both terms increases for higher values of the measuring temperature and lower values of the emissivity.

In expression (7) for A', the predominant factor is the term

$$e_\lambda^{-bp}=e_\lambda^{-0.528\phi}. \tag{8}$$

It is seen that the apparent emission constant will always be larger than the true value and that the ratio will be larger the higher the work function and the lower the emissivity. From the complete expression (7) it can also be seen that A' increases with increasing values of the measuring temperature.

A check on the numerical example discussed earlier can be obtained by substituting the values of the spectral emissivity (i.e., 0.438) and of de_λ/dT_B (i.e., 2.32×10^{-5} deg.$^{-1}$) for tungsten[1] at 2000°K ($T_B=1860$°K) in Eqs. (6) and (7). The results are $\phi'=4.58$ volts and $A'=746$ amp./cm^2 deg.^{2}, in good agreement with the values $\phi'=4.57$ volts and $A'=698$ amp./cm^2 deg.^{2} obtained numerically. If the de_λ/dT_B term is neglected in the expression for ϕ', one obtains $\phi'=4.54$ volts and $A'=578$ amp./cm^2 deg.^{2}. In general, therefore, the effect of this term is not negligible.

In conclusion it may be said that the use of brightness temperatures instead of true temperatures in the construction of Richardson plots will result in apparent work functions which differ only slightly from the true value, but the apparent emission constant obtained from such a plot may be greater than the real value by more than an order of magnitude. These errors will be greater the higher the measuring temperature and the lower the spectral emissivity of the material in question. In the case of the emission constant the error will also be greater the higher the work function. The variation of the emissivity with temperature also contributes an appreciable effect.

[2] In terms of true temperature, Eqs. (6) and (7) may be written

$$b'=b-2T\left[\frac{Tp\log e_\lambda}{1-Tp\log e_\lambda}\right]-(b+2T)\frac{(T^2p/e_\lambda)(de_\lambda/dT)}{1+(T^2p/e_\lambda)(de_\lambda/dT)}, \tag{6'}$$

$$A'=A(1-Tp\log e_\lambda)^2e_\lambda^{(b'-2b)p}e^{-(b'-b)/T}. \tag{7'}$$

Stroboscopic Mapping of Time-Variable Fields

L. Marton and D. L. Reverdin
National Bureau of Standards, Washington, D. C.
March 8, 1950

SEVERAL publications appeared[1–3] on the mapping of steady electrostatic or magnetic fields using the deflections of a viewing electron-beam. We have contemplated for some time the possibility of extending the method to include time-varying fields by the use of a stroboscopic technique. A need for this modification arose in an extensive series of studies of the static field of a cut-off magnetron.[4] In these experiments an electron beam was sent axially through the static magnetron in order to view the space-charge field. The filament heating current, however, generated a magnetic field which masked the space-charge field completely. To eliminate the effect of the filament heating current, the heating

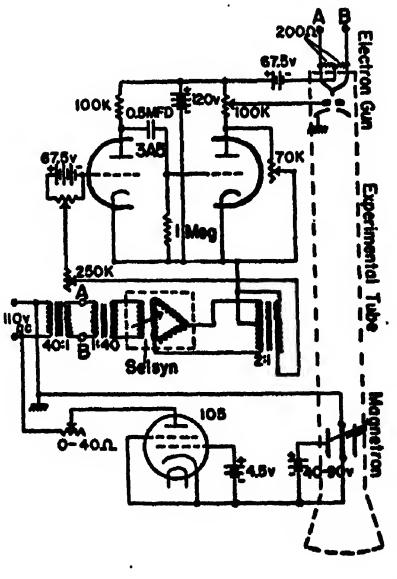

FIG. 1.

was produced by a half-wave rectifier, and the observation of the space-charge distribution was restricted to the other half-cycle.

Figure 1 shows a schematic circuit diagram. Pulse operation of the observing electron beam was achieved by a square-wave modulation of the electron gun bias potential.

An interesting observation while carrying out these experiments was that the image appeared considerably sharper when the stroboscopic method was used than in a steady-state observation. No complete explanation for the sharpening of the image can be offered at this time, but there is good indication that the pulsing of the observing beam reduced the effect of 60-cycle stray fields always present in the laboratory.

The stroboscopic method is applicable in principle to the observation of any repetitive, time-variable fields up to very high frequencies. At very high frequencies there are two serious limiting factors. One is the speed with which the current of the observing beam can be modulated; the second is due to the transit time of the electrons in the field to be observed. The first limitation is the less serious one, since by beam deflection methods instead of biasing of a control electrode, very high frequency pulses can be generated. The second limitation is the more serious one because it requires an increasingly stiff electron beam to keep the transit time low while the sensitivity of the method varies inversely with beam stiffness. A vague estimate of the practical upper frequency limit at which the method can be applied without undue experimental difficulties can be set at about 300 Mc, the present upper limit of oscillograph operation.

Announcement

From time to time, the Institute has received inquiries from subscribers for information as to where and how they may have their copies bound. After investigation the Institute has found that this may be best accomplished by selecting a capable bindery that will work to our specifications and produce a well-bound volume at as low a price as possible. The necessary arrangements have been completed with the Book Shop Bindery, 308 West Randolph Street, Chicago 6, Illinois.

The volumes will be bound in the best grade of washable buckram with facsimile gold stamping on the spine and the subscriber's name in gold on the front cover. A distinctive color for each of the Journals has been selected as listed below. Advertising matter and covers are removed before binding. The price of $3.00 per volume applies to any of these journals regardless of size. Issues, comprising complete volumes, should be sent by prepaid express or parcel post to the Book Shop Bindery. Bound volumes will be shipped approximately 30 days after receipt. Return transportation will be prepaid when remittance accompanies order.

No deviation in color or specification can be allowed in view of the favorable price.

Results of Recent Hypersonic and Unsteady Flow Research at the Langley Aeronautical Laboratory

JOHN V. BECKER

Chief of Compressibility Research Division, Langley Aeronautical Laboratory, National Advisory Committee for Aeronautics, Langley Air Force Base, Virginia

INTRODUCTION

THE extremely high speeds and altitudes now contemplated in supersonic aircraft design involve many new compressible flow problems which, only a few years ago, were either unrecognized or of purely academic interest. This situation has naturally resulted in a greatly increased concentration of effort in basic compressible flow research at establishments such as the NACA. The purpose of this paper is to review briefly some recent results obtained at Langley in projects of this character dealing with hypersonic and unsteady flows. Similar exploratory work in small-scale facilities is in progress at the Ames and Lewis Laboratories of the NACA.

THE 11-INCH HYPERSONIC TUNNEL

The eventual need for a wind tunnel capable of speeds in the range of 5 to 10 times the speed of sound was envisioned in 1945, and we undertook the development of a pilot model of such a facility at that time. The pressure ratios and other important design factors for hypersonic tunnels were then unknown, and this uncertainty pointed towards a blowdown type of tunnel sufficiently flexible in design to permit easy modification. A schematic drawing of the facility is shown in Fig. 1. The combination of a 50-atmosphere supply tank and a vacuum receiving tank affords a starting pressure ratio of several thousand. It was recognized that large reductions in the operating pressure ratio might be achieved through the use of a variable second throat provided that adverse flow separation effects did not occur. Provision was therefore made in the design for quickly reducing the second throat area after starting of the flow.

Two nozzles were designed by the characteristics method for $M=7.0$; one was a conventional single-step type as indicated on Fig. 1, and the second was a two-step design which expanded first in the vertical plane to a Mach number of about 4.5 and then in the horizontal plane to $M=7.0$. The test sections in each case are 10.55 in. deep by 10 in. wide. The single-step nozzle was found to produce acceptably uniform flow at the test section and a mean Mach number of 6.9 as determined from static and total-pressure measurements in the stream. Difficulty was encountered in the two-step nozzle caused by non-uniform boundary layers at the entrance to the second step.

During the preliminary design studies, it became obvious that the temperature in the test section would drop to the liquefying temperature of air at a Mach number of about 4.5 if the air in the settling chamber were maintained at room temperature. For higher speeds, the air temperature would fall far below the liquefying temperature, even if large degrees of supersaturation were assumed. Experience with water-vapor condensation suggested that considerable supersaturation might exist in air. However, the uncertainty as to what would actually happen in air led us to incorporate a heater which can maintain stagnation air temperature up to 1300°F abs. The possibility of air liquefaction can thus be eliminated in our tunnel for Mach numbers up to approximately 8.0. Incorporation of the heater has the obvious additional advantage of making possible studies of temperature effects not only in connection with the condensation phenomena, but also in heat transfer research in this tunnel. As an incidental advantage, the heater also appreciably lengthens the test runs. A water-cooled heat exchanger installed ahead

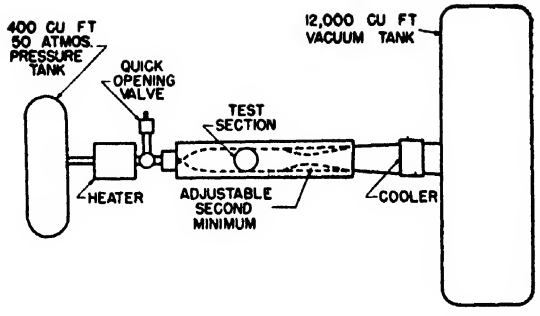

FIG. 1. Schematic drawing of NACA 11-in. hypersonic tunnel.

of the vacuum tank has a similar beneficial effect on the running time. Runs of about 25 sec. duration are obtained without the use of the adjustable second throat. With the second throat immediately adjusted to a reduced area after starting, runs of 60 to 90 sec. are obtained, the time varying with model support configuration.

The tunnel functioned satisfactorily during its first runs on November 26, 1947.

AIR CONDENSATION EXPERIMENTS

Pressure-distribution data have been obtained along the parallel sidewalls of the nozzles of the 11-in. hypersonic tunnel for stagnation temperatures ranging from high values for which condensation is impossible to low values for which the components of air must either be highly supersaturated or condensed. It was found that even for the lowest stagnation temperatures the longitudinal pressure distributions were smooth; no condensation shock was apparent. In this respect, our data agree with results obtained in the 5-in. hypersonic tunnel at California Institute of Technology and in the 2.5-in. $M=4.5$ tunnel at Princeton. Had it been impossible for us to vary temperature, the lack of any apparent condensation shock probably would have led us to the conclusion that no condensation was occuring. Further analysis of the pressure data, however, reveals that, while no discontinuities occurred along the nozzles, there was a significant change in the pressure at all stations along the nozzle when the temperature was allowed to fall below saturation values. Figure 2 shows this effect for various stations along the two nozzles. The left diagram of Fig. 2 shows the results for three stations in the forward part of the nozzle at which the Mach numbers at high temperatures were 5.47, 5.75, and 6.09. The right diagram shows the results for the test-section stations of the two nozzles investigated where the Mach numbers as determined from wall static pressures were 6.56 and 6.76. The pressure ratio at any of these stations was not much affected by decreasing the temperature until the saturation region was reached. Here a marked increase in pressure (decrease in Mach number) was noted. In the entire first step of the two-step nozzle in which the temperature never fell below saturation values, there were no appreciable pressure variations with temperature. These results seem to indicate that condensation, if it is actually present, is a gradual process occurring along the entire region of the nozzle where the temperatures are appreciably below the saturation value. The possibility that these pressure ratio changes are due to viscous or heat transfer effects rather than condensation has not yet been eliminated. However, tests made over a range of stagnation pressures at temperatures above the saturation level indicated no appreciable Reynolds number effects. Instead of the indicated decrease in Mach number with decreasing T_0 in the saturation region (Fig. 2), the effect of the corresponding Reynolds number increase produced a small increase in Mach number.

In recent years, the nucleation theory developed by Volmer,[1] which successfully predicts the condensation of water vapor, has been used by several investigators,[2–4] for example, to estimate the degree of supersaturation of oxygen that might be expected. These calculations, when applied to our conditions, predict high degrees of supersaturation terminated by a condensation shock. An assumption common to all of the theoretical work is that no foreign particles are present which might act as condensation nuclei and thus reduce the probability of high degree supersaturation. In our air stream, there are three possibilities: carbon dioxide crystals, water crystals, and oxide dust from the heater. Water is present only to the extent of about two parts in a million, and thus probably can be neglected. It is also doubtful whether enough oxide particles are present

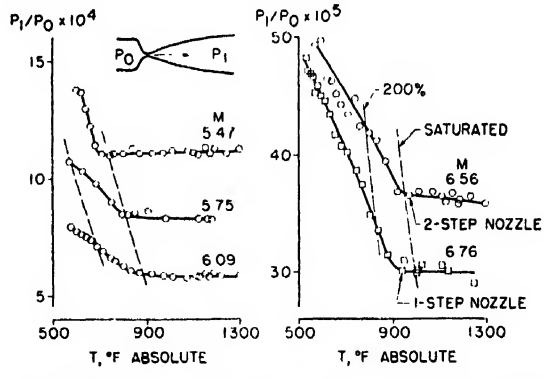

FIG. 2. Effect of stagnation temperature on the static pressure at each of several stations along the nozzle. (The stations are designated in terms of the roughly constant Mach number existing at each station for temperatures above saturation.)

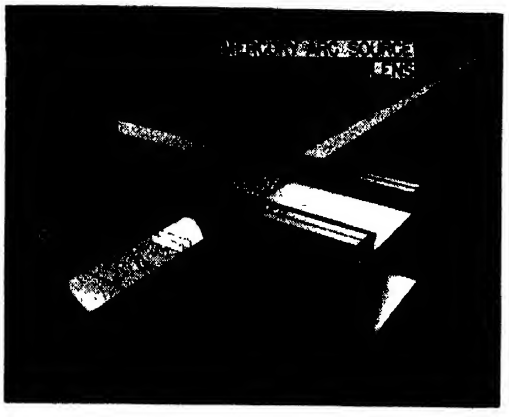

FIG. 3. Set-up of light-scattering experiment.

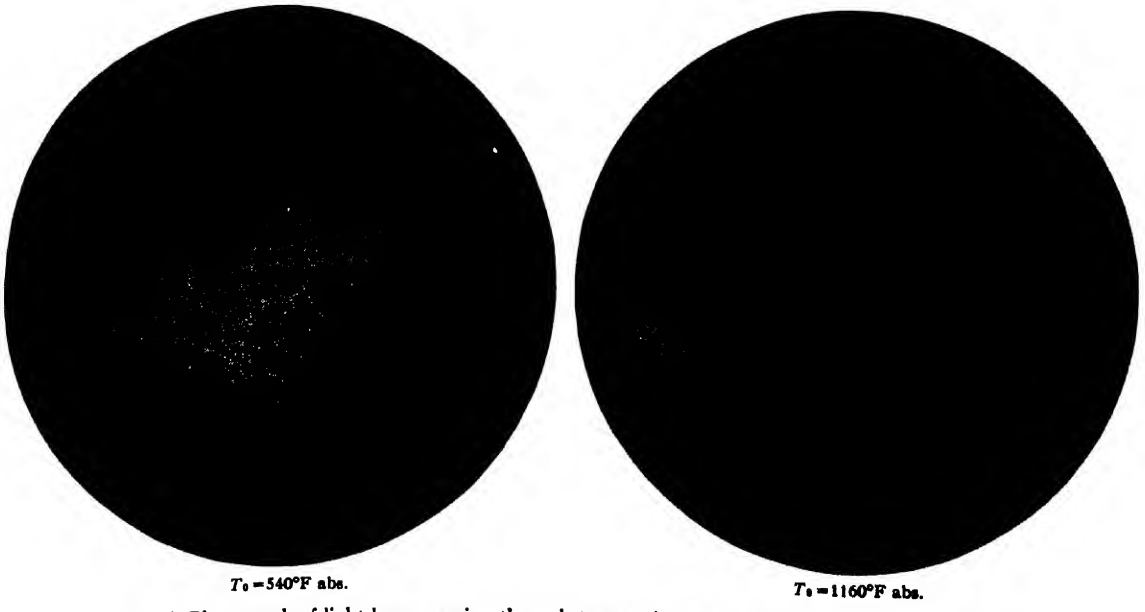
to be significant. If the carbon dioxide solidifies without becoming highly supersaturated, a significant number of solid particles would form in the flow at temperatures somewhat below those corresponding to the saturation of oxygen. Under these circumstances, the theoretical predictions of high supersaturation and condensation shock would have to be modified.

A simple optical experiment has been made which is of interest in connection with the condensation question. Figure 3 shows the experimental setup. An approximately parallel beam of light is passed through the test-section windows with the test chamber darkened. For the no-flow condition, all that can be seen are the reflections where the beam passes through the windows. When the stagnation temperature is at its usual elevated value, 1160°F abs., there is no evidence of any particles in the flow, the oxide particles apparently not being numerous enough to show up (Fig. 4). When the flow is not heated, however, strong scattering of the light beam occurs suggesting the presence of a large number of small liquid or solid particles. Near the walls in the high temperature region of the boundary layer, the light scattering disappears entirely. It is conceivable, of course, that this phenomenon is caused by CO_2 particles rather than by liquid oxygen or nitrogen particles. The possibility has also been advanced that the scattering is caused by liquid oxygen particles of subcritical size, as considered in the Volmer theory. Another conceivable explanation is that photo-nucleation is occurring. This test, therefore, does not provide completely conclusive evidence of condensation of the components of air.

Additional experimental work on the condensation problem is planned but there is a limit to what can be accomplished in the tunnel. It appears to us that cloud chamber techniques can be used to advantage in the study of this problem. Another possibility suggested by Donaldson at Langley is to utilize the sudden expansion in a suitably designed shock tube to simulate the rapid changes in temperature and pressure of a supersonic nozzle. The experimental information obviously needed includes degrees of supersaturation, condensation time factors, and the effects of gas mixtures and foreign nuclei on the condensation phenomena.

FLOW VISUALIZATION AT LOW PRESSURES

Our experience with the 11-in. tunnel indicates that the limit of usefulness of the schlieren method of flow visualization is reached at a pressure of about 1 mm of mercury for slender test models at $M=7.0$. To obtain significant results at these conditions, we use a sensitive system in which the light is passed through the test section twice. A single 10-in. mirror is used located close to one side of the tunnel and ground to the rela-



$T_0 = 540°F$ abs. $T_0 = 1160°F$ abs.

FIG. 4. Photograph of light beam passing through test section taken from same viewpoint as Fig. 3.

tively long radius of curvature of 20 feet. In terms of Mach number, the estimated limiting value for this schlieren system is about $M=10$ for a 50-atmosphere stagnation pressure. For higher hypersonic tunnel speeds, and also for low density aerodynamic research at all speeds, other methods of flow visualization are needed.

We were fortunate to have Dr. Joseph Kaplan as a consultant on this problem during the summer of 1948. He suggested use of the little-understood phenomenon of the afterglow that persists in nitrogen which has been excited by an electrical discharge as a means of flow visualization. Acting on this suggestion, Williams and Benson set up a low pressure supersonic nozzle in which the afterglow principle was applied successfully for the first time[5] in August 1948. The apparatus used is shown on Fig. 5. Nitrogen is ducted through the exciting discharge tube, through a grounded screen which greatly reduces the number of ions present but affects the afterglow only slightly, and thence into the supersonic nozzle. The brightness of the glow can be increased by increasing the energy of the exciter, either by the addition of more arcs or by increasing the power. It is interesting to note that the grounded screen has little effect on the brightness. Figure 6 shows the nozzle flow for three pressure ratios less than that required for starting, which was about 20 to 1. The uniform brightness of the afterglow after starting and the patterns about a 15° double-wedge model are illustrated in Fig. 7. The high pressure region behind the shock has greater brightness than the main stream. Separation occurs at the point of maximum thickness of the wedge-shaped model at the low static pressure of this test, 3 mm of mercury.

The nitrogen afterglow appears to be usable at static pressures as low as 100 microns and perhaps lower. We have also successfully used other gases including dry air, oxygen, and argon, although their afterglows are not as bright as that of nitrogen. A small amount of iodine vapor appreciably increased the brightness of nitrogen afterglow. It is probable that other combinations can be found having more intense afterglows.

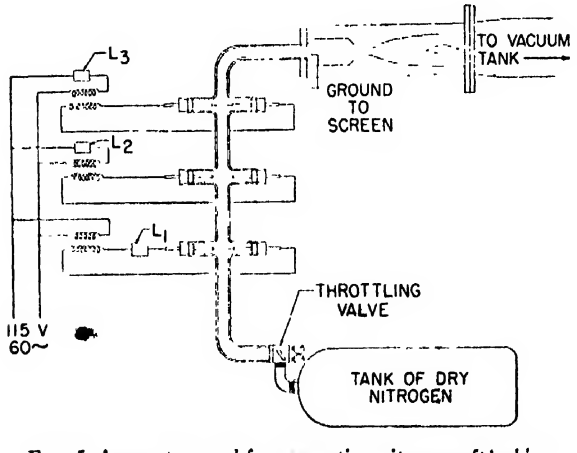


FIG. 5. Apparatus used for generating nitrogen afterglow in a supersonic nozzle.

[5] T. W. Williams and J. M. Benson, Preliminary Investigation of the Use of Afterglow for Visualizing Low-Density Compressible Flows, NACA RM I9A24a, February 15, 1949.

The question arises as to whether the presence of the glow has any aerodynamic effects on the flow. Studies made by Rayleigh[6] indicated that the decay of the glow was accompanied by a high rate of heat release, a phenomenon which would be expected to produce important aerodynamic effects in a supersonic nozzle. This possibility has recently been investigated by Benson at Langley. He finds that in our application for which the glow has a life of about one sec., the temperature rise is of the order of 30° to 90°C. This corresponds to a temperature rise of only a small fraction of a degree during the transit of the gas through a supersonic nozzle. Thus the aerodynamic effect is expected to be negligible. Benson also finds no appreciable change in viscosity due to the presence of the glow. Schlieren and afterglow photographs obtained for static pressures of 6 to 9 mm of mercury correlate satisfactorily. In summary, the afterglow technique at its present stage of development appears to be a reliable and convenient method of flow visualization for low pressure aerodynamic research.

BOUNDARY-LAYER EFFECTS AT HYPERSONIC SPEEDS

It is well known that the effect of the boundary layer on the pressure distribution about aerodynamic bodies at both subsonic and supersonic speeds is restricted to the rear or trailing portion of the body. In this region, adverse pressure gradients occur which cause the boundary layer to thicken greatly or to separate from the surface, with associated large effects on the surface pressures. Over the forward part of the body, the boundary layer for Reynolds numbers in the practical range is too thin to have a measurable effect on the pressures. This fact is well established for the entire speed range for which pertinent data are available in aeronautical literature.

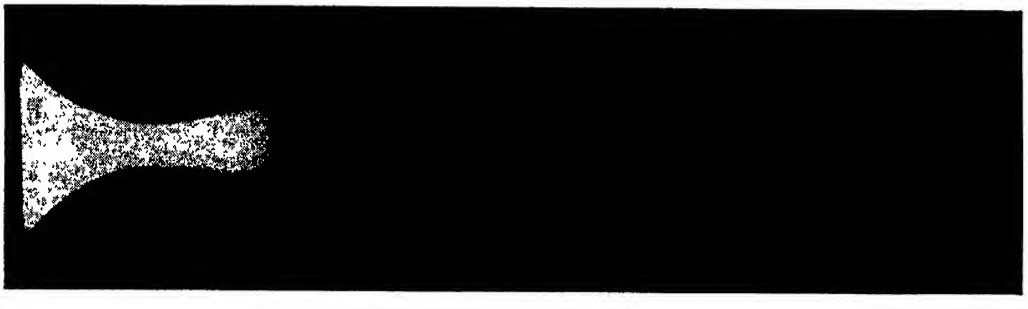
The change from low supersonic to hypersonic speeds involves a many-fold increase in boundary-layer thickness for a given value of the Reynolds number. Recent calculations and tests in the 11-in. hypersonic tunnel at $M=6.9$ have brought to light the fact that the thickness becomes so great as to cause a large distortion of the pressure diagram over the forward portion of airfoils. The usual separation effects over the rearward portion are also present.

Figure 8 shows the calculated growth of the laminar boundary layer on a flat plate as a function of Mach number. The calculations are based on the usual compressible-flow boundary-layer assumptions with the added assumption of a linear velocity profile. The latter

[6] S. K. Mitra, *Active Nitrogen—A New Theory* (Indian Press, Ltd., Calcutta, 1945).

(A) Pressure ratio approximately 9 to 1

(B) Pressure ratio approximately 10 to 1



(C) Pressure ratio approximately 11 to 1

FIG. 6. Nozzle flow patterns obtained with nitrogen afterglow at pressure ratios below that required for starting.

assumption is justified on the grounds that over the forward part of a flat plate at our test Reynolds number the boundary layer is known to be laminar and that theoretical considerations[7,8] reveal that the profile is expected to be nearly linear at hypersonic speeds. (See upper diagram on Fig. 8.) Furthermore, the calculated chordwise growth of the displacement thickness is insensitive to the profile shape chosen. Figure 8 shows that the displacement thickness at $M=7$ is about 10 times that at $M=1.0$ for a constant value of $x/(R_x)^{1/2}$, where x is the distance from the leading edge of the plate and R_x is the Reynolds number based on the length x. The increase is associated with the large temperature rise in the boundary layer at high Mach numbers and to the corresponding viscosity increase near the surface.

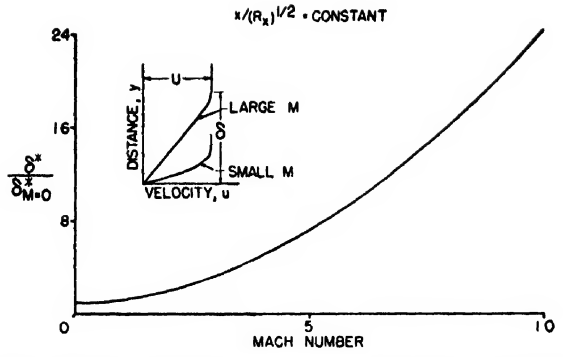

FIG. 8. Effect of Mach number on the displacement thickness of the laminar boundary layer on a flat plate.

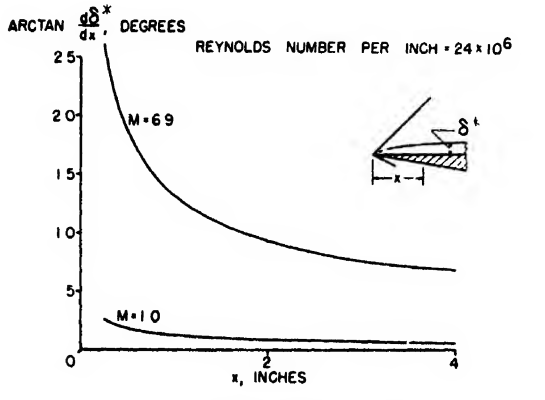

FIG. 9. Slope of the effective surface of the boundary layer along a flat plate.

Figure 9 presents the effective change in slope of the surface of the plate due to growth of the boundary layer. The effect, of course, is a maximum near the leading edge. At the 0.20-in. station, for example, the slope increase is about 2.3° or the equivalent of a four-percent-thick wedge.

The calculated pressure increments corresponding to the slopes of Fig. 9 are plotted on Fig. 10 as fractions of the stream static pressure. For comparison, the results of actual measurements for a flat surface parallel to the stream in the 11-in. hypersonic tunnel are also given. It will be seen that the pressures near the leading edge are markedly altered by the boundary-layer effect; a pressure rise of about 0 7 of stream pressure occurs at the 0.25-in. station. The agreement between theory and experiment appears surprisingly close when it is considered that no account was taken of the effect on the boundary-layer development of either the bow shock or the streamwise pressure gradient.

A schlieren photograph of the flow over a flat surface, taken at a static pressure of 5 mm of mercury, abs., is shown on Fig. 11. The significant part of this photograph is the upper surface of the wedge, alined so as to be accurately parallel to the flow. The lower shock in Fig. 11 is due to the inclined lower surface and has no significance in the present discussion. The shock caused by the boundary layer can be seen to be curved near the nose as required by the effectively curved surface corresponding to the chordwise growth of the boundary layer. The thick boundary layer itself can also be seen; the apparent thickness agrees approximately with the calculated values.

Two obvious practical effects of this phenomenon are to increase the pressure drag of hypersonic airfoils and to alter appreciably the characteristics of leading-edge control devices.

UNSTEADY FLOWS

Research in the field of unsteady flows is receiving increasing attention partly because of the possibilities of using unsteady flows to advantage, for example, in compressors, pulse-jet engines, and high speed wind tunnels, and partly because of serious adverse effects due to unsteady flows on the performance of supersonic inlets, diffusers, and other aircraft components. In the field of useful applications is the familiar "comprex" compressor, designed by Seippell, in which moving compression and expansion waves perform the func-

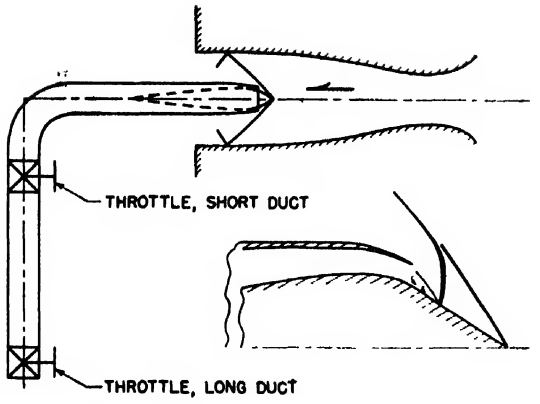

FIG. 12. Supersonic inlet test configuration and sketch of shock-induced separation on conical nose.

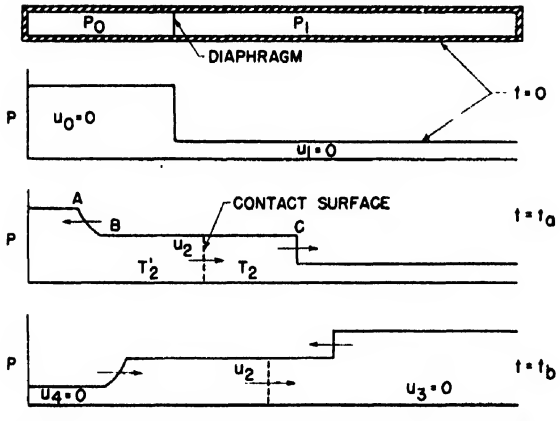

FIG. 13. Illustration of shock tube pressure distributions.

tions of a mechanical piston.[9] Another useful unsteady flow device is the shock tube, which has been used, for example, by Smith at Princeton to study shock reflections[10] and by Geiger and others at the University of Michigan as an intermittent flow wind tunnel.[11]

Adverse unsteady flow phenomena on aircraft wing sections arising from shock boundary-layer interaction at high speeds have been studied for a decade or more and these phenomena continue to present some of the most difficult problems of high speed research. Recently Ferri at Langley has discovered an interesting case of unsteady flow due to shock boundary-layer interaction at the entrance of an axially symmetric supersonic inlet. Figure 12 illustrates the experimental set-up used. The inlet is shown inserted in the test region of a supersonic nozzle which produced a Mach number of 1.90. Back pressure in the duct was varied by means of a throttle, and tests were made with two alternate throttle locations as shown on Fig. 12. The flow pulsations occurred when it was attempted to reduce the mass flow into the inlet by closing the throttle and thereby forcing the normal shock to move from its design location (just inside the inlet) to an external position on the conical central body, thus permitting spillage of some of the approaching air. The external position of the shock is illustrated on the lower sketch of Fig. 12. The basic cause of the pulsations was the abrupt occurrence of shock-induced separation resulting from failure of the boundary layer on the cone to negotiate the strong normal shock in its external position. This separation produced an abrupt reduction in the mass flow entering the inlet and a corresponding drop in back pressure in the duct. The sudden drop in back pressure is equivalent in its effect to a sudden opening of the throttle and thus the shock was momentarily drawn into the inlet again, after which the process repeated itself. The phenomenon was initiated solely by the external shock-induced separation and was in no way connected with internal diffuser or burner disturbances. As would be expected, however, the length of the internal duct had a marked effect on the frequency and character of the pulsations once they had started. The "long duct" configuration (Fig. 12) had lower frequency but larger amplitude pulsations. For both duct configurations the pulsations were of such violence as to prohibit any useful applications of this inlet. Various means of preventing periodic separation on the cone are being studied and there is promise that this type of unsteady flow can be eliminated.

As a basis for experimental study of some of the more difficult unsteady flow problems previously mentioned, Huber has investigated in some detail the phenomena in a simple shock tube.[12] The objectives of this work were to develop suitable pressure-measuring equipment

and to determine how closely the one-dimensional theory predicts the actual phenomena in the tube. For the benefit of those unfamiliar with the shock tube, Fig. 13 has been prepared to illustrate its action. The tube has two chambers separated by a diaphragm and containing a gas (or two gases) at different pressures. When the diaphragm bursts, a shock proceeds towards the low pressure end of the tube at a low supersonic speed and a rarefaction wave proceeds in the opposite direction at the speed of sound. Between these disturbances, the pressure is constant at the value P_2 and a flow is produced of velocity u_2 in the direction of the low pressure end. The surface of contact between the gas originally at high pressure and that at low pressure represents a temperature and entropy discontinuity, since the air to the right has increased in temperature due to the shock passage, while that at the left has decreased in temperature due to the action of the rarefaction. When the shock strikes the end of the tube, it is reflected and proceeds in the opposite direction, reducing the flow velocity in the tube to zero and increasing the pressure. The rarefaction wave has a similar action at the opposite end of the tube. It is important to note that any compressive disturbance behind the shock quickly catches up with it because of the velocity u_2 and the higher speed of sound behind the shock. The initial rarefaction wave tends to spread out, however, because the velocity of advance of a wave

FIG. 17. Schlieren photographs of the shock-tube phenomena at various times (seconds) after bursting of the diaphragm.

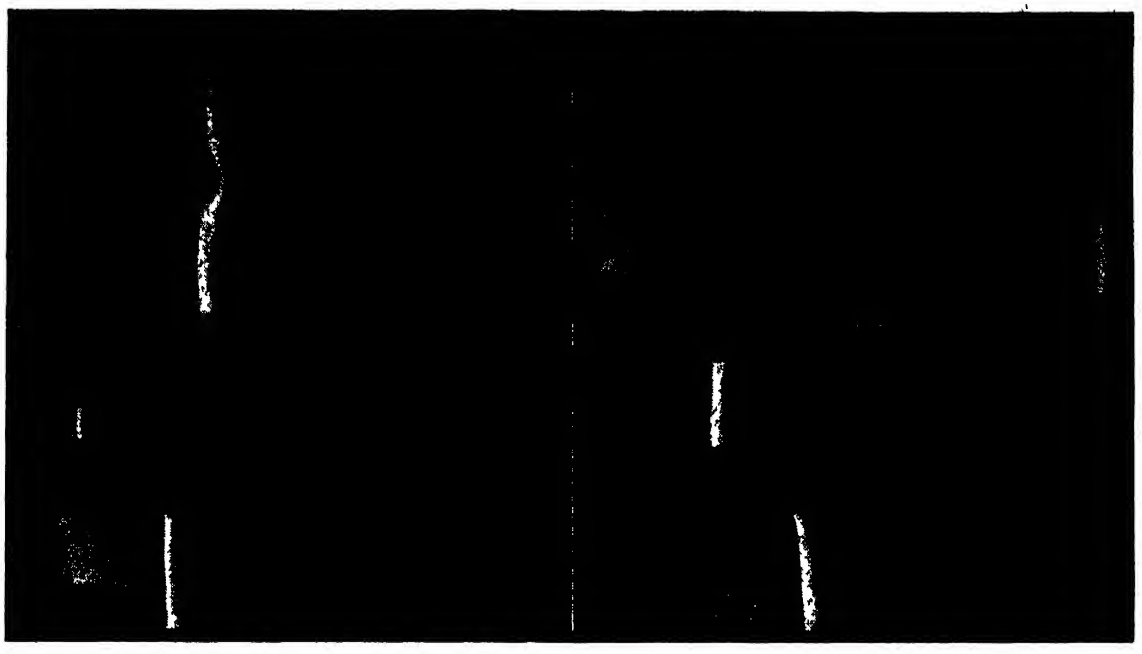

FIG 18 Schlieren photographs of a shock traveling from left to right against subsonic flow in a channel containing an asymmetrical divider.

behind the rarefaction front is retarded by u_2 and by the reduced speed of sound.

Figure 14 shows the theoretical positions of the disturbances as functions of time. Interactions among the various disturbances occur and after the first cycle the flow becomes increasingly complex. The attenuation of the disturbances due to wall friction has been studied by Donaldson[13] and found to be very small in a tube of these proportions for any one cycle. The method of characteristics provides a tool for calculating these interactions and reflections. Neglecting friction and following the work of Guderley and others, Hess[14] has successfully applied the characteristics method to several much more difficult cases—for example, to the starting of flow in a variable cross-section supersonic nozzle when a diaphragm or quick-acting valve is opened at the throat.

Huber's tests were made with air, using an initial pressure ratio of 2.0. The internal cross section of the shock tube was 3×3 inches in size. The tube length varied from 56 to 104 in. the high pressure chamber being 32 in. long and the low pressure chamber being variable in length from 24 to 72 in. Figure 15 illustrates the pressure measuring crystal used. This is a commercial unit $\frac{5}{8}$ in. in outside diameter selected for its properties of high acoustic impedance, high sensitivity, and absence of cavity resonance. The crystal did not perform well when mounted in rubber, when a small air cavity and leakage were present, or when it was slightly misaligned.

The pressure traces produced by the crystal when mounted in each of two positions on the low pressure side of the diaphragm are presented in Fig. 16. In the upper diagram, the crystal was near the diaphragm and the trace shows the pressure rise due to the shock to take place over a measurable time increment. This result is caused primarily by failure of the diaphragm to burst instantaneously as a perfectly plane surface. In this connection, it is of interest to mention that of several materials tried for the diaphragm, the best was tracing paper—both because of its disintegration into many small pieces and because it had less stretch than the other materials. The number of thicknesses used was selected to match the pressure differential. Figure 16 also shows the reflected rarefaction zone and the slight rise in pressure due to reflection of the rarefaction from the temperature discontinuity. In general, the data are in reasonable agreement with the theoretical predictions.

The lower diagram of Fig. 16 was taken with the pick-up farther away from the diaphragm and with a shorter chamber. Here the shock is more nearly plane as would be expected at a greater distance from the initial burst because lagging disturbances have had time to catch up with the shock front. The small discontinuity in the theoretical curve at $t = 5.2$ and 8,1 milliseconds is due to reflection of the shock from the temperature discontinuity at the contact surface. Again there is reasonable agreement with the theory.

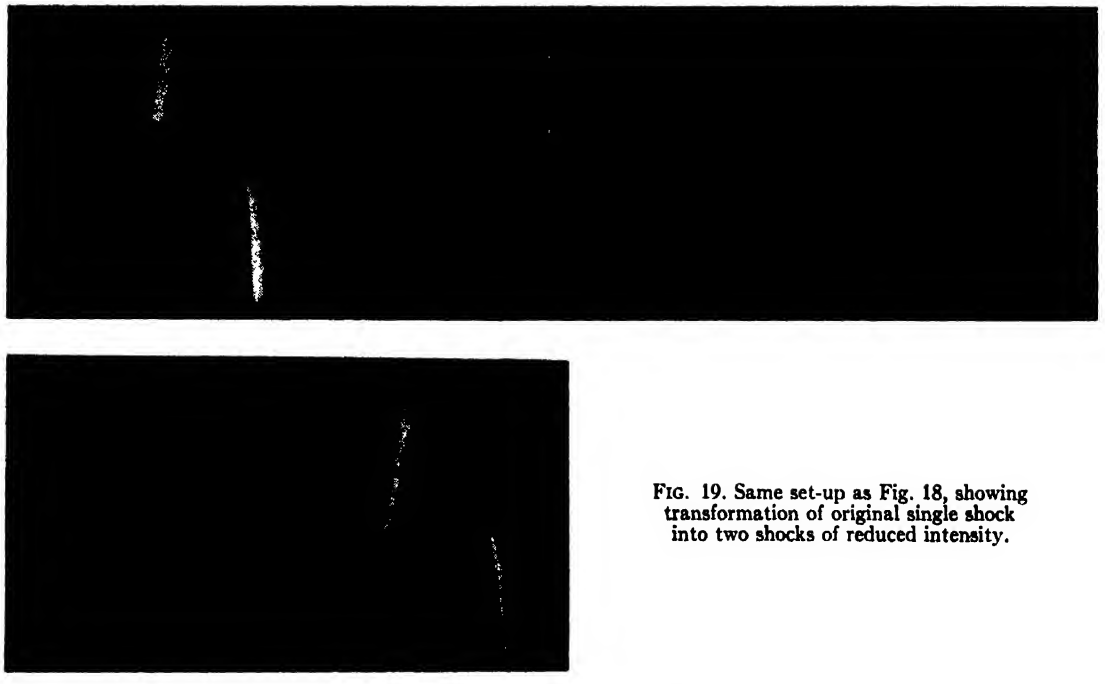

FIG. 19. Same set-up as Fig. 18, showing transformation of original single shock into two shocks of reduced intensity.

Schlieren photographs of the disturbances are shown on Fig. 17. The first picture, ($t=0.4\times10^{-3}$ sec.), taken just downstream of the ruptured diaphragm, shows the "shock" as a wide band. This explains why it did not appear as a discontinuity in the pressure trace. A few tube widths farther downstream, ($t=1.1\times10^{-3}$ sec.) the shock appears as a nearly plane discontinuity, although all of the reflections generated earlier have not yet caught up with it. The third picture, ($t=2.0\times10^{-3}$ sec.), shows the shock immediately after reflection from the end of the low pressure chamber. The oblique disturbances are believed to be reflections of the shock from the walls which were generated as a result of initial curvature of the reflected shock produced by deformation of the 11/16-in. thick end plate. The fourth picture ($t=2.7\times10^{-3}$ sec.) shows the reflected shock passing through the temperature discontinuity. This "discontinuity" is actually a turbulent band—in this case about one tube width in thickness. The finite thickness and turbulence are due mainly to irregularities introduced by the bursting of the diaphragm. Distortions of the shock in passage through this region are evident.

It is concluded from Huber's work that the only significant departures from the one-dimensional shock tube theory arise from the finite time and distortions associated with the rupturing of the diaphragm.

The final subject to be discussed briefly is related to the unsteady flow problem of supersonic diffusers. It is well known that the normal shock in supersonic diffusers oscillates in position due to pressure disturbances from the subsonic part of the diffuser itself or from the combustion chamber. The distance between the mean position of the shock and the throat of the diffuser must be increased as the amplitude of the oscillations increase. For maximum diffuser pressure recovery, the shock must be located as closely as possible to the diffuser throat and this requires therefore that the oscillations be minimized or, in the ideal case, eliminated.

A scheme proposed by Ferri for reducing the strength of the disturbances which generate the oscillations of the shock has been the subject of a preliminary investigation, results of which are illustrated in Figs. 18 and 19. These figures show schlieren photographs of a compressive disturbance (weak shock) traveling to the right against a subsonic flow ($M\approx0.2$) in a tube of square cross section. In the middle of the tube is an asymmetrically shaped two-dimensional body which splits the subsonic flow into two smaller channels of unequal area and velocity. The disturbance divides into two parts upon contacting this central body (upper right picture of Fig. 18). When the two shocks emerge into the channel at the forward end of the divider (lower pictures of Fig. 18) the upper shock lags behind the lower due to the greater retardation provided by the higher speed subsonic flow in the upper passage. Upon leaving the divider (upper pictures of Fig. 19) each shock tends to spread across the entire channel, forming a final configuration of two disturbances (lower picture of Fig. 19) each having about half of the intensity of the original shock. Of course, the rear shock will eventually overtake and coalesce with the leading shock if the duct is long enough. Numerous variations of this scheme suggest themselves. For example, a greater number of channels can be used to reduce further the strength of the initial disturbance or to produce any desired pulsation frequency. Considerable further theoretical and experimental research is required to explore the many possible applications of this principle.

Contributed Original Research

Modulation Conversion in a Wave Guide

PAUL S. ROGELL
Hazeltine Electronics Corporation, Little Neck, New York
(Received November 29, 1949)

Theory and design equations are presented for the conversion of a microwave, narrow-band f-m signal into very nearly a pure a-m signal within an ordinary wave guide of specified dimensions. Frequency relationships and guide dimensions are arranged so that the f-m side bands are shifted with respect to the carrier until they become a-m side bands at the guide output. A complex intelligence signal may be transmitted with negligible distortion if it is used to amplitude modulate an intermediate carrier which frequency modulates the microwave carrier.

IT is often desirable to utilize an amplitude-modulated signal at microwave frequencies. Since the generation of a microwave frequency-modulated signal is not difficult, the desired operation could be carried out if one possessed the means of converting a microwave f-m signal into an a-m signal. Such a conversion can be accomplished in an ordinary wave guide.

The basic principle employed is the fact that in a wave guide operated near cut-off the phase velocity of a single-frequency signal varies widely with the frequency of the signal. Down such a guide, the low frequency components of a signal travel faster than do the high frequency components. It is possible to adjust the position of the cut-off and the length of the guide so that the frequency components of an f-m wave at the input of the guide will rearrange themselves to form very nearly a pure a-m wave at the output.

The vectorial representation of a narrow band f-m wave, consisting of only a carrier and the first two side bands, is shown by Fig. 1a. It can be seen from the figure that as the carrier rotates, the two side bands add up so as to impart an alternating component to the speed of rotation of the carrier. In the figure, ω_c is the carrier angular frequency and ω_m is the angular frequency of a single-frequency modulating signal.

Suppose that the f-m signal of Fig. 1a be introduced into a wave guide operated near cut-off. Each of the three components of the signal will be changed in amplitude and phase upon arriving at the guide output. Let us arrange the parameters of the system so that the lower side band is shifted 450° and the upper side band 270°, each with respect to the carrier. Expressions for the relations that must hold among the parameters to achieve these phase shifts are developed in Appendix A. Also, let us assume that the side bands are equally attenuated. Actually, the resultant side bands are not quite equal, and the output contains a little phase modulation (see Appendix B).

Under the above conditions for phase and amplitude changes, the output signal may be represented by the vector diagram of Fig. 1b. The output is a pure a-m signal, since the two side bands add up so as to impart an alternating component to only the amplitude of the carrier.

It is generally desirable to use a complex wave, not a single frequency, as the transmitted information. To accomplish such a transmission, it would seem natural to merely allow ω_m to be variable. However, the phase shifts of the side bands with respect to the f-m carrier are intimately associated with the frequency separation of those side bands from the carrier. Varying ω_m, therefore, would destroy the proper phase relations necessary to produce an a-m signal. The difficulty can be overcome by using the signal of frequency ω_m as an intermediate carrier that is amplitude modulated by the intelligence. In this case, the output signal is a microwave carrier amplitude modulated by an a-m intermediate carrier. The intelligence introduces a distortion term, but as long as the highest intelligence frequency is less than one-tenth the intermediate-carrier frequency, less than one percent distortion is introduced.

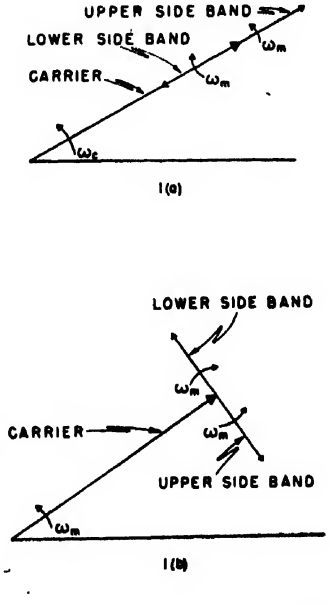

FIG. 1. Idealized vector diagrams for the f-m signal into the guide, and the a-m signal at the guide output.

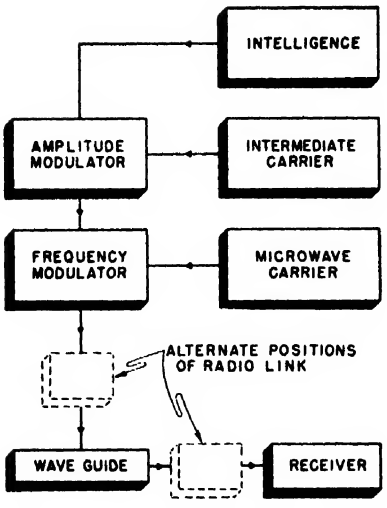

FIG. 2. Block diagram of the complete system.

The case of a variable intelligence frequency is analyzed in Appendix C.

The receiver used in the system could consist merely of two stages of crystal detection together with a suitable amount of amplification.

A simplified block diagram of the entire system is shown in Fig. 2. If the radio link were placed after the wave guide, then an a-m carrier would be transmitted, and a simple receiver could be employed. If the radio link were placed before the wave guide, then an f-m carrier would be transmitted, and the wave guide coupled to the crystals would act as a frequency-modulation detector.

Design equations for the wave-guide dimensions and for frequency relationships are developed in the Appendices. Either the guide output or the input should be variable in longitudinal position so as to secure exactly the desired length. As another design consideration, it would probably be necessary to use crystal stability when generating the intermediate and microwave carriers.

Suppose an amplitude-modulated signal is desired at a carrier frequency of 3000 mc. Let the wave guide be rectangular, carrying the TE_{10} mode. Let the guide cut-off be 2960 mc, necessitating a transverse guide dimension of 5.06 cm. Then the design equations show that the intermediate-carrier frequency must be 33.2 mc, and the guide length must be 1.30 meters. The band width required would be 73.0 mc. Intelligence frequencies ranging from 0 to 3.3 mc would yield less than one percent amplitude distortion in the guide output. There would be a maximum frequency deviation at the guide output of 0.58 mc. This deviation is not large enough to affect the crystal detection in the receiver. The amplitude of the f-m side bands in the guide output relative to the a-m side bands would be 0.0091.

Under the above conditions, the guide output is nearly pure amplitude modulation, since the amplitude of the f-m side bands is less than one percent of the a-m side band amplitude, and there is less than one percent quadrature-component amplitude distortion.

APPENDIX A

Let us investigate the relations that must exist among the system parameters if the side bands of the f-m carrier are to be shifted in phase by the proper amounts. The phase constant of a single-frequency wave in a guide may be expressed in terms of the frequency of the wave and the cut-off frequency of the guide.[1] We may write,

$$\beta_1=(\omega_c/c)\{[1+(\omega_m/\omega_c)]^2-(\omega_{co}/\omega_c)^2\}^{\frac{1}{2}}, \tag{1}$$

where β_1 is the phase constant of the upper side band, ω_{co} is the guide cut-off frequency, and c is the speed of light. MKS units are used throughout.

Let δ be the difference in frequency between the lower side band and guide cut-off. That is,

$$\delta=\omega_c-\omega_{co}-\omega_m.$$

Neglecting terms of the order of $(\omega_m/\omega_c)^2$ compared to one, we may write,

$$(\omega_{co}/\omega_c)^2=[1-(\omega_m+\delta)/\omega_c]^2\approx 1-2[(\omega_m+\delta)/\omega_c],$$

and

$$[1+(\omega_m/\omega_c)]^2\approx 1+2\omega_m/\omega_c.$$

Substituting the approximate forms just derived into Eq. (1)

$$\beta_1\approx 1/c[2\omega_c(2\omega_m+\delta)]^{\frac{1}{2}}.$$

Similarly, it can be shown that

$$\beta_2\approx 1/c(2\omega_c\delta)^{\frac{1}{2}},$$
$$\beta_c\approx 1/c[2\omega_c(\omega_m+\delta)]^{\frac{1}{2}},$$

where β_2 and β_c are the phase constants of the lower side band and the carrier respectively.

The ratio of the phase shift in the lower side band to the shift in the upper side band is

$$\frac{(\beta_c-\beta_2)l}{(\beta_1-\beta_c)l}\approx\frac{(\omega_m+\delta)^{\frac{1}{2}}-\delta^{\frac{1}{2}}}{(2\omega_m+\delta)^{\frac{1}{2}}-(\omega_m+\delta)^{\frac{1}{2}}}, \tag{2}$$

where l is the length of the guide. This ratio varies from one to about 2.42 as ω_m varies from zero to $(\omega_c-\omega_{co})$. $5\pi/2$ and $3\pi/2$ were chosen as the smallest phase shifts that would accomplish the desired modulation conversion and still have a ratio between one and 2.42. Setting the right side of Eq. (2) equal to 5/3, and solving for ω_m, we find

$$\omega_m=(240/49)\delta,$$

or

$$\omega_m=240/289(\omega_c-\omega_{co}). \tag{3}$$

Substituting the values for β_c, β_2, and ω_m into the equation for the phase shift of the lower side band,

$$l=5\pi/2(\beta_c-\beta_2),$$

we find

$$l=\frac{17\pi c}{4[2\omega_c(\omega_c-\omega_{co})]^{\frac{1}{2}}}. \tag{4}$$

The guide length and intermediate carrier frequency are determined from Eqs. (3) and (4) given the carrier and cut-off frequencies.

If TE_{10} propagation is used in a rectangular guide, then the transverse guide dimension, a, is[2]

$$a=\pi c/\omega_{co}.$$

---

[1] See, for example, S. Ramo and J. R. Whinnery, *Fields and Waves in Modern Radio* (John Wiley and Sons, Inc., New York, 1944), p. 297.

[2] See reference 1, Table 9.04.

APPENDIX B

This section considers the attenuation of the carrier and the first two side bands between guide input and output. The attenuation constant, α, for a wave of angular frequency ω, in a square guide propagating the TE_{10} mode is[2]

$$\alpha=\frac{\omega_{co}}{\pi c}\left(\frac{\omega\epsilon}{2\sigma}\right)^{\frac{1}{2}}\frac{[1+2(\omega_{co}/\omega)^2]}{[1-(\omega_{co}/\omega)^2]^{\frac{1}{2}}},$$

where ϵ is the dielectric constant within the guide, and σ is the conductivity of the guide walls.

The ratios of the output to input amplitudes for the carrier, the upper side band, and the lower side band will be $\exp(-\alpha_1 l)$, $\exp(-\alpha_2 l)$, and $\exp(-\alpha_3 l)$, respectively, where α_1, α_2, and α_3 are the attenuation constants for waves of frequencies ω_c, $\omega_c+\omega_m$, and $\omega_c-\omega_m$, respectively. The output a-m wave may be written,

$$e_{out}=AE_c\{\sin\omega_c t-(Bk/2)[\cos(\omega_c+\omega_m)t-D\cos(\omega_c-\omega_m)t]\}, \quad (5)$$

where E_c is the input carrier amplitude, k is the degree of modulation, and A, B and D are attenuation factors, that is,

$$A=\exp(-\alpha_1 l),$$
$$B=\exp[-(\alpha_2-\alpha_1)l],$$
$$D=\exp[-(\alpha_3-\alpha_2)l].$$

The constant A would merely change the apparent carrier amplitude and the constant B would change the apparent degree of modulation. Neither A nor B would influence the purity of the a-m output signal.

The constant D is the relative amplitude of the side bands. Let us consider the two unequal side bands to be two equal side bands of amplitude D plus a single side band of amplitude $1-D$. The maximum phase deviation of the output carrier would be $(1-D)/2$ radians, so the maximum frequency deviation would be $(1-D/2)\omega_m$. The amplitude of the first-order f-m side bands is proportional to $J_1[(1-D)(\omega_m/2)/\omega_m]$ or to $J_1[(1-D)/2]$, where J_1 is the Bessel function of first kind, first order. For small arguments,

$$J_1[(1-D)/2]\approx(1-D)/4$$

and the amplitude of the f-m side bands relative to the a-m side bands is $(1-D)/4D$. Using the values of the numerical example in the text, together with

$$\sigma_{copper}=5.80\times10^7$$
$$\epsilon=8.85\times10^{-12}$$

it is found that

$$D=0.965$$

The relative strength of the f-m side bands is 0.0091, and the maximum frequency deviation is 0.58 mc.

APPENDIX C

Let ω_s be the variable frequency of an intelligence signal, and let this signal amplitude-modulate the intermediate carrier. The new amplitude of the intermediate carrier, E_m', is

$$E_m'=E_m(1+M_s\cos\omega_s t)$$

where E_m is the original intermediate-carrier amplitude, and M_s is the degree of modulation by the intelligence. The instantaneous frequency of the f-m input, ω_i, is now

$$\omega_i=\omega_c[1+M_m E_m(1+M_s\cos\omega_s t)\cos\omega_m t],$$

where M_m is the degree of modulation by the intermediate carrier. The guide input, e, is

$$e=E_c\sin\left(\int_0^t\omega_i dt\right).$$

Using standard forms to integrate, and neglecting terms of order of magnitude ω_s^2 compared to those of order of magnitude ω_m^2, we have

$$e=E_c\sin\left\{\omega_c t+\frac{M_m E_m\omega_c}{\omega_m}\left[(1+M_s\cos\omega_s t)\sin\omega_m t-\frac{M_s\omega_s}{\omega_m}\sin\omega_s t\cos\omega_m t\right]\right\}. \quad (6)$$

The last term in Eq. (6) is a distortion term. Its amplitude relative to the amplitude of the desired signal is ω_s/ω_m, and it is in quadrature with the desired signal. Therefore, if ω_s/ω_m never exceeds one-tenth, the distortion will be less than one percent.

The band width is

$$BW=2(\omega_m+\omega_{s_{max}})\approx2.2\omega_m,$$

where $\omega_{s_{max}}$ is the highest intelligence frequency. Substituting from Eq. (3),

$$BW=1.83(\omega_c-\omega_{co}). \quad (7)$$

Equation (7) is a design equation. Given the carrier frequency, cut-off may be chosen from considerations of band width, and the tolerable amount of f-m signal in the output (see Appendix B).

Measurement of Self-Diffusion of Silver without Radioactive Tracers*

G. C. KUCZYNSKI
Sylvania Electric Products, Inc., Bayside, New York
(Received September 23, 1949)

A new method dispensing with the use of radioactive tracers has been developed for measurement of volume self-diffusion. The method is based upon the relationship of the rate of sintering of metallic wires to the coefficients of self-diffusion. The values of the self-diffusion coefficients for silver as measured by this method are in good agreement with those obtained by the radioactive tracers method.

SELF-DIFFUSION implies the diffusion of the atoms of a given substance into itself. Until recently, the detection of such a process was possible only by measurement of the rate of penetration of the radioactive isotope into another stable isotope of the same chemical element.

This method when first introduced by von Hevesy[1-3] was restricted to the study of diffusion of the naturally radioactive elements such as lead[4] and bismuth.[5] The discovery of artificial radioactivity removed this obstacle and allowed the determination of self-diffusion coefficients of copper, gold, silver and zinc using improved methods.[6,7]

In the previous work of this author,[8] the relationship of the radius x of the interface between the sintered particles to the coefficient D of volume self-diffusion was established.

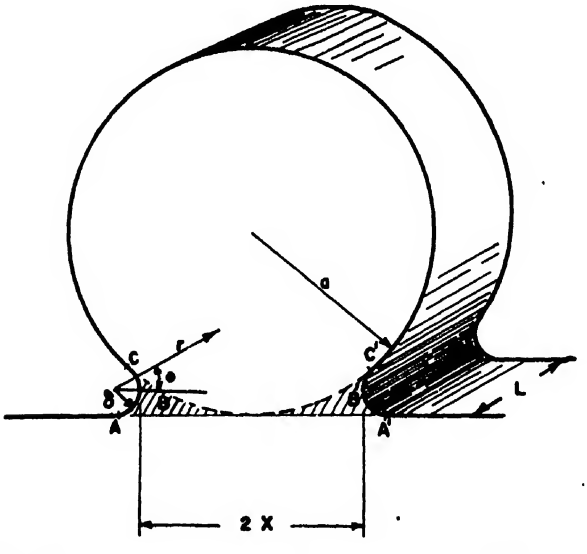

FIG. 1. Schematic representation of a wire bonded to a cylinder.

This relationship is as follows:*

$$D=k/(40\gamma\delta^3)(T/t)(x^5/a^2), \qquad (1)$$

where k is Boltzmann's constant, γ the surface energy of the metal δ the interatomic distance, T the temperature of sintering on the Kelvin scale, t time of sintering and a the original radius of the particle. Work with small metallic particles is laborious and does not yield accurate results. The examination of the graphs contained in the above mentioned paper reveals a definite linear relationship between $(x^5/a^2)T/t$ and $1/T$. However, the spread of points is too large for accurate determination of the coefficient of diffusion. In his communication to the American Physical Society,[9] the author was able to report some of the diffusion coefficients of silver determined by a new method consisting of sintering of silver wires to cylindrical silver pieces. The detailed description of this method and results obtained is the subject of this paper. The new method allows to determine the self-diffusion of most metals without use of radioactive tracers.

THEORETICAL CONSIDERATIONS

The wire in contact with the plate of the same metal forms a system which is not in equilibrium because its total surface free energy is not a minimum. During heating, the space between the wire and the plate

gradually fills up forming a neck bounded by two cylindrical concave surfaces ABC and $A'B'C$ in Fig. 1.

As in the case of sintering of the spherical metallic particles,[8] self-diffusion is responsible for the formation of this neck. If we assume the vacancy theory of diffusion, then the volume directly underneath the concave surfaces of the neck should have an excess concentration ΔC of holes over the equilibrium concentration C_0. This difference in concentration between the volume underneath the concave surface of the neck and the other parts of the system creates the diffusion gradient necessary for the flow of atoms into the neck area and thus promotes gradual filling up of the latter. The equation of flow can then be written as follows:

$$A\,|(\partial\Delta C/\partial r)_{r=\rho}|\,D'=dV/dt, \qquad (2)$$

where A is the surface through which the vacancies enter the system, V the filled volume between the wire and the plate indicated by shaded area in Fig. 1 $(\partial\Delta C/\partial r)_{r=\rho}$ the gradient of vacancy concentration on the surface of the radius of curvature ρ (such as surface which contour is indicated in Fig. 1 by ABC and $A'B'C$) and D the coefficient of vacancy diffusion. The relationship between the D' and D the coefficient of atomic diffusion is $D'C_0=D$ where C_0 as before designates the equilibrium concentration of vacancies.

We shall first evaluate the excess hole concentration ΔC. The free energy increase of the system, due to the dissolution of n vacancies raising the concentration from C_0 to $C_0+\Delta C$ is $nkT\ln(C_0+\Delta C/C_0)$ or if ΔC is small $nkT(\Delta C/C_0)$. At the same time, there is the energy decrease due to the decrease of the pressure γ/ρ over the neck area. This energy decrement is approximately $n\delta^3(\gamma/\rho)$ if the diameter of the vacancy is equal to the atomic diameter δ. At equilibrium, these two energies have to be equal which results in the following expression for the increment of concentration under the neck area

$$\Delta C=(\delta^3\gamma/kT\rho)C_0. \qquad (3)$$

This excess concentration of holes causes the diffusion

of atoms from the inner parts of the system to the neck. When the current is established $\partial C/\partial t=0$ and the concentration will be given by the solution of the Laplace equation

$$\nabla^2 C=0$$

this solution is a function of the radius r drawn from the center of curvature 0 (Fig. 1) of the neck area and the angle θ of this radius with a direction perpendicular to the axis of the wire and parallel to the plate and also passing through the center of curvature. Obviously ρ does not change along the length of the wire. Such a solution can be written in the form

$$C=\sum_{n/0}^{\infty}\frac{C_n\cos n\theta}{r^n},$$

or

$$\Delta C=\sum_{n/1}^{\infty}\frac{C_n\cos n\theta}{r^n}, \tag{4}$$

where

$$\Delta C=C-C_0.$$

Expression (4) should be approximately equal to (3) on the surface of the neck, where $r=\rho$, which implies that $|C_n|$ for $n>1$ are small and corresponding terms can be neglected in our approximation. We may accept, therefore, that

$$\Delta C\cong\delta^3\gamma C_0/kTr$$

and

$$(\partial\Delta C/\partial r)_{r=\rho}=-(\delta^3\gamma C_0/kT\rho^2). \tag{5}$$

Simple geometrical considerations based upon Fig. 1 lead to the following equations which are valid provided $x/a<\cdot 3$

$$\rho=(x^2/4a),\quad A=(\pi x^2L/2a),\quad V=(x^3L/2a),$$

where L is the length of the sintered wire. Inserting these values into (5) and (2) and noting the $D'C_0=D$, we obtain

$$(80\pi/3)(\delta^3\gamma a^2/kTx^4)D=dx/dt,$$

and after integration

$$x^5/a^2=(80\pi/3)(\delta^3\gamma/kT)Dt. \tag{6}$$

Using this equation, we may express the coefficient of diffusion D as a function of the readily measurable variables x, a, T and t.

$$D=3/80\pi(kT/\delta^3\gamma t)x^5/a^2. \tag{7}$$

It has to be noted that in the above derivation, it was tacitly assumed that the contour of the neck ABC in Fig. 1 is semicircular. If it were not so, then there would be a difference of concentration of vacancies proportional to the difference of the inverse radius of the smallest and largest radius of curvature and the diffusion current would tend to equalize the curvature. It is, therefore, reasonable to assume the contour to be circular.

THE EXPERIMENTAL METHOD

As can be seen from the brief introduction, the determination of the coefficient of self-diffusion reduces itself to the sintering of a wire to a large block of the same metal and subsequent measurement of the width $2x$ of the interface formed. In order to demonstrate that in this case the mechanism of sintering is diffusion, the experimental test of Eq. (6) is necessary.

The experiments were performed on very pure silver metal. The sintering of the wire to a flat base was not successful because it was difficult to obtain good contact between the wire and the base. This problem was solved

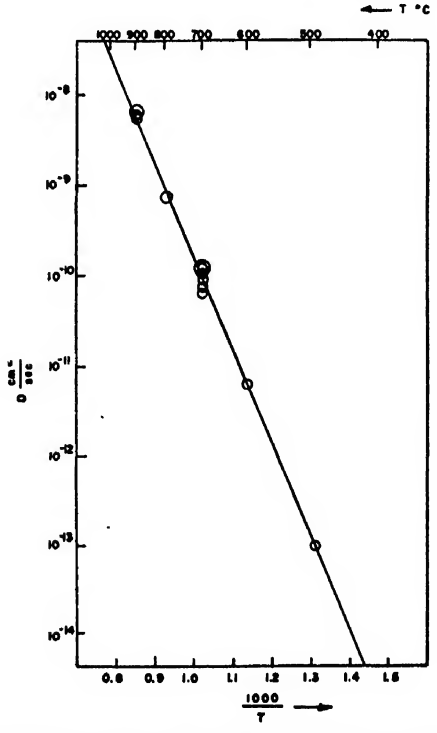

FIG. 4. Variation of volume self-diffusion coefficient of silver with temperature as determined from sintering experiments.

by winding the 0.005 in. diameter silver wire on a cylindrical piece of the same material of about ¼ in. diameter. This diameter was found large enough to allow to neglect the curvature of the cylinder and so consider it as approximately flat. Good care was taken to tighten the wire well on the cylinder without, however, introducing much plastic deformation in the interface. Specimens prepared in this manner were heated in hydrogen, air or argon at 900, 800, 700, 600 and 460°C for various periods of time, as indicated in Table I. After heating, the specimens were nickel plated in order to avoid loosening or deformation of the interfaces during the subsequent metallographic operations. Plated cylinders with wires sintered to them were then mounted in Bakelite and cut, in order to obtain a diametral cross section of the wire in contact with the base.

The results of the measurements of the diameter of the neck, sometimes show large scattering of values, due to more or less perfect contact along the wire. In order to assure maximum accuracy, a great number of readings were taken (more than twenty per temperature-time run) and the most probable diameter was determined from the frequency of occurrence curves.

The plane of the cut was not necessarily perpendicular to the axis of the wire and consequently the width of the interface $2x$ between the wire and the cylinder observed on the cross section was not the true one. This, however, was easily corrected as the apparent distortion of the interface and the known diameter of the wire are in the same proportion as the true interface width and the true wire diameter, known from micrometric measurements. The true width of the interface then was evaluated by multiplying its measured value by the ratio of the true diameter of the wire to its value as measured with the micrometer. Some examples of the polished sections prepared in the manner outlined above are shown in Fig. 2.

RESULTS

Table I lists the half width values of the interface x, along with the radius of wire a, the x/a ratio and the coefficient of self-diffusion D calculated from Eq. (4). The last column contains details of the atmosphere used for each particular heat treatment. It is convenient to convert (6) into logarithmic relationship after dividing both sides by a^5

$$5\log\frac{x}{a}=\log t+\log\left(\frac{80\pi}{3}\frac{\delta^3\gamma D}{kTa^3}\right);$$

the last term is constant at a given temperature. By plotting $\log x/a$ *versus* $\log t$ one can obtain the exponent, which in the case of diffusion flow should be 5, by simple determination of the slope of the obtained straight line.

The $\log x/a/\log t$ plots at 900°C and 700°C are given in Fig. 3. The points fall on the straight lines whose inverse slopes are 5.0 and 5.1 respectively, indicating that the relationship $x^5\sim t$ holds, as should be expected when the diffusion flow is responsible for sintering. The fact that the points corresponding to the heat treatments in three different atmospheres fall on the same straight line, seems to indicate that in the case of silver bonding of wires or particles together is not affected by the surrounding atmosphere, as long as it is neutral. At 700°C, air can be considered neutral to silver.

Figure 4 represents the semilogarithmic plot of $\ln D$ *versus* $1000/T$. The experimental points fall very well on the straight line. The coefficient of self-diffusion of silver as determined from this graph is $D=0.9e^{-45,700/RT}$* and agrees very well with that obtained by W. A. Johnson[7] who used the radioactive isotope method for its determination. Johnson obtained $D=0.89e^{-45,900/RT}$. The value obtained from the experiments of sintering of silver spheres[8] was $D=0.60e^{-45,000/RT}$. As we can see all three values are in close agreement indicating that the wire method may well be used in the determination of the coefficients of self-diffusion of metals. Its greatest advantage is simplicity and great saving of time. In cases like aluminum where the radioactive isotopes are not available the wire method is the only one which permits determination of the self-diffusion coefficient.

ACKNOWLEDGMENTS

The author wishes to express his gratitude to W. E. Kingston, Manager of Sylvania Metallurgical Laboratories, for his support of this project. He also wishes to thank H. Lipson of Sylvania Electric Products, Inc. for his aid in processing the specimens and Mrs. L. Roth for her skillful metallographic work.

* In the calculation of D the value of surface energy for liquid silver, 1000 ergs/cm² was adopted, although it was expected that the surface energy for solid metal should be somewhat higher. However, the error introduced by this choice should not change the order of magnitude of the coefficient of diffusion.

A Graphical Analysis of the Interference Patterns of an Elevated Ultra-High Frequency Antenna under Conditions of Atmospheric Stratification*

F. R. Abbott and C. J. Fisher
U. S. Navy Electronics Laboratory, San Diego, California
(Received September 6, 1949)

Analytical computation of the detailed lobe structure of an elevated meter or centimeter band antenna for a standard atmosphere is quite tedious. In case there are discontinuities in the gradient of refractive index the analysis becomes hopelessly involved.

This paper presents a straightforward method of graphical analysis for the optical region, equally applicable to a standard or stratified atmosphere.

INTRODUCTION

A PICTORIAL presentation of the lobe structure of the low angle radiation pattern from an elevated microwave or v.h.f. antenna is usually constructed with a distorted scale. Horizontal distances may be compressed to a millionth while vertical dimensions are reduced to 1/10,000 or less. Thus elevation angles are greatly exaggerated.

It is advantageous to use such a distorted representation in the construction of ray diagrams. It is very significant that the path difference between intersecting rays under such a transformation is easily measureable and is directly reducible to the path difference of the corresponding rays at full scale.

Thus, if one is concerned with a centimeter or so path length difference between two rays intersecting at a distance of twenty miles, it becomes possible to construct the rays on a distorted scale drawing and measure the path difference on the drawing. The measured path difference multiplied by a constant factor gives the difference for the actual rays and the relative phase is thus determined.

Geometrical path differences on a drawing may be measured to a high degree of accuracy using an ordinary engineer's map measure, the rolling wheel of which has been graduated. It will be shown that the additional term included in the optical path difference may be determined by planimeter measurements of the area enclosed between the rays.

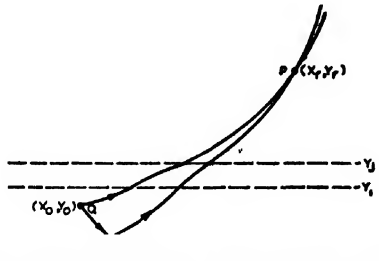

FIG. 1. Two optical paths for radiation proceeding from a source, Q, and traveling through an inversion layer between Y_i and Y_j to a point of intersection, P.

* M. E. Hall of the U. S. Navy Electronics Laboratory Antenna Range staff assisted in the preparation of the material for publication.

THEORY

Consider radiation proceeding from a source at Q to an arbitrary point, P, by two alternate optical paths. The second ray may have been occasioned by a reflection as indicated in Fig. 1 or by other means.

Formally, the optical path length of either ray is given by

$$S=\int_{X_0Y_0}^{X_rY_r} n\,dL, \tag{1}$$

in which n is the refractive index and dL is the element of geometrical path length which, in turn, is given by

$$dL=[1+(dY/dX)^2]^{\frac{1}{2}}dX \cong[1+\tfrac{1}{2}(dY/dX)^2-\tfrac{1}{8}(dY/dX)^4+\cdots]dX. \tag{2}$$

The third and all ensuing terms in the expression for dL are very small for rays at low vertical angles and will henceforth be disregarded. The refractive index of the lower atmosphere, designated by n, is assumed to be dependent only on the elevation. It is further assumed that the vertical refractive index curve, $n=f(Y)$, may be replaced by a series of sections over which dn/dY is constant. n is expressible as

$$n=1+q(Y), \tag{3}$$

in which $q(Y)$ is a small fraction, generally 0.0004 or less for the case considered.[1] The radius of curvature of rays in a medium of slowly changing refractive index is given by[2]

$$1/R=(d/dY)\log n=(1/n)(dn/dY). \tag{4}$$

For values of n very close to unity

$$1/R\cong(dn/dY). \tag{5}$$

The two rays in Fig. 1 thus proceed through three zones. In the lower zone the refractive index is increasing with increased altitude and since a ray bends into the denser medium, the curvature is upward. From elevations Y_i to Y_j the refractive index is decreasing and the

[1] I. Katz and J. M. Austin, "Qualitative survey of meteorological factors affecting microwave propagation," M.I.T. Radiation Lab. Report No. 488 (June 1, 1944).

[2] P. K. L. Drude, *The Theory of Optics* (Longmans, Green and Company, New York, 1902), p. 306.

curvature is downward. Above Y_j the refractive index increases and the curvature is again upward.

Designate the quantities associated with the two rays by the subscripts a and b, respectively. The path lengths from Eqs. (1)–(3) become

$$S_a \approx \int_{X_0}^{X_r} [1+q(Y)_a][1+\tfrac{1}{2}(dY/dX)_a^2]dX, \quad (6)$$

and

$$S_b \approx \int_{X_0}^{X_r} [1+q(Y)_b][1+\tfrac{1}{2}(dY/dX)_b^2]dX. \quad (7)$$

By neglecting terms of the order $\frac{1}{2}q(Y)(dY/dX)^2$ and higher, the optical path difference becomes

$$S_b-S_a \approx \int_{X_0}^{X_r} [q(Y)_b-q(Y)_a + \tfrac{1}{2}(dY/dX)_b^2-\tfrac{1}{2}(dY/dX)_a^2]dX. \quad (8)$$

Designating the vertical gradient of refractive index by $n'=dn/dy$, we have

$$q(Y)_b-q(Y)_a=n_b-n_a=\int_{Y_a}^{Y_b} n'dY,$$

and

$$S_b-S_a=\tfrac{1}{2}\int_{X_0}^{X_r} [(dY/dX)_b^2-(dY/dX)_a^2]dX + \int_{X_0}^{X_r}\int_{Y_a}^{Y_b} n'dYdX. \quad (9)$$

The first integral in Eq. (9) is simply the geometrical path length difference for the two rays and is expressible as L_b-L_a.

Since the gradient of refractive index, n', is constant except for discontinuities at $Y=Y_i$ and $Y=Y_j$ the double integral is equivalent to the sum of the three area integrals, each multiplied by the value of n' for the area concerned. This is expressible by $\sum_i n_i'A_i$ in which A_i is the area characterized by a refractive index gradient n_i' and bounded by the paths a and b and the elevation levels Y_i and/or Y_j.

Thus, the optical path difference becomes

$$S_b-S_a=L_b-L_a+\sum n_i'A_i. \quad (10)$$

The construction of a ray diagram involves the reduction in dimensions expressed by

$$dy=CdY, \qquad dx=DdX, \quad (11)$$

in which C and D assume values of the order of 1/10,000

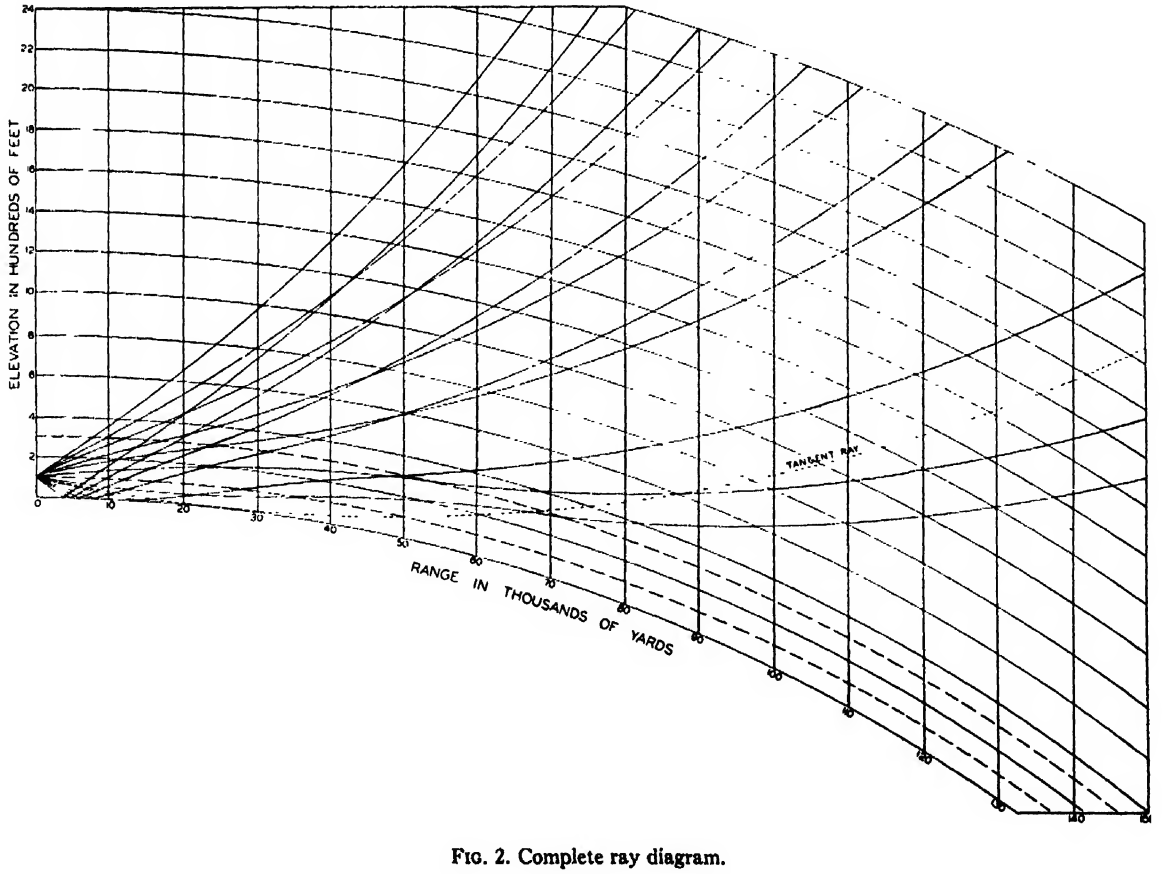

FIG. 2. Complete ray diagram.

and 1/1,000,000, respectively. In the scale coordinates Eq. (8) becomes

$$s_b - s_a = \frac{D}{2C^2}\int_{X_0}^{X_r}[(dy/dx)_b^2 - (dy/dx)_a^2]dx + \frac{1}{CD}\int_{X_0}^{X_r}\int_{Y_a}^{Y_b} n'dydx, \quad (12)$$

which like (9) is expressible as

$$s_b - s_a = D/C^2(l_b - l_a) + 1/CD\sum_i n_i'\alpha_i, \quad (13)$$

where α and l are the reduced scale area and length symbols.

The radius of curvature of the rays on the reduced scale drawing is proportional to the radius of curvature of the actual rays. The proportionality factor is determined as follows:

From elementary calculus the radius of curvature of the actual rays is given by

$$R = \frac{[1+(dY/dX)^2]^{\frac{3}{2}}}{d^2Y/dX^2}.$$

For rays near grazing incidence $(dY/dX)^2$ is very small so that

$$1/R \approx d^2Y/dX^2. \quad (14)$$

The reduced scale radius, r, follows from the transformation of Eqs. (11) applied to (14) and is given by

$$1/r \approx C/D^2 d^2Y/dX^2. \quad (15)$$

By Eq. (5), Eq. (15) becomes

$$1/r \approx (C/D^2)n'. \quad (15a)$$

Introducing r_i, the scale radius of curvature of the rays, into Eq. (13) we have for the path difference

$$s_b - s_a = (D/C^2)[(l_b - l_a) + \sum_i \alpha_i/r_i]. \quad (16)$$

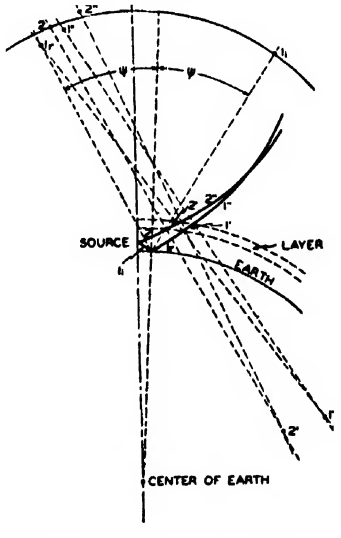

FIG. 3. Illustration of method of construction of a ray diagram.

As is shown in the Appendix the modification of the actual index of refraction curve does not alter the total path length difference of any pair of intersecting rays. It has been shown[3] that to construct a diagram in which the rays in regions of standard refraction are represented by straight lines requires the use of an effective earth's radius equal to 4/3 the actual radius of the earth. This defines the slope of a ray passing from the source through any point.

Since it is imperative to keep the angle of inclination of rays and the scaled earth surface small in order that the neglected terms of Eq. (2) do not introduce appreciable error, a curve of modified index has been selected that will minimize both. This curve is such that the resultant curvature of both the surface of the earth and the rays in regions of standard refraction is equal to half the curvature of the earth's surface relative to a ray in standard atmosphere obtained from the above relation. This gives a radius of curvature for both rays in the region of standard refraction and the surface of the earth equal to 8/3 the actual radius of the earth. Thus, from Eq. (15) the scaled earth radius equals $(D^2/C)R_e$, where R_e is the modified radius of earth curvature and is equal to 8/3 actual earth radius.

In the actual construction of a ray diagram appropriate values of the scale factors, C and D, are chosen and the earth's surface is drawn using the resulting value for the scaled earth radius as given above. The diagram shown in Fig. 2 was drawn on a chart 27×40 in. on which one inch vertical represents 150 ft. and one inch horizontal represents 2 miles. A layer of inversion of refractive index is indicated as being between the dashed lines. The transformation constants, C and D, assume values of 1/1800 and 1/144,000, respectively and result in a scaled earth radius of 58 in.

CONSTRUCTION OF RAY DIAGRAM

Using the location of the source of radiation as center, an arc of scaled earth radius is struck above the line representing the earth's surface. Equally spaced points along this arc provide centers of curvature for equally spaced rays emanating from the source. Consider a direct and reflected ray whose centers, for the sake of explanation of construction, shall be the arbitrary points, 2 and 1_i, respectively, as shown in Fig. 3. When a direct ray, such as ray No. 2, is incident on the lower boundary of an inversion layer the curvature reverses in sign. The new center lies on an extension of the line passing through the center of curvature of the incident ray and the point of incidence. The radius of curvature of the ray while passing through the inversion layer is again defined by Eq. (15) and can be found from the modified index curve. This procedure is repeated when the ray meets the upper boundary of the layer and the new center is found on an extension of the second radius

[3] Schelleng, Burrows, and Ferrell, "Ultra-short-wave propagation," Proc. I.R.E. 21, 427 (1933).

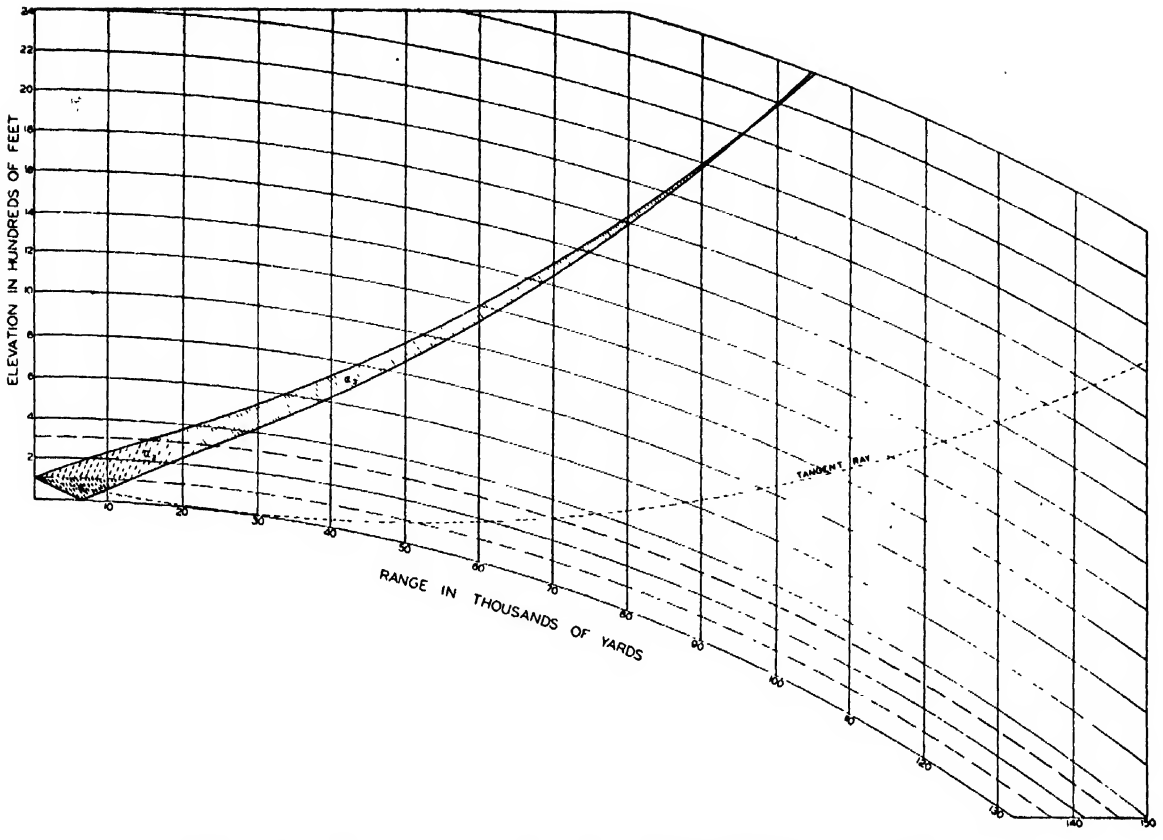

FIG. 4. Areas, α_i, used in evaluating the resultant field, E, of Eq. (17) at any point of intersection.

passing through the point of incidence at the top of the layer. This is shown as line 2′2″ in Fig. 3.

In the case of a ray reflected from the earth's surface such as ray No. 1 in Fig. 3, an extension of the earth's radius is drawn through the point of reflection. Since the angle of reflection is equal to the angle of incidence, the center of curvature of the reflected ray is found on a line making an angle, ψ, with this extension of the earth's radius. The reflected ray from this point on is constructed exactly as the direct ray given above.

The areas, α_i, of Eq. (16) bounded by the two rays and the levels of discontinuity in refractive index gradient shown in Fig. 4 are measured with a planimeter. The geometrical path difference is measured by running a map measure forward over one ray and backward along the alternate ray to the starting point. It should be remembered that terms of α_i/r_i are added algebraically and due regard should be given to change of sign of r_i when the direction of curvature changes.

It is essential to select values of C and D such that the slope of the rays remains small. Otherwise the disregarded terms of Eq. (2) become excessively large.

The intensity of each component of the field normally decreases with distance in accordance with the inverse distance law of radiation fields. The two factors necessary to account for such variation are designated by $1/(d)^{\frac{1}{2}}$ and $1/(\delta)^{\frac{1}{2}}$ where δ is the distance between individual rays of the ray system at a distance, d, from the transmitter.

We then finally obtain the resultant field, E, at any point of intersection of two rays with reference to E_0, the field at some reference distance, d_0, in the form

$$\frac{E}{E_0}=\frac{1}{(d)^{\frac{1}{2}}}\left\{\frac{1}{(\delta_a)^{\frac{1}{2}}}+\frac{\rho}{(\delta_b)^{\frac{1}{2}}}\exp j\beta\left[\phi+\frac{D}{C^2}\left(l_b-l_a+\Sigma_i\frac{\alpha_i}{r_i}\right)\right]\right\}, \quad (17)$$

where $\beta=2\pi/\lambda$, δ_0 is the ray spacing at distance d_0 from the source, usually taken as one meter, and the subscripts, a and b, refer to the direct and reflected rays, respectively. Equation (17) is valid so long as $1/(\delta)^{\frac{1}{2}}$ is finite.

The phase shift, ϕ, and the magnitude, ρ, are introduced to allow for phase rotation and change of intensity of the lower ray on reflection. In the case of horizontally polarized waves propagated over sea water, ϕ goes to $\lambda/2$, and ρ becomes unity.

Figure 5 is a plot of the field pattern of a 3000-Mc source elevated 100 ft. above the surface of the earth. It was secured by evaluating Eq. (17) at all the points of intersection of rays on the corresponding ray diagram.

The foregoing method of analysis presents an unique

and simple procedure for computation of the radiation field in the optical zone, for an elevated very high frequency antenna in any type of stratified atmosphere. Good correlation has been obtained between the measured field in the optical zone under conditions of atmospheric stratification and the calculated field for the same condition.

A complete field analysis below the optical horizon must include diffracted, scattered and partially reflected components of radiation[4] none of which is considered in the above analysis.

A number of predicted low level coverage diagrams similar to Fig. 5 are available in reports WP-11, WP-14, and WP-15 of the U. S. Navy Radio and Sound Laboratory.[5] These include patterns of 200- and 3000-mcs sources for 13 types of non-linear atmospheric refractive index gradients.

APPENDIX. PROOF OF THE INVARIANCE OF OPTICAL PATH DIFFERENCE TO THE CURVATURE IMPOSED ON SPACE BY THE USE OF A MODIFIED INDEX OF REFRACTION

There are a variety of forms that the modified index of refraction curve may take as is shown in Fig. 6. Each one lends more or less convenience to a given application. It would be well to ask what effect the modification of the gradient of the index of refraction has on the analysis presented.

The path difference for the two rays depicted in Fig. 1 is given by an expression of the form

$$S_b - S_a = (L_b - L_a) + \Sigma_i A_i/R_i,$$

where $L_b - L_a$ is the geometric path length difference and A_i is the area bounded by the rays in the i region. R_i is the radius of curvature of the ray in the i region.

For values of n close to unity,

$$1/R \approx dn/dY \approx d^2Y/dX^2,$$

which leads to

$$S_b - S_a = (L_b - L_a) + \Sigma_i n' A_i. \tag{18}$$

From Eq. (8) we see that the geometric path length difference is expressible as

$$L_b - L_a = \tfrac{1}{2}\int [(dY/dX)_b^2 - (dY/dX)_a^2]dX$$

$$= \tfrac{1}{2}\int [(Y_b')^2 - (Y_a')^2]dX. \tag{19}$$

Let z_a be the slope of the reflected ray at the point of reflection and z_b be the slope of the direct ray at the point of reflection. Then

$$Y_a' = z_a - \int_0^X n_a' dX, \tag{20}$$

$$Y_b' = z_b - \int_0^X n_b' dX. \tag{20a}$$

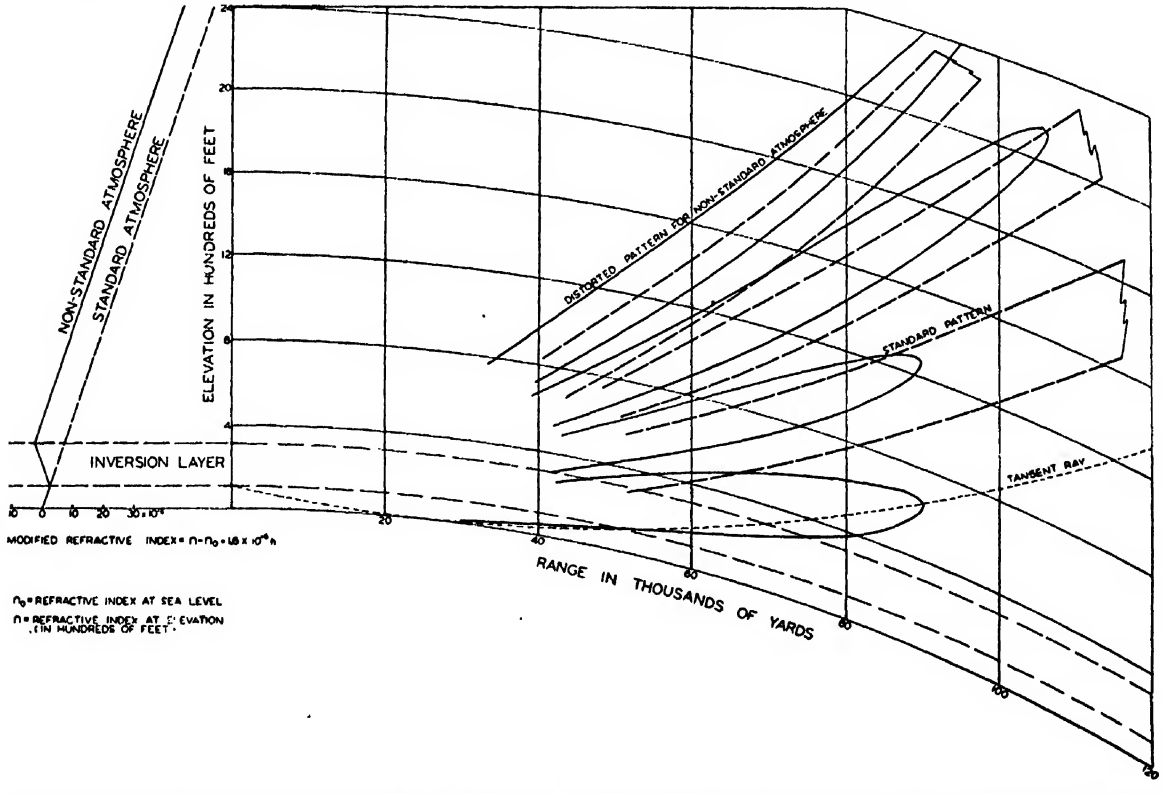

FIG. 5. Plot of a field pattern showing low level coverage for a modified refractive index equal to $n - n_0 + 1.8 \times 10^{-6}h$, where n_0 is the refractive index at sea level and n is the refractive index at elevation h. (h is measured in hundreds of feet.)

[4] J. B. Smith and L. G. Trolese, "Propagation of radio waves in the lower troposphere," Proc. I.R.E. 35, No. 11, 1198–1202 (November, 1947).

[5] U. S. N. R. and S. Lab. Report WP-11, "Procedure and charts for estimating low level coverage of shipboard 200 mcs radars under conditions of pronounced refraction" (April 10, 1944). U. S. N. R. and S. Lab. Report WP-14, "Predicted low level coverage of S-band radars as affected by weather" (November 1, 1944). U. S. N. R. and S. Lab. Report WP-15, "Predicted low level coverage of 200 mcs radars as affected by weather" (November 4, 1944).

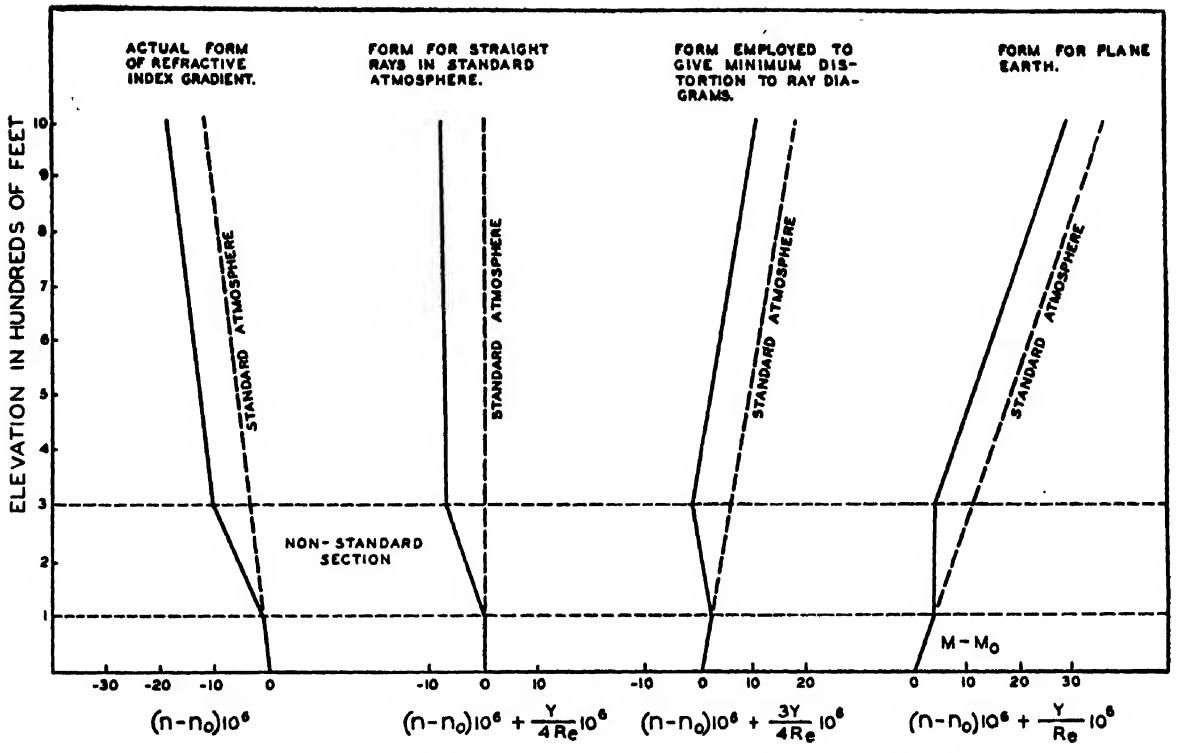

FIG. 6. Four useful types of representation of atmospheric refractive index gradient. All represent the same condition.

Let n' be modified by an amount, k, and designate the new slopes by U_a' and U_b'. It is seen from Fig. 6 that the factor, k, assumes values of $(Y/R_e)10^6$, $(Y/4R_e)10^6$ etc., where Y is the elevation in hundreds of feet and R_e is the radius of the earth.

$$U_a' = z_a - \int_0^X (n_a' + k)dX, \tag{21}$$

$$U_b' = z_b - \int^X (n_b' + k)dX. \tag{21a}$$

From (21) and (21a)

$$U_b' - U_a' = z_b - z_a - \int^X (n_b' - n_a')dX = Y_b' - Y_a', \tag{22}$$

$$U_b' + U_a' = z_b + z_a - \int_0^X (n_b' + n_a')dX - 2k\int_0^X dX = Y_b' + Y_a' - 2kX. \tag{23}$$

Hence,

$$(U_b')^2 - (U_a')^2 = (U_b' - U_a')(U_b' + U_a') = (Y_b')^2 - (Y_a')^2 - (Y_b' - Y_a')2kX. \tag{24}$$

Let Δ_g be the increment in geometric path length difference that results from modifying n' by the factor k. From Eq. (19)

$$\Delta_g = \tfrac{1}{2}\left\{\int[(U_b')^2 - (U_a')^2]dX - \int[(Y_b')^2 - (Y_a')^2]dX\right\}. \tag{25}$$

By substituting (24) in (25) we see that

$$\Delta_g = -k\int_Q^P (Y_b' - Y_a')XdX. \tag{26}$$

Integrating Eq. (26) by parts and letting

$$u = X; \quad du = dX,$$

and

$$dv = (Y_b' - Y_a')dX; \quad v = Y_b - Y_a,$$

we see that

$$\Delta_g = -k\left[X(Y_b - Y_a)\Big|_Q^P - \int_Q^P (Y_b - Y_a)dX\right]. \tag{27}$$

In the first term, $Y_b - Y_a$ is equal to zero at the points P and Q since the rays cross and the difference in height is zero. The integral term represents the area, A, bounded by the two rays. Therefore, $\Delta_g = kA$.

From Eq. (18), the purely optical contribution to path difference is given by the term $\Sigma_i n_i' A_i$. By modifying the refractive index gradient by a factor, k, this term takes the form $\Sigma_i (n_i' + k)A_i$.

Let Δ_0 be the variation in the purely optical component of the path length difference of two rays passing through media having refractive indices n and $(n+k)$, respectively. Then

$$\Delta_0 = \Sigma_i n_i' A_i - \Sigma_i (n_i' + k)A_i = -\Sigma_i kA_i.$$

Since $\Sigma_i A_i$ represents the total area, $\Delta_0 = -kA$.

Thus, the total change in path length difference observed when n is modified by a factor, k, is

$$\Delta_t = \Delta_g + \Delta_0 = kA - kA = 0.$$

It is important to note that the relative total path length difference is independent of the modification of the gradient of the index of refraction.

It is elementary to prove that the elevation and distance to the point of intersection of two rays is also independent of the choice of modified index.

The Determination of the Impulsive Response of Variable Networks

LOTFI A. ZADEH
Columbia University, New York, New York
(Received November 21, 1949)

Starting with the differential equation relating the output and the input of a linear varying-parameter network, it is shown that the impulsive response of the system is related to a Green's function associated with the system through a linear operator which is the adjoint of the right-hand operator in the given differential equation. A perturbation procedure for the determination of the impulsive response of a slowly varying network is outlined. Use of the method is illustrated by a simple example involving a band width-modulated RC half-section.

GENERAL THEORY

THE term *variable network* is commonly used to describe a network in which one or more element-values are dependent upon a combination of the three variables—time, input, and output. The variability of transmission characteristics of variable networks makes them ideally suited for many applications in the fields of communication and control. In practice, however, the use of variable networks has been, and still is, very limited mainly because of the lack of adequate means for their analysis, synthesis and mechanization.

The most basic problem in the theory of variable networks is that of analysis. In general, the analysis of a variable network in which the element-values are functionals of the input, output, and time, presents mathematical problems of a prohibitive degree of complexity—problems which for all practical purposes are unsolvable except through use of high speed automatic computers. There are, however, certain classes of variable networks which are amenable to purely analytical treatment. The most important of these is the class of so-called linear varying-parameter networks, that is, linear networks in which the element-values are functions of time only, and are independent of both the input and the output. Familiar examples of such networks are the amplitude and frequency modulators and—as a limiting case—the ordinary fixed linear networks. To simplify the terminology, the term *variable network* as used in this paper will refer to a linear varying-parameter network.

The behavior of a variable network may be described in several different ways—some of which are implicit and some explicit. Usually, the behavior is described *implicitly* by means of a differential equation relating the output of the network, $e_2(t)$, to the input $e_1(t)$. This equation is, in general, of the form

$$[a_n(t)p^n+\cdots+a_1(t)p+a_0(t)]e_2(t) = [b_m(t)p^m+\cdots+b_1(t)p+b_0(t)]e_1(t), \quad (1)$$

where $p=d/dt$ and the a's and b's are known functions of time. Equation (1), which is sometimes referred to as the *fundamental* equation of the system, may be written more compactly as

$$L(p;t)e_2(t)=K(p;t)e_1(t), \quad (2)$$

where $L(p;t)$ and $K(p;t)$ stand, respectively, for the left-hand and right-hand operators in Eq. (1). The input $e_1(t)$ is usually assumed to be zero for $t<0$, and the network itself is assumed to be unexcited, though not necessarily fixed, prior to $t=0$. Thus, the problem of the determination of the response to a specified input $e_1(t)$ reduces to the solution of the differential equation represented by Eq. (1), subject to homogeneous initial conditions at $t=0-$.

A commonly used form of *explicit* description of the behavior of a variable network is based on the notion of the *impulsive response* of the network. The impulsive response $W(t,\xi)$ is defined as the response of the system at $t=t$ to a unit impulse applied at $t=\xi$. In other words, $W(t,\xi)$ is the solution of the equation

$$L(p;t)W(t,\xi)=K(p;t)\delta(t-\xi), \quad (3)$$

where $\delta(t-\xi)$ represents a unit impulse at $t=\xi$. The salient property of $W(t,\xi)$ is that the response to any given input $e_1(t)$, may be expressed in terms of $W(t,\xi)$ and $e_1(t)$ through the superposition integral

$$e_2(t)=\int_{-\infty}^{\infty} W(t,\xi)e_1(\xi)d\xi. \quad (4)$$

Thus, when the behavior of a network is described by means of its impulsive response, the determination of the response of the network to any given input reduces to performing the relatively simple operation expressed by Eq. (4).

A more convenient form of explicit description of the behavior of a variable network is based on the notion of the *system function*[1] of the network. Briefly, the system function of a variable network is defined as a function $H(j\omega;t)$ such that $H(j\omega;t)e^{j\omega t}$ represents the steady-state response of the network to $e_1(t)=e^{j\omega t}$. In other words, the system function $H(j\omega;t)$ is the complex envelope of the response of the network to $e^{j\omega t}$. It is shown in [1] that $H(j\omega;t)$ is the steady-state solution of the differential equation

$$L(p+j\omega;t)H(j\omega;t)=K(j\omega;t), \quad (5)$$

and that $H(j\omega;t)$ and $W(t,\xi)$ are related to each other

[1] L. A. Zadeh, "Frequency analysis of variable networks," Proc. I.R.E. 38, 291–299 (1950).

by the relations:

$$H(j\omega; t)=\int_{-\infty}^{\infty} W(t, \xi)e^{-j\omega(t-\xi)}d\xi \tag{6}$$

and

$$W(t, \xi)=\frac{1}{2\pi}\int_{-\infty}^{\infty} H(j\omega; t)e^{j\omega(t-\xi)}d\omega. \tag{7}$$

The salient characteristic of $H(j\omega; t)$ is that the response to any given input $e_1(t)$ may be expressed in terms of $H(j\omega; t)$ and $e_1(t)$ through the relation

$$e_2(t)=\mathfrak{L}^{-1}\{H(s; t)E_1(s)\}, \tag{8}$$

where $E_1(s)$ is the Laplace transform of $e_1(t)$ and $\mathfrak{L}^{-1}$ represents the inverse Laplace transformation. In evaluating the inverse Laplace transform of $H(s; t)E_1(s)$, t should be treated as if it were a constant parameter. Thus, when the behavior of a variable network is described by means of its system function $H(j\omega; t)$, the determination of the response of the network to any given input requires only the use of a standard table of Laplace transforms. This constitutes one of the advantages of describing the behavior of a variable network by its system function $H(j\omega; t)$ rather than by its impulsive response $W(t, \xi)$.

The central problem in the analysis of a variable network is that of obtaining an explicit description of the behavior of the network starting from an implicit description of the behavior. In other words, the problem is to determine either the impulsive response $W(t, \xi)$ or the system function $H(j\omega; t)$ from the knowledge of the fundamental equation of the system. In general, this problem cannot be solved exactly, so that in most cases it is necessary to use approximate methods for the determination of $W(t, \xi)$ or $H(j\omega; t)$. The problem of the determination of $H(j\omega; t)$ is treated in [1]. The problem to be considered in the following is that of the determination of $W(t, \xi)$ in the case of slowly varying networks. In such networks the coefficients $a_\nu(t)$ and $b_\mu(t)$ in Eq. (1) do not vary appreciably over the effective duration[2] of the impulsive response of the network. Most of the variable networks encountered in practice belong to this category.

DETERMINATION OF $W(t, \xi)$

From the definition of the impulsive response of a variable network it follows that $W(t, \xi)$ is the solution of Eq. (3) subject to homogeneous initial conditions at $t=\xi-$. On the other hand, the commonly used Green's function $G(t, \xi)$, which is associated with Eq. (2), is in effect the impulsive response of a system whose fundamental equation is

$$L(p; t)e_2(t)=e_1(t). \tag{9}$$

Stated more precisely, $G(t, \xi)$ is the solution of the differential equation

$$L(p; t)G(t, \xi)=\delta(t-\xi), \tag{10}$$

subject to homogeneous initial conditions at $t=\xi-$, or equivalently, to the following conditions:

$$G^{(\lambda)}(t, \xi)_{t=\xi+}=0, \quad \lambda=0, 1, 2, \cdots, n-2,$$
$$G^{(n-1)}(t, \xi)_{t=\xi+}=\frac{1}{a_n(\xi)}, \tag{11}$$

at $t=\xi+$. In view of Eqs. (3) and (10) it is evident that $W(t, \xi)$ and $G(t, \xi)$ are closely related to each other. To obtain the form of this relation it is sufficient to apply the superposition integral to Eq. (9), treating $K(p; t)\delta(t-\xi)$ as the input to the system described by Eq. (9). Thus, we find

$$W(t, \xi)=\int_{-\infty}^{\infty} G(t, u)[K(p; u)\delta(u-\xi)]du, \tag{12}$$

where u is the variable of integration and $p=d/du$. Making use of the identity

$$\int_{-\infty}^{\infty} f(u)p^k\delta(u-\xi)du\equiv(-1)^k f^{(k)}(\xi), \tag{13}$$

Eq. (12) reduces to the desired relation, namely,

$$W(t, \xi)=b_0(\xi)G(t, \xi)-\frac{\partial}{\partial\xi}[b_1(\xi)G(t, \xi)]$$
$$+\cdots+(-1)^m\frac{\partial^m}{\partial\xi^m}[b_m(\xi)G(t, \xi)]. \tag{14}$$

This relation may be expressed more compactly in the form

$$W(t, \xi)=K^*(p; \xi)G(t, \xi) \tag{15}$$

where p should be interpreted as $d/d\xi$, and the operator $K^*(p; \xi)$ is the adjoint of $K(p; \xi)$.

Equation (15) shows that the problem of the determination of $W(t, \xi)$ may be reduced to the somewhat simpler problem of finding a Green's function satisfying the initial conditions expressed by Eq. (11). This, evidently, is equivalent to finding the impulsive response of the system described by Eq. (9).

In finding $G(t, \xi)$ we shall make use of the assumption that the operator $L(p; t)$ does not vary appreciably over the effective duration of $G(t, \xi)$. In general, Eq. (10) may be rewritten as

$$L(p; \xi)G(t, \xi)=\delta(t-\xi)+[L(p; \xi)-L(p; t)]G(t, \xi), \tag{16}$$

where the coefficients in $L(p; \xi)$ are the constants $a_\nu(\xi)$ and $b_\mu(\xi)$, which are the values of $a_\nu(t)$ and $b_\mu(t)$ at the instant of application of the unit impulse. Now since the network has been assumed to be a slowly varying one, $a_\nu(t)$ and $b_\mu(t)$ will not differ appreciably from $a_\nu(\xi)$ and

[2] The effective duration of a signal is, roughly speaking, the length of the interval outside of which the amplitude of the signal is small by comparison with its maximum value.

$b_\mu(\xi)$ over the effective duration of $G(t, \xi)$. Hence, the second term in the right-hand member of Eq. (16) may be regarded as a perturbation and accordingly a perturbation procedure[3] may be used for the determination of $G(t, \xi)$.

As the first step in the procedure, $G(t, \xi)$ is expressed in the form of a perturbation series

$$G(t, \xi)=G_1(t, \xi)+G_2(t, \xi)+G_3(t, \xi)+\cdots, \quad (17)$$

where $G_1(t, \xi)$ is the first approximation to $G(t, \xi)$, and $G_2(t, \xi)$, $G_3(t, \xi)$, etc., are the successive correction terms. Substituting this series into Eq. (16), it is found that Eq. (16) reduces to a set of iterative relations

$$L(p; \xi)G_1(t, \xi)=\delta(t-\xi), \quad (18)$$

$$L(p; \xi)G_{k+1}(t, \xi) = [L(p; \xi)-L(p; t)]G_k(t, \xi), \quad k=1, 2, \cdots, \quad (19)$$

which formally provide the solution of the problem.

The formal solution represented by Eqs. (18) and (19) may be simplified to a considerable extent, first, by making further use of the assumption that $L(p; t)$ is a slowly varying function of time, and second, by expressing Eqs. (18) and (19) in Laplace transform form. Thus, expanding the right-hand operator in Eq. (19) in a Taylor series around $t=\xi$ and neglecting all but the first, say, N terms in this expansion and also in Eq. (17),[4] the iterative relation expressed by Eq. (19) assumes the following form:

$$-L(p; \xi)G_{k+1}(t, \xi)\cong\left[(t-\xi)\frac{\partial L(p; \xi)}{\partial \xi}+\frac{1}{2!}(t-\xi)^2\frac{\partial^2 L(p; \xi)}{\partial \xi^2}+\cdots+\frac{1}{N!}(t-\xi)^N\frac{\partial^N L(p; \xi)}{\partial \xi^N}\right]G_k(t, \xi). \quad (20)$$

Next, transforming both sides of Eq. (20) with respect to $t'=t-\xi$ and letting $F_k(s; \xi)$ (or simply F_k) represent the Laplace transform of $G_k(t, \xi)$, we obtain:

$$F_1=1/L(s; \xi) \quad (21)$$

and

$$F_{k+1}\cong F_1\left\{\frac{\partial}{\partial s}\left[F_k\frac{\partial L(s; \xi)}{\partial \xi}\right]+\cdots+\frac{(-1)^{N-1}}{N!}\times\frac{\partial^N}{\partial s^N}\left[F_k\frac{\partial^N L(s; \xi)}{\partial \xi^N}\right]\right\}, \quad k=1, 2, \cdots. \quad (22)$$

The above relations express essentially the solution of the problem. It will be noted that from these relations the terms F_1, F_2, F_3, etc. can be obtained in succession by using nothing more complicated than routine differentiation. Once F_1, F_2, F_3, etc. have been determined, the terms $G_1(t, \xi)$, $G_2(t, \xi)$, $\cdots$, $G_N(t, \xi)$, forming the Nth order approximation to $G(t, \xi)$, can be found by using a table of Laplace transforms. And finally, the Nth order approximation to $W(t, \xi)$ is obtained in the form

$$W(t, \xi)\cong W_1(t, \xi)+W_2(t, \xi)+\cdots+W_N(t, \xi), \quad (23)$$

by substituting the Nth order approximation to $G(t, \xi)$ into Eq. (15). These, in brief, are the steps leading to the determination of $W(t, \xi)$.

In most practical cases Eq. (23) develops as a power series in a small parameter. Thus the questions of convergence and the accuracy of the obtained approximation to $W(t, \xi)$ can usually be resolved without significant difficulties. Actually, many if not most of the variable networks encountered in practice are such that the first two or three terms in Eq. (23) provide an adequate approximation to $W(t, \xi)$.

The use of the foregoing method is well illustrated by a simple example for which an exact solution can be obtained by classical methods. Consider a low pass *RC* half-section with a periodically varying band width. The behavior of such a network is described by the first-order differential equation

$$(p+1+\epsilon\cos\omega_0 t)e_2(t)=(1+\epsilon\cos\omega_0 t)e_1(t), \quad (24)$$

where

$$\epsilon=\frac{\text{amplitude of band width variation}}{\text{mean band width}},$$

$$\omega_0=\frac{\text{frequency of band width variation}}{\text{mean band width}},$$

$$t=\text{actual time}\times\text{mean band width}.$$

Using the standard method of solution of first-order equations, the impulsive response of the network is found to be

$$W(t, \xi)=(1+\epsilon\cos\omega_0\xi)\times\exp[-(t-\xi)-(\epsilon/\omega_0)(\sin\omega_0 t-\sin\omega_0\xi)]. \quad (25)$$

Using the approximate method, we find

$$F_1=\frac{1}{L(s; \xi)}=\frac{1}{s+1+\epsilon\cos\omega_0\xi} \quad (26)$$

and

$$F_2=\frac{\epsilon\omega_0\sin\omega_0\xi}{(s+1+\epsilon\cos\omega_0\xi)^3}, \quad (27)$$

from which

$$W(t, \xi)\cong(1+\epsilon\cos\omega_0\xi)[1+(\epsilon\omega_0/2)(t-\xi)^2\sin\omega_0\xi]\times\exp[-(t-\xi)(1+\epsilon\cos\omega_0\xi)]. \quad (28)$$

[3] The perturbation method used in the sequel is based on Schelkunoff's wave perturbation method, "Approximate solution of linear differential equations," Bell Sys. Tech. J. 27, 350–364 (1948).

[4] In some cases the number of terms conserved in the two expansions need not be the same.

It can easily be verified that Eq. (28) is in agreement with Eq. (25) up to the first-order terms in ω_0. Thus, whenever the frequency of band width variation is reasonably small by comparison with the mean band width, Eq. (28) provides an adequate approximation to the impulsive response of the network. A higher order approximation may be obtained, if necessary, by continuing the iteration beyond F_2.

An Extension of Wiener's Theory of Prediction*

LOTFI A. ZADEH AND JOHN R. RAGAZZINI
Department of Electrical Engineering, Columbia University, New York, New York
(Received November 14, 1949)

The theory of prediction described in this paper is essentially an extension of Wiener's theory. It differs from the latter in the following respects.

1. The signal (message) component of the given time series is assumed to consist of two parts, (a) a non-random function of time which is representable as a polynomial of degree not greater than a specified number n and about which no information other than n is available; and (b) a stationary random function of time which is described statistically by a given correlation function. (In Wiener's theory, the signal may not contain a non-random part except when such a part is a known function of time.)
2. The impulsive response of the predictor or, in other words, the weighting function used in the process of prediction is required to vanish outside of a specified time interval $0 \leq t \leq T$. (In Wiener's theory T is assumed to be infinite.)

The theory developed in this paper is applicable to a broader and more practical class of problems than that covered in Wiener's theory. As in Wiener's theory, the determination of the optimum predictor reduces to the solution of an integral equation which, however, is a modified form of the Wiener-Hopf equation. A simple method of solution of the equation is developed. This method can also be applied with advantage to the solution of the particular case considered by Wiener. The use of the theory is illustrated by several examples of practical interest.

I. INTRODUCTION

PREDICTION—in the broad sense of the term—consists essentially of estimating the values of some function of time on the basis of a time series which may or may not contain random errors. For instance, a typical problem in prediction is as follows. Given a time series $e_1(t)$ which is composed of a signal $s(t)$ and a random disturbance (noise) $N(t)$; provide an estimate of $s(t+\alpha)$, α being a positive constant, as a continuous function of time. More generally, the quantity to be estimated may be a functional of $s(t)$ such as ds/dt, $\int s dt$, etc. In forming such estimates the mathematical operations that may be employed are usually limited by practical considerations. Thus, in most cases the operator furnishing the estimate must be linear and fixed in addition to the obvious requirement of being physically realizable. The physical counterpart of such an operator is what is commonly known as a predictor or an estimator.

It is evident that a function of time cannot be predicted intelligently unless sufficient *a priori* information is available about both the function and the errors. The nature of such information, as well as the characteristics of the signal and noise, can assume a variety of forms. Of these the more common ones have been investigated in recent years with the result that for certain classes of time series it is now possible to design predictors which make optimum use of the *a priori* information concerning the signal and the noise. Thus, when the given time series is stationary and the correlation functions of the signal and noise are known, one can use Wiener's theory[1] to arrive at the specifications of the optimum predictor, that is, one minimizing the mean-square value of the prediction error. On the other hand, when, as is often the case in practice, the given time series is non-stationary, the available theories of prediction, notably Phillips and Weiss' theory,[2] do not lead to the best possible predictor except for a narrow class of time series. It is possible, however, to extend Wiener's theory in many different directions thereby making it applicable to a wider class of problems than is covered by either Wiener's or Phillips and Weiss' theories in their present forms. One such extension is discussed in this paper. A feature of the extension is that the signal (message) is assumed to consist of a stationary component superimposed on a non-random function of time which is known to be representable as a polynomial of degree less than or equal to a specified number n. It will also be shown that the general method developed for treating this problem can be applied with advantage to the solution of many cases of practical

interest as well as the particular case considered by Wiener.

II. FORMULATION

Consider a given time series $e_1(t)$ which is the sum of a function $s(t)$ (signal) and a stationary random disturbance $N(t)$. Let $s^*(t)$ be the quantity to be estimated and let $s^*(t)$ be related to $s(t)$ through a given linear operator $K(p)$, i.e.,

$$s^*(t)=K(p)s(t). \tag{1}$$

$K(p)$ may be thought of as the system function of an *ideal predictor*, i.e., a predictor capable of perfect prediction in the absence of noise. In many cases, particularly those involving actual prediction, the operator $K(p)$ is not physically realizable so that the process of estimation cannot be carried out exactly even in the absence of random disturbances.

Frequently it will be convenient to use a different, though equivalent representation of Eq. (1), i.e.,

$$s^*(t)=\int_{-\infty}^{\infty} k(\tau)s(t-\tau)d\tau, \tag{2}$$

where τ is the variable of integration and $k(t)$ represents the impulsive response of the ideal predictor. $K(p)$ shall be referred to as the ideal prediction operator. As a matter of convenience, the more common of the many possible forms which $K(p)$ and $k(t)$ can assume are given in Table I.

Like all theories of prediction, the theory to be described applies only to a special class of time series. The time series to be considered in the work which follows will be assumed to consist of a signal $s(t)$ and noise $N(t)$, with the signal being composed of a random component $M(t)$ superposed upon a non-random function of time $P(t)$, i.e.,

$$s(t)=M(t)+P(t). \tag{3}$$

The assumptions made concerning the characteristics of $P(t)$, $M(t)$, and $N(t)$, are as follows:

(a) $P(t)$ is assumed to be representable as a polynomial in t of degree not higher than a specified number n.

(b) $M(t)$ and $N(t)$ are stationary functions of time described respectively by their auto-correlation functions $\psi_M(\tau)$ and $\psi_N(\tau)$.

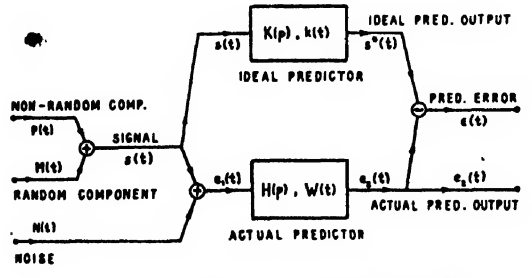

FIG. 1. Flow diagram of prediction process.

TABLE I. Common forms of the prediction operators $K(p)$ and $k(t)$.

Relation between $s^*(t)$ and $s(t)$	Significance of the quantity to be estimated	$K(p)$	$k(t)$
$s^*(t)=s(t)$	Present value of $s(t)$	1	$\delta(t)$
$s^*(t)=\dot{s}(t)$	Present value $\dot{s}(t)$	p	$\delta^{(1)}(t)$
$s^*(t)=\ddot{s}(t)$	Present value of $\dot{s}(t)$	p^2	$\delta^{(2)}(t)$
$s^*(t)=s(t-\alpha)$	Past or future value of $s(t)$ depending respectively on whether α is a positive or negative constant	$e^{-\alpha p}$	$\delta(t-\alpha)$

Note.—$\delta(t)$ denotes a unit impulse at $t=0$, and $\delta^{(\nu)}(t)$ stands for the νth derivative of $\delta(t)$ with respect to t (time).

(c) $M(t)$ and $N(t)$ have zero mean and are uncorrelated. This assumption is introduced only for the purpose of simplification and is not essential to the analysis. The condition expressed by (c) prevails in most practical cases.

Referring to Fig. 1, these inputs are shown being applied to the actual predictor whose system function is $H(p)$ and whose impulsive response is $W(t)$. The output of the predictor, $e_2(t)$, may be expressed in operational form

$$e_2(t)=H(p)e_1(t) \tag{4}$$

or, alternatively, in the form of a superposition integral

$$e_2(t)=\int_0^{\infty} W(\tau)e_1(t-\tau)d\tau. \tag{5}$$

An important characteristic of the actual predictor is the so-called prediction or estimation error ϵ, which is defined as the difference between the output of the predictor and the quantity to be estimated, $s^*(t)$. Equation-wise this is:

$$\epsilon=e_2(t)-s^*(t). \tag{6}$$

If there were no noise and if $K(p)$ were physically realizable there would be no prediction error and $H(p)$ would be identical with $K(p)$. This, of course, is the trivial case of the prediction problem. In what follows it will be assumed that either because of the presence of noise or physical unrealizability of $K(p)$, or both, $H(p)$ cannot be the same as $K(p)$.

The available *a priori* information about $s(t)$ and $N(t)$ is assumed to consist of n, $\psi_M(\tau)$, and $\psi_N(\tau)$. The problem is to specify the system function or the impulsive response of a predictor that would minimize in a certain sense the prediction error $\epsilon=e_2(t)-s^*(t)$. By analogy with Wiener's theory it will be postulated that the optimum predictor is the one in which: (a) the ensemble mean of ϵ is equal to zero (for all values of t), and (b) the ensemble variance of ϵ is a minimum. Denoting the ensemble average by the symbol $\langle\ \rangle_{Av}$, these conditions read:

$$\text{(a)}\quad \langle\epsilon\rangle_{Av}=0 \text{ or, equivalently, } \langle e_2(t)\rangle_{Av}\equiv\langle s^*(t)\rangle_{Av}, \tag{7}$$

$$\text{(b)}\quad \sigma^2=\langle\epsilon^2\rangle_{Av}=\text{minimum}, \tag{8}$$

where σ^2, the ensemble variance of ϵ, is equal to the mean-square value of the prediction error. In what follows, conditions (a) and (b) will be used as the basis for the determination of the optimum predictor.

III. DETERMINATION OF THE IMPULSIVE RESPONSE OF THE OPTIMUM PREDICTOR

It will be recalled that the output of a predictor may be expressed in the form of a superposition integral

$$e_2(t)=\int_0^\infty W(\tau)e_1(t-\tau)d\tau \tag{9}$$

where τ is a dummy variable and $W(t)$ represents the impulse response of the predictor. In practice it is usually found necessary to restrict the duration of sampling of the input time series to a finite constant T, meaning in other words that $W(t)$ must be zero outside the interval $0\leq t\leq T$. To place this property in evidence Eq. (9) will be written in the following form:

$$e_2(t)=\int_0^T W(\tau)e_1(t-\tau)d\tau. \tag{10}$$

In the limiting case where the duration of sampling is infinite ($T\to\infty$) Eq. (10) becomes identical with Eq. (9).

By hypothesis,

$$e_1(t)=P(t)+M(t)+N(t). \tag{11}$$

Substituting Eq. (11) into Eq. (10) and making use of the identity

$$P(t-\tau)\equiv P(t)-\tau\dot{P}(t)+\frac{\tau^2}{2!}\ddot{P}(t)+\cdots+(-1)^n\frac{\tau^n}{n!}P^{(n)}(t), \tag{12}$$

it is found that $e_2(t)$ may be expressed as:

$$e_2(t)=\mu_0P(t)-\mu_1\dot{P}(t)+\frac{\mu_2}{2!}\ddot{P}(t)+\cdots+(-1)^n\frac{\mu_n}{n!}P^{(n)}(t)+\int_0^T W(\tau)M(t-\tau)d\tau+\int_0^T W(\tau)N(t-\tau)d\tau, \tag{13}$$

where μ_0, μ_1, μ_2, etc., designate the moments of $W(t)$, i.e.,

$$\mu_\nu=\int_0^T \tau^\nu W(\tau)d\tau,\quad \nu=0, 1, 2, \cdots n. \tag{14}$$

Since $M(t)$ and $N(t)$ are stationary (with zero mean), it follows that the ensemble means of $e_2(t)$ and $s^*(t)$ depend only on the non-random component of the signal, i.e.,

$$\langle e_2(t)\rangle_{Av}=\int_0^T W(\tau)P(t-\tau)d\tau \tag{15}$$

or

$$\langle e_2(t)\rangle_{Av}=\mu_0P(t)-\mu_1\dot{P}(t)+\frac{\mu_2}{2!}\ddot{P}(t)+\cdots+(-1)^n\frac{\mu_n}{n!}P^{(n)}(t), \tag{16}$$

and

$$\langle s^*(t)\rangle_{Av}=\langle K(p)s(t)\rangle_{Av} \tag{17}$$

or

$$\langle s^*(t)\rangle_{Av}=K(p)P(t). \tag{18}$$

Comparing Eqs. (16) and (18), condition (a) is reduced to

$$K(p)P(t)\equiv\mu_0P(t)-\mu_1\dot{P}(t)+\frac{\mu_2}{2!}\ddot{P}(t)+\cdots+(-1)^n\frac{\mu_n}{n!}P^{(n)}(t). \tag{19}$$

Equation (19), being an identity, determines the values of μ_0, μ_1, $\cdots$, and μ_n. In other words, *the ideal prediction operator $K(p)$ determines through Eq. (19) the first $n+1$ moments of the impulsive response of the optimum predictor.*

As an illustration of the foregoing statement consider a case where the quantity to be estimated is the derivative of $s(t)$, i.e., $s^*(t)=\dot{s}(t)$. For this case Eq. (19) reduces to

$$\dot{P}(t)\equiv\mu_0P(t)-\mu_1\dot{P}(t)+\frac{\mu_2}{2!}\ddot{P}(t)+\cdots+(-1)^n\frac{\mu_n}{n!}P^{(n)}(t), \tag{20}$$

and a term by term comparison of the left-hand and right-hand sides of Eq. (20) yields:

$$\begin{aligned}\mu_0&=\int_0^T W(\tau)d\tau=0\\ \mu_1&=\int_0^T \tau W(\tau)d\tau=-1\\ \mu_2&=\int_0^T \tau^2W(\tau)d\tau=0\\ &\cdots\\ \mu_n&=\int_0^T \tau^nW(\tau)d\tau=0.\end{aligned} \tag{21}$$

These, therefore, are the $n+1$ constraints which the impulsive response of a derivative estimating network must satisfy.

As the second example consider a case where $K(p)s(t)=s(t-\alpha)$, α being a positive or negative constant. For

this case Eq. (19) reads

$$P(t-\alpha)\equiv\mu_0 P(t)-\mu_1\dot{P}(t)+\frac{\mu_2}{2!}\ddot{P}(t)+\cdots+(-1)^n\frac{\mu_n}{n!}P^{(n)}(t). \quad (22)$$

Rewriting $P(t-\alpha)$ as

$$P(t-\alpha)\equiv P(t)-\alpha\dot{P}(t)+\frac{\alpha^2}{2!}\ddot{P}(t)+\cdots+(-1)^n\frac{\alpha^n}{n!}P^{(n)}(t), \quad (23)$$

and making in Eq. (22) a term-by-term comparison of the coefficients of $P(t)$, $\dot{P}(t)$, etc., it is easily found that:

$$\begin{aligned}\mu_0&=\int_0^T W(\tau)d\tau=1\\ \mu_1&=\int_0^T \tau W(\tau)d\tau=\alpha\\ &\cdots\\ \mu_n&=\int_0^T \tau^n W(\tau)d\tau=\alpha^n,\end{aligned} \quad (24)$$

which thus represent the constraints imposed upon $W(t)$ in case the quantity to be estimated is $s(t-\alpha)$.

The problem that remains to be solved is that of minimizing σ^2. For this purpose it will be necessary to develop an explicit expression for σ^2 in terms of $W(t)$ and the auto-correlation functions of the signal and noise. Assuming that condition (a) is satisfied, it follows from inspection of Eqs. (6), (13), and (19) that the prediction error is given by the expression

$$\epsilon=\int_0^T W(\tau)[M(t-\tau)+N(t-\tau)]d\tau-K(p)M(t) \quad (25)$$

or equivalently

$$\epsilon=\int_0^T W(\tau)[M(t-\tau)+N(t-\tau)]d\tau-\int_{-\infty}^{\infty}k(\tau)M(t-\tau)d\tau \quad (26)$$

where $k(t)$ is the impulsive response of the ideal predictor. The mean-square value of ϵ may be written as

$$\sigma^2=\langle\epsilon^2\rangle_{Av}=\lim_{L\to\infty}\frac{1}{L}\int_0^L \epsilon^2 dt \quad (27)$$

or

$$\sigma^2=\lim_{L\to\infty}\frac{1}{L}\int_0^L dt\left\{\int_0^T W(\tau)[M(t-\tau)+N(t-\tau)]d\tau-\int_{\infty}^{\infty}k(\tau)M(t-\tau)d\tau\right\}^2. \quad (28)$$

A typical term of Eq. (28) such as

$$\lim_{L\to\infty}\frac{1}{L}\int_0^L dt\left[\int_0^T W(\tau)M(t-\tau)d\tau\right]^2 \quad (29)$$

is expressible in the form of a triple integral

$$\int_0^T\int_0^T d\tau_1 d\tau_2 W(\tau_1)W(\tau_2)\times\lim_{L\to\infty}\frac{1}{L}\int_0^L M(t-\tau_1)M(t-\tau_2)dt \quad (30)$$

which in view of the definition of the auto-correlation function of $M(t)$, i.e.,

$$\psi_M(\tau)=\lim_{L\to\infty}\frac{1}{L}\int_0^L M(t)M(t-\tau)dt \quad (31)$$

may be written as

$$\int_0^T\int_0^T W(\tau_1)W(\tau_2)\psi_M(\tau_1-\tau_2)d\tau_1 d\tau_2. \quad (32)$$

Proceeding similarly in the case of other terms, Eq. (28) reduces finally to the following expression:

$$\begin{aligned}\sigma^2=&\int_0^T\int_0^T W(\tau_1)W(\tau_2)[\psi_M(\tau_1-\tau_2)\\ &+\psi_N(\tau_1-\tau_2)]d\tau_1 d\tau_2\\ &-2\int_{\infty}^{\infty}\int_0^T W(\tau_1)k(\tau_2)\psi_M(\tau_1-\tau_2)d\tau_1 d\tau_2\\ &+\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}k(\tau_1)k(\tau_2)\psi_M(\tau_1-\tau_2)d\tau_1 d\tau_2\end{aligned} \quad (33)$$

where, to recapitulate: τ_1, τ_2 = dummy variables; $W(t)$ = impulsive response of the predictor; $\psi_M(\tau)$ = auto-correlation function of $M(t)$ [$M(t)$ is the stationary part of the input signal]; $\psi_N(\tau)$ = auto-correlation function of $N(t)$ [$N(t)$ is the input noise]; $k(t)$ = impulsive response of the ideal predictor.

Returning to the problem of minimization of σ^2 it will be noted first that the last term in Eq. (33) is independent of $W(t)$ and hence, insofar as minimization of σ^2 is concerned, need not be considered. Second, it will be recalled that $W(t)$ is subject to the $n+1$ constraints

expressed by Eq. (14); therefore, the problem of minimizing σ^2 with respect to the class of $W(t)$'s satisfying Eq. (14) reduces essentially to an isoperimetric problem in the calculus of variations. Following the standard approach to such problems, one is led to minimizing the following expression:

$$I=\sigma^2-2\lambda_0\mu_0-2\lambda_1\mu_1-\cdots-2\lambda_n\mu_n \tag{34}$$

or, more explicitly

$$I=\int_0^T W(\tau_1)d\tau_1\Big\{\int_0^T W(\tau_2)[\psi_M(\tau_1-\tau_2)+\psi_N(\tau_1-\tau_2)]d\tau_2-2\int_{-\infty}^{\infty}k(\tau_2)\psi_M(\tau_1-\tau_2)d\tau_2-2\lambda_0-2\lambda_1\tau_1-\cdots-2\lambda_n\tau_1^n\Big\} \tag{35}$$

where the constants $\lambda_0, \lambda_1, \cdots, \lambda_n$, are the Lagrangian multipliers. Proceeding in the usual manner, that is, setting the variation of I equal to zero, it is easily found that I and hence σ^2 is a minimum provided $W(t)$ satisfies the following integral equation:

$$\int_0^T W(\tau)[\psi_M(t-\tau)+\psi_N(t-\tau)]d\tau=\lambda_0+\lambda_1 t+\cdots+\lambda_n t^n+\int_{-\infty}^{\infty}k(\tau)\psi_M(t-\tau)d\tau,\quad 0\leq t\leq T. \tag{36}$$

This equation together with the $n+1$ constraints expressed by Eq. (14) provides the basis for the determination of the optimum predictor. It will be observed that in the particular case where $n=0$, $T=\infty$, and $k(t)=\delta(t+\alpha)$ [$\delta(t)$ standing, as usual, for a unit impulse at $t=0$], Eq. (36) reduces to

$$\int_0^{\infty} W(\tau)[\psi_M(t-\tau)+\psi_N(t-\tau)]d\tau=\psi_M(t+\alpha),\quad t>0 \tag{37}$$

which is essentially the integral equation of Wiener's theory. On the other hand, in the special case where $M(t)\equiv 0$, Eq. (36) reduces to

$$\int_0^T W(\tau)\psi_N(t-\tau)d\tau=\lambda_0+\lambda_1 t+\cdots+\lambda_n t^n,\quad 0\leq t\leq T \tag{38}$$

which is the integral equation of Phillips and Weiss' theory. Thus, the integral equations of Wiener's, and Phillips and Weiss' theories are special cases of Eq. (36).

IV. SOLUTION OF THE INTEGRAL EQUATION

In the general case where $\psi_M(\tau)$ and $\psi_N(\tau)$ are prescribed but otherwise arbitrary auto-correlation functions, the complicated nature of the integral equation makes it appear that the solution of Eq. (36) is a formidable problem. In reality, the problem is not as difficult as it may seem, for by using a procedure to be described, the general case can be reduced to a special case which has a simple solution.

Preliminary to the discussion of this procedure it will be expedient to introduce the spectral densities of $M(t)$, $N(t)$, and $M(t)+N(t)$. Denoting these by $S_M(\omega^2)$, $S_N(\omega^2)$, and $S(\omega^2)$, respectively, and recalling that the spectral density of a function is the inverse Fourier transform of its auto-correlation function,[1] it follows that

$$S_M(\omega^2)=\int_{-\infty}^{\infty}\psi_M(\tau)e^{-i\omega\tau}d\tau \tag{39}$$

$$S_N(\omega^2)=\int_{-\infty}^{\infty}\psi_N(\tau)e^{-i\omega\tau}d\tau \tag{40}$$

and

$$S(\omega^2)=S_M(\omega^2)+S_N(\omega^2). \tag{41}$$

Now the spectral density function $S(\omega^2)$ may be factored[1] into the product of two conjugate factors

$$S(\omega^2)=G(j\omega)\cdot G(-j\omega) \tag{42}$$

such that both $G(j\omega)$ and $1/G(j\omega)$ are analytic in the right half of the $j\omega$-plane. Usually $S(\omega^2)$ is assumed to be a rational function of ω^2 of the form

$$S(\omega^2)=[A(\omega^2)/B(\omega^2)], \tag{43}$$

where $A(\omega^2)$ and $B(\omega^2)$ are polynomials in ω^2. For such cases the process of factorization is quite straightforward as can be seen from the following examples:

(a) $S(\omega^2)=\omega^2$; $\quad G(j\omega)=j\omega$.

(b) $S(\omega^2)=\dfrac{1}{\omega^2+\omega_0^2}$; $\quad G(j\omega)=\dfrac{1}{j\omega+\omega_0}$.

(c) $S(\omega^2)=\dfrac{\omega^2+a^2}{\omega^4+b^2\omega^2+c^4}$;

$$G(j\omega)=\frac{j\omega+a}{(j\omega)^2+j\omega(b^2+2c^2)^{\frac{1}{2}}+c^2}.$$

To summarize, a rational spectral density function may be written as

$$S(\omega^2)=|G(p)|^2_{p=j\omega} \tag{44}$$

where $G(p)$ is of the form:

$$G(p)=\frac{Q(p)}{R(p)}=\frac{a_0+a_1p+\cdots+a_mp^m}{b_0+b_1p+\cdots+b_lp^l}, \tag{45}$$

and the polynomials $Q(p)$ and $R(p)$ do not have any zeros in the right half of the p-plane.

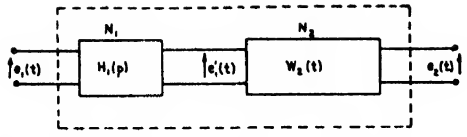

FIG. 2. Division of the predictor into the component networks N_1 and N_2.

The outline of the procedure used[3] for the solution of Eq. (36) can be best explained with reference to Fig. 2. The predictor N is assumed to be composed of two networks N_1 and N_2. The function of N_1 is to suitably modify some of the characteristics of the input time series $e_1(t)$, while that of N_2 is to provide the desired prediction through operating on the time series $e_1'(t)$, which is the output of N_1. It will be seen later that it is possible to choose N_1 in such a manner that the determination of the impulsive response of N_2 becomes an easily solvable problem. Then, once $W_2(t)$ (the impulsive response of N_2) is determined, the impulsive response of N, $W(t)$, can easily be found from the relation

$$W(t)=H_1(p)W_2(t), \tag{46}$$

where $H_1(p)$ is the system function of N_1. The choice of $H_1(p)$ and the problem of determination of $W_2(t)$ are discussed in the sequel.

It is evident that the problem of determination of $W_2(t)$ is similar to that of the determination of $W(t)$, except that the characteristics of the input time series are different for the two problems. An inspection of the integral equation (36) shows that it can be solved rather easily when the input to the predictor consists of a polynomial in t and a stationary component whose spectral density is a polynomial in ω^2. Therefore, in order to make the determination of $W_2(t)$ a simple problem, it is necessary to provide N_2 with an input which has this property. It is not difficult to verify that such a condition will obtain if, and only if, the system function of N_1 is chosen to be

$$H_1(p)=R(p), \tag{47}$$

where $R(p)$ is the denominator of $G(p)$ [cf. Eq. (45)]. With this choice of $H_1(p)$ the input to N_2 will consist of a polynomial in t of the same degree[4] as $P(t)$, and a stationary component $M'(t)+N'(t)$ whose spectral density is

$$S'(\omega^2)=|H_1(j\omega)|^2S(\omega^2) \tag{48}$$

or, in view of Eqs. (43), (44), and (47),

$$S'(\omega^2)=A(\omega^2), \tag{49}$$

where $A(\omega^2)$ is the numerator of $S(\omega^2)$. It will be noted that $A(\omega^2)$ is a polynomial of the form

$$A(\omega^2)=\gamma_0+\gamma_1\omega^2+\cdots+\gamma_m\omega^{2m}, \tag{50}$$

and correspondingly the auto-correlation function of $M'(t)+N'(t)$ is

$$\psi_{M'}(\tau)+\psi_{N'}(\tau)=\gamma_0\delta(\tau)-\gamma_1\delta^{(2)}(\tau)+\cdots+(-1)^m\gamma_m\delta^{(2m)}(\tau), \tag{51}$$

where $\delta^{(\nu)}(\tau)$ represents the impulse function of νth order [i.e., the νth derivative of the unit impulse function $\delta(\tau)$].

In addition to $\psi_{M'}(\tau)+\psi_{N'}(\tau)$, a number of other quantities associated with the input to N_2 enter the integral equation satisfied by $W_2(t)$. The significance of each of these quantities, as well as their expressions, are as follows:

(a) $S_{M'}(\omega^2)=$ spectral density of $M'(t)$
$$=S_M(\omega^2)|R(j\omega)|^2. \tag{52}$$

(b) $\psi_{M'}(\tau)=$ auto-correlation function of $M'(t)$
$$=\frac{1}{2\pi}\int_{-\infty}^{\infty}S_M(\omega^2)|R(j\omega)|^2e^{j\omega\tau}d\omega. \tag{53}$$

(c) $k'(t)=$ ideal impulsive response for N_2
$$=[1/R(p)]k(t). \tag{54}$$

In terms of these quantities the integral equation satisfied by $W_2(t)$ reads:

$$\int_0^{\infty}W_2(\tau)[\psi_{M'}(t-\tau)+\psi_{N'}(t-\tau)]d\tau=\lambda_0'+\lambda_1't+\cdots+\lambda_n't^n+\int_{-\infty}^{\infty}k'(\tau)\psi_{M'}(t-\tau)d\tau, \quad t\geq 0. \tag{55}$$

It will be noticed that in the case of $W_2(t)$ the upper limit of the integral is infinity, while in the case of $W(t)$ [cf. Eq. (36)] it is T. The explanation for this difference is that $W_2(t)$ need not vanish for $t>T$, even though $W(t)$ is required to do so. Thus in general, $W_2(t)$ will be piecewise analytic in the interval $0<t<\infty$ as is illustrated in Fig. 3. Denoting the parts of $W_2(t)$ extending over the intervals $0\leq t\leq T$ and $T<t<\infty$ by $U(t)$ and $V(t)$, respectively, the relation connecting $W(t)$ and $W_2(t)$ [cf. Eq. (46)] may be rewritten in the following form:

$$W(t)=R(p)U(t) \tag{56a}$$

and

$$0=R(p)V(t). \tag{56b}$$

These relations show that $W(t)$ is completely determined by the part of $W_2(t)$ which extends over the interval $0\leq t\leq T$; the form of $W_2(t)$ outside this interval is irrelevant to the determination of $W(t)$.

[3] The appendix of a report by Bode, Blackman, and Shannon, "Data smoothing and prediction in fire-control systems," Research and Development Board, Washington, D. C. (August, 1948), contains a brief exposition of a method which is similar in certain respects to the method described here.

[4] It is tacitly assumed that $R(p)$ does not have a zero at the origin or, in other words, that $S(\omega^2)$ does not have a pole at zero frequency.

Returning to the integral equation (55), it will be noted that the range of integration $0\leq\tau<\infty$ may be divided into two parts, $0\leq\tau\leq T$ and $T<\tau<\infty$, involving $U(t)$ and $V(t)$, respectively. Since $V(t)$ is determined by Eq. (56b) to within a finite number of constants, the integral equation in question degenerates into an integral equation involving only $U(t)$:

$$\int_0^T U(\tau)[\psi_M'(t-\tau)+\psi_N'(t-\tau)]d\tau=\lambda_0'+\lambda_1't+\cdots+\lambda_n't^n+\int_{-\infty}^{\infty}k'(\tau)\psi_M'(t-\tau)d\tau,\quad 0\leq t\leq T. \quad (57)$$

Upon substitution of Eqs. (52), (53), and (54), and performing minor simplifications, Eq. (57) reads

$$\int_0^T U(\tau)[\gamma_0\delta(t-\tau)-\gamma_1\delta^{(2)}(t-\tau)+\cdots+(-1)^m\gamma_m\delta^{(2m)}(t-\tau)]d\tau=\lambda_0'+\lambda_1't+\cdots+\lambda_n't^n+\frac{1}{2\pi}\int_{-\infty}^{\infty}S_M(\omega^2)K(j\omega)R(-j\omega)e^{j\omega t}d\omega. \quad (58)$$

Making use of the identity

$$\int_0^T U(\tau)\delta^{(2\nu)}(t-\tau)d\tau\equiv p^{2\nu}U(t), \quad (59)$$

Equation (58) may be rewritten as

$$[\gamma_0-\gamma_1p^2+\cdots+(-1)^m\gamma_mp^{2m}]U(t)=\lambda_0'+\lambda_1't+\cdots+\lambda_n't^n+\frac{1}{2\pi}\int_{-\infty}^{\infty}S_M(\omega^2)K(j\omega)R(-j\omega)e^{j\omega t}d\omega. \quad (60)$$

Since in this equation the left-hand side operator is simply $A(-p^2)$ [cf. Eq. (50)], the integral equation (57) finally reduces to the following differential equation:

$$A(-p^2)U(t)=\lambda_0'+\lambda_1't+\cdots+\lambda_n't^n+\frac{1}{2\pi}\int_{-\infty}^{\infty}S_M(\omega^2)K(j\omega)R(-j\omega)e^{j\omega t}d\omega. \quad (61)$$

The general solution of this equation is of the form:

$$U(t)=A_0'+A_1't+\cdots+A_n't^n+B_1'\exp(\alpha_1t)+B_2'\exp(\alpha_2t)+\cdots+B_{2m}'\exp(\alpha_{2m}t)+\frac{1}{2\pi}\int_{-\infty}^{\infty}\frac{S_M(\omega^2)}{A(\omega^2)}K(j\omega)R(-j\omega)e^{j\omega t}d\omega,\quad 0\leq t\leq T, \quad (62)$$

where A_0', A_1', $\cdots$, A_n' and B_1', B_2', $\cdots$, B_{2m}' are as yet undetermined constants, and α_1, α_2, $\cdots$, α_{2m} are the roots of the characteristic equation

$$A(-p^2)=0. \quad (63)$$

In brief, Eq. (62) provides an explicit expression for $U(t)$ involving $2m+n+1$ undetermined constants. Availability of such an expression reduces the problem of determination of $W(t)$ to a relatively routine matter which is discussed in the following section.

V. DERIVATION OF AN EXPLICIT EXPRESSION FOR $W(t)$

Recalling that $W(t)$ is related to $U(t)$ through the operational relation

$$W(t)=R(p)U(t), \quad (56a)$$

and substituting $U(t)$ as given by Eq. (62) into Eq. (56a), it is readily found that in the most general case $W(t)$ is given by the following expression:

$$W(t)=[u(t)-u(t-T)]\Big\{A_0+A_1t+\cdots+A_nt^n+B_1\exp(\alpha_1t)+\cdots+B_{2m}\exp(\alpha_{2m}t)+\frac{1}{2\pi}R(p)\int_{-\infty}^{\infty}\frac{S_M(\omega^2)}{A(\omega^2)}K(j\omega)R(-j\omega)e^{j\omega t}d\omega\Big\}+C_1\delta(t)+\cdots+C_{l-m}\delta^{(l-m-1)}(t)+D_1\delta(t-T)+\cdots+D_{l-m}\delta^{(l-m-1)}(t-T) \quad (64)$$

where the A's, B's, C's, and D's are as yet undetermined constants, and the unit step functions $u(t)$ and $u(t-T)$ are used simply to indicate that $W(t)$ is zero outside the interval $0\leq t\leq T$. The impulse functions contained in the expression for $W(t)$ arise from operation by $R(p)$ on the discontinuities of $U(t)$ at $t=0$ and $t=T$. It will be observed that the order of these impulse functions does not exceed $l-m-1$, which is one-half the order of the zero of $S(\omega^2)$ at infinity minus one. This is due to the fact that the first $m-1$ derivatives of $U(t)$ vanish at $t=0$ and $t=T$. It is not difficult to verify that if this would not have been the case, the mean-square error at the output of N_2 would be infinite.

Having obtained the general expression for $W(t)$ in the form of Eq. (64), there remains the problem of determination of the $2l+n+1$ unknown constants. These can be found in the following manner:

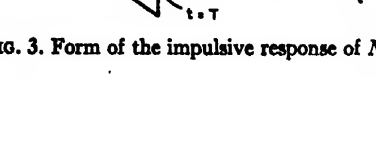

FIG. 3. Form of the impulsive response of N_2.

1. Substituting $W(t)$ as given by Eq. (64) into the integral equation (36) and requiring that the equation be satisfied identically, leads to $2l$ linear homogeneous equations in the A's, B's, C's, and D's.

2. Substituting $W(t)$ as given by Eq. (64) into the $n+1$ moment equations

$$\int_0^T \tau^\nu W(\tau)d\tau=\mu_\nu, \quad \nu=0, 1, 2, \cdots, n \qquad (65)$$

yields other $n+1$ linear equations. These $n+1$ equations, together with the $2l$ equations obtained in (1), provide a system of $2l+n+1$ linear equations in the unknown constants. Solution of this system gives the values of the A's, B's, C's, and D's and thus completes the process of determination of $W(t)$.

It should be remarked that in some cases it is advantageous to deal with the system function $H(p)$ of the predictor, rather than with its impulsive response $W(t)$. In such cases one can use a transformed form of the integral equation (36) which is as follows:

$$\frac{1}{2\pi}\int_{-\infty}^{\infty} H(j\omega)S(\omega^2)e^{j\omega t}d\omega=\lambda_0+\lambda_1 t+\cdots+\lambda_n t^n$$
$$+\frac{1}{2\pi}\int_{-\infty}^{\infty} S_M(\omega^2)K(j\omega)R(-j\omega)e^{j\omega t}d\omega. \qquad (66)$$

Using Eq. (64), the solution of this equation may be written directly as

$$H(p)=\int_0^T (A_0+A_1 t+\cdots+A_n t^n)e^{-pt}dt$$
$$+\frac{B_1}{p+\alpha_1}+\frac{B_2}{p+\alpha_2}+\cdots+\frac{B_{2m}}{p+\alpha_{2m}}$$
$$-\left\{\frac{B_1\exp(\alpha_1 T)}{p+\alpha_1}+\frac{B_2\exp(\alpha_2 T)}{p+\alpha_2}+\cdots\right.$$
$$\left.+\frac{B_{2m}\exp(\alpha_{2m}T)}{p+\alpha_{2m}}\right\}e^{-pT}+\frac{1}{2\pi}R(p)\int_0^T dte^{-pt}$$
$$\times\int_{-\infty}^{\infty}\frac{S_M(\omega^2)}{A(\omega^2)}K(j\omega)R(-j\omega)e^{j\omega t}d\omega$$
$$+C_1+C_2p+\cdots+C_{l-m}p^{l-m-1}$$
$$+(D_1+\cdots+D_{l-m}p^{l-m-1})e^{-pT}. \qquad (67)$$

The undetermined constants involved in this expression are found in the same manner as in the case of $W(t)$, that is, $H(p)$ as given by Eq. (67) is substituted into the integral equation (66) and the resulting expression is treated as an identity. The $2l$ linear relations between $A_0, A_1, A_2, \cdots$, etc., which are obtained in this manner are adjoined to the $n+1$ relations resulting from Eq. (65); then the system of linear equations in the unknown constants is solved for $A_0, A_1, A_2, \cdots$, etc.

In order to facilitate application of the techniques described in the preceding sections, a summary of the procedure for the determination of $W(t)$ (or $H(p)$) is given in Section VI. Furthermore, actual use of the procedure is illustrated by a few practical examples at the end of the section.

VI. SUMMARY OF THE PROCEDURE FOR DETERMINATION OF $W(t)$ AND $H(p)$

The complete expressions for $W(t)$ (the impulsive response of the optimum predictor) and $H(p)$ (the system function of the optimum predictor) are given by Eqs. (64) and (67). In order to avoid the necessity for reference to preceding sections, the meaning of all symbols appearing in these equations is given:

$u(t)$ = unit step function.
T = duration of sampling (settling time).
$A_0, A_1, \cdots, A_n, B_1, B_2, \cdots, B_{2m}, C_1, C_2, \cdots, C_{l-m}, D_1, D_2, \cdots, D_{l-m}$ = undetermined constants.
n = degree of the polynomial component of the input signal.
$S_M(\omega^2)$ = spectral density of $M(t)$[$M(t)$ is the stationary part of the input signal].
$S(\omega^2)$ = spectral density of $M(t)+N(t)$[$N(t)$ is the input noise].
$A(\omega^2)$ = numerator of $S(\omega^2)$.
$B(\omega^2)$ = denominator of $S(\omega^2)$.
$Q(j\omega)$ = a factor of $A(\omega^2)$ containing all the zeros in right half of the $j\omega$-plane.
$R(j\omega)$ = a factor of $B(\omega^2)$ containing all the zeros in the left half of the $j\omega$-plane.
$2l$ = degree of $B(\omega^2)$.
$2m$ = degree of $A(\omega^2)$.
$\alpha_1, \alpha_2, \cdots, \alpha_{2m}$ = roots of the characteristic equation $A(-p^2)=0$.
$\delta(t)$ = unit impulse function.
$\delta^{(\nu)}(t)$ = νth derivative of $\delta(t)$.

The undetermined constants occurring in the expression for $W(t)$ [and $H(p)$] can be found in the following manner.

1. $W(t)$ as given by Eq. (64) is substituted into the integral equation (36) and the resulting expression is treated as an identity. This gives $2l$ homogeneous linear equations in the unknown constants. Same equations can be obtained by substituting $H(p)$, as given by Eq. (67), into the integral equation (66).

2. $W(t)$ as given by Eq. (64) is substituted into the $n+1$ constraint equations

$$\int_0^T \tau^\nu W(\tau)d\tau=\mu_\nu, \quad \nu=0, 1, \cdots, n. \qquad (14)$$

where the μ_ν are determined by the choice of the prediction operator $K(p)$ [cf. Eq. (19)]. The resulting $n+1$ linear equations in the unknown constants are adjoined to the $2l$ equations obtained from (1). The set of $2l+n+1$ linear equations thus obtained is solved for the undetermined constants $A_0, A_1, \cdots, D_{l-m}$. This concludes the process of determining $W(t)$ [or $H(p)$].

VII. ILLUSTRATIVE EXAMPLES

Example 1. Wiener's Theory

Wiener's theory is, in the main, a study of the particular case in which $P(t)\equiv 0$, $T=\infty$ and $K(p)=e^{-ap}$. For this case Eq. (64) gives

$$W(t)=u(t)\left\{\frac{1}{2\pi}R(p)\times\int_{-\infty}^{\infty}\frac{S_M(\omega^2)}{A(\omega^2)}K(j\omega)R(-j\omega)e^{j\omega(t-\alpha)}d\omega+B_1\exp(\alpha_1 t)+\cdots+B_{2m}\exp(\alpha_{2m}t)\right\}. \quad (68)$$

The exponential terms appearing in Eq. (68) may be made to vanish through a slight rearrangement of the factors in the first term of Eq. (68). The resulting expression for $W(t)$ is the same as that obtained by using Wiener's theory, namely,

$$W(t)=u(t)\frac{1}{2\pi}\frac{R(p)}{Q(p)}\times\int_{-\infty}^{\infty}\frac{S_M(\omega^2)}{Q(-j\omega)}R(-j\omega)e^{j\omega(t-\alpha)}d\omega. \quad (69)$$

The rearrangement amounts, essentially, to choosing a particular solution of Eq. (61) which differs from the one chosen before by the exponential terms of Eq. (68). The same result may be achieved directly by choosing $H_1(p)$ [cf. Eq. (47)] as

$$H_1(p)=R(p)/Q(p).$$

With this choice of $H_1(p)$ [in place of the one expressed by Eq. (47)] the various quantities entering Eq. (55) become:

$$S'(\omega^2)=1,$$
$$\psi_M'(\tau)+\psi_N'(\tau)=\delta(\tau),$$
$$S_M'(\omega^2)=S_M(\omega^2)|R(j\omega)/Q(j\omega)|^2,$$
$$K'(j\omega)=K(j\omega)Q(j\omega)/R(j\omega),$$

and hence the integral equation (55) reduces to

$$W_2(t)=u(t)\frac{1}{2\pi}\int_{-\infty}^{\infty}\frac{S_M(\omega^2)}{Q(-j\omega)}K(j\omega)R(-j\omega)e^{j\omega t}d\omega; \quad (55a)$$

Eq. (69) then follows immediately from the relation connecting $W(t)$ and $W_2(t)$ [cf. Eq. (46)].

Example 2

The assumptions made here are as follows:

1. $M(t)\equiv 0$.
2. $n=1$.
3. $\psi_N(\tau)=e^{-a|\tau|}$; $S_N(\omega^2)=\dfrac{2a}{\omega^2+a^2}$.

The choice of the prediction operator is left open.

Solution

For this case $A(-p^2)=2a$, and hence $\alpha_1=\cdots=\alpha_{2m}=0$. Also, $l=1$, $M\equiv 0$; hence Eq. (64) gives

$$W(t)=A_0+A_1t+C_1\delta(t)+D_1\delta(t-T), \quad (70)$$

and

$$H(p)=\frac{A_0}{p}(1-e^{-pT})+\frac{A_1}{p}\left(\frac{1}{p}-\frac{e^{-pT}}{p}+Te^{-pT}\right)+C_1+D_1e^{-pT}. \quad (71)$$

Substituting $H(p)$ as given by Eq. (71) into the integral equation

$$\frac{1}{2\pi}\int_{-\infty}^{\infty}\frac{2a}{a^2-p^2}H(p)e^{pt}dp=\lambda_0+\lambda_1t,\quad 0\le t\le T, \quad (72)$$

and requiring that this equation be satisfied identically, leads to the following relations:

$$aA_0-A_1-a^2C_1=0, \quad (73)$$

$$aA_0+(aT+1)A_1-a^2D_1=0. \quad (74)$$

Furthermore, substituting $W(t)$ as given by Eq. (70) into the constraint equations

$$\int_0^T W(\tau)d\tau=\mu_0 \quad (75)$$

and

$$\int_0^T \tau W(\tau)d\tau=\mu_1, \quad (76)$$

yields

$$A_0T+A_1(T^2/2)+C_1+D_1=\mu_0, \quad (77)$$

and

$$A_0(T^2/2)+A_1(T^3/3)+D_1T=\mu_1. \quad (78)$$

The unknown constants A_0, A_1, C_1, and D_1 can be readily found from the solution of Eqs. (73), (74), (77), and (78). Thus,

$$A_0=\mu_0\frac{4a(a^2T^2+3aT+3)}{(a^2T^2+6aT+12)(aT+2)}-\mu_1\frac{6a^2}{a^2T^2+6aT+12}, \quad (79)$$

$$A_1=-\mu_0\frac{6a^2}{a^2T^2+6aT+12}+\mu_1\frac{12a^2}{T(a^2T^2+6aT+12)}, \quad (80)$$

$$C_1=\mu_0\frac{2(2a^2T^2+9aT+12)}{(a^2T^2+6aT+12)(aT+2)}-\mu_1\frac{6(aT+2)}{T(a^2T^2+6aT+12)}, \quad (81)$$

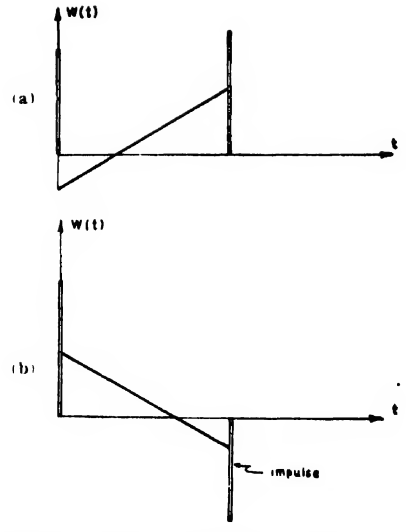

FIG. 4. Shapes of optimum weighting functions. (a) For the best value of $s(t)$. (b) For the best value of $s(t-\alpha)$ (α-negative).

and

$$D_1=-\mu_0\frac{2aT(aT+3)}{(a^2T^2+6aT+12)(aT+2)}+\mu_1\frac{6(aT+2)}{T(a^2T^2+6aT+12)}. \quad (82)$$

Whenever the stationary part of the input signal is zero [i.e., $M(t)\equiv 0$], the mean-square value of the prediction error assumes the simple form

$$\sigma^2=\mu_0\lambda_0+\mu_1\lambda_1+\cdots+\mu_n\lambda_n, \quad (83)$$

which may be readily established by substituting Eq. (36) into the general expression for σ^2 [cf. Eq. (33)]. For the particular case under consideration Eq. (83) gives

$$\sigma^2=\mu_0^2\frac{8(a^2T^2+3aT+3)}{(a^2T^2+6aT+12)(aT+2)}+\mu_1^2\frac{24a}{T(a^2T^2+6aT+12)}-\mu_0\mu_1\frac{24a}{(a^2T^2+6aT+12)}. \quad (84)$$

The expressions given above are valid for any choice of the prediction operator. For the particular case in which the predictor is called upon to furnish the best possible estimate of the present value of $\dot{s}(t)$, the values of μ_0 and μ_1 are, respectively,

$$\mu_0=0 \quad [\text{cf. Eq. (21)}] \quad \mu_1=-1. \quad (85)$$

On the other hand, in the case of the estimation of $s(t+\alpha)$ (i.e., the value of $s(t)$ α-seconds in the future)

$$\mu_0=1 \quad [\text{cf. Eq. (24)}] \quad \mu_1=-\alpha. \quad (86)$$

The shapes of $W(t)$ for these two particular cases are illustrated in Fig. 4.

Example 3

The case to be considered here is the same as that treated in Example 2, except that the auto-correlation function of $N(t)$ is assumed to be of the form

$$\psi_N(\tau)=e^{-a|\tau|}\cos\omega_0\tau, \quad (87)$$

with the associated spectral density function being

$$S_N(\omega^2)=\frac{2a(a^2+\omega_0^2+\omega^2)}{\omega^4+2(a^2-\omega_0^2)\omega^2+(a^2+\omega_0^2)^2}. \quad (88)$$

This form of spectral density function is of considerable practical importance since it provides a reasonably good approximation to many of the actual spectra encountered in practice.

Solution

By Eq. (64), the weighting function for this case is of the form

$$W(t)=A_0+A_1t+B_1e^{bt}+B_2e^{-bt}+C_1\delta(t)+D_1\delta(t-T), \quad 0\le t\le T, \quad (89)$$

where $b=(a^2+\omega_0^2)^{\frac{1}{2}}$. Substituting $W(t)$ as given by Eq. (89) into Eq. (36), and requiring that Eq. (36) be satisfied by $W(t)$ establishes four linear algebraic equations between the six constants A_0, A_1, B_1, B_2, C_1, D_1. These are:

$$\begin{aligned}
&-2ab^2A_0+2(a^2-\omega_0^2)A_1-b^3B_1+b^3B_2+C_1=0,\\
&2\omega_0^2b^2A_0-4a\omega_0^2A_1+b^3(b-a)B_1+b^3(b+a)B_2=0,\\
&-2ab^2A_0+2(\omega_0^2-a^2-aTb^2)A_1+\frac{e^{bT}}{2b}B_1-\frac{e^{-bT}}{2b}B_2+D_1=0,\\
&2\omega_0^2b^2A_0+2\omega_0^2(2a+b^2T)A_1+b^3(b+a)e^{bT}B_1+b^3(b-a)e^{-bT}B_2=0.
\end{aligned} \quad (90)$$

The constraints imposed by the prediction operator $K(p)$ are given by Eq. (14); they are:

$$\int_0^T W(\tau)d\tau=\mu_0, \quad (75)$$

and

$$\int_0^T \tau W(\tau)d\tau=\mu_1. \quad (76)$$

The requirement that $W(t)$ must satisfy Eqs. (75) and (76) leads to two additional linear equations. These are:

$$2bTA_0+bT^2A_1+2(e^{bT}-1)B_1-2(e^{-bT}-1)B_2 +2bC_1+2bD_1=\mu_0,$$

and

$$3b^2T^2A_0+2b^2T^3A_1+b[e^{bT}(bT-1)+1]B_1 -6[e^{-bT}(bT+1)-1]B_2+6b^2D_1=\mu_1. \quad (91)$$

The coefficients A_0, A_1, B_1, B_2, C_1, D_1 of Eq. (89) are the solutions of the six linear equations (90) and (91).

The expression for the mean-square value of the prediction error can be conveniently expressed in terms of A_0 and A_1. Thus, making use of Eq. (83) it is readily found that

$$\sigma^2=(2a/b^2)(\mu_0A_0+\mu_1A_1). \quad (92)$$

This completes essentially the solution of the problem.

Potential Flow into Circumferential Openings in Drain Tubes*

DON KIRKHAM

Iowa State College Agricultural Experiment Station, Department of Agronomy and Department of Physics, Ames, Iowa

(Received December 22, 1949)

A theoretical analysis of the effect of the spaces between drain tube units as used in the artificial drainage of soil is given. The problem is one of potential flow; therefore, the results are applicable to heat flow, etc. The basic problem solved is that for axially symmetric flow from an external cylindrical boundary at constant potential to a series of equal, equally spaced openings at a lower potential, all located axially on, and comprising a part of, the otherwise impervious drain tube. The radii of the open sections and impermeable sections of the drain tube are equal. The basic problem is extended to obtain the solution to the practical problem—the seepage of ground water into drain tubes beneath a horizontal water table. The exact solution of the basic problem is not suitable for numerical work. Accordingly, approximate solutions of specified uncertainty are derived and are utilized for tabulation of numerical results. As an example, the analysis shows, in the case of 6 in. diameter drain tubes having 1 ft. long impermeable sections and buried 4 ft. deep in uniformly permeable soil, that increasing the openings from $\frac{1}{32}$ in. width to $\frac{1}{4}$ in. width will increase the flow 36 percent; while embedding the tubes in gravel, to make the $\frac{1}{32}$ in. openings of effectively infinite width, will increase the flow 180 percent.

IN the drainage of soil, for agricultural use, for foundations, roads, or for dams, excess ground water is generally removed by drain tubes installed two or more feet below the soil surface. These tubes consist, in most cases, of 1 ft. long sections of impervious pipe, either tile or cement, fitted together axially, except for a space left between individual units, to permit the water to enter. In practice the opening between the units is usually small. It may be less than 1/64 in. or, as much as $\frac{1}{4}$ in. But if the tubes are embedded in gravel, as is sometimes the case, the open space between the pipe units becomes effectively infinite. This is a consequence of the negligible loss of head which results when water seeps through gravel as compared with water seeping through soil. In this paper the effect of width of opening between the pipe units on drainage rate will be analyzed. As the problem is one of potential theory, the results will be applicable to other physical problems as flow of heat, electricity, etc.[1]

In the actual drainage problem the drain tubes are installed in a nearly horizontal position in the soil. Therefore if the soil is water-saturated to the surface of the ground, the soil surface is an equipotential plane, and the flow problem may be solved by the method of images.

AXIAL FLOW

Before applying the method of images it is convenient to solve a simpler problem: that of axially symmetrical flow for the system indicated in Fig. 1. Here, because of symmetry, only a section $ABCD$ need be considered. This section is bounded by inner and outer cylindrical surfaces at $r=a$ and $r=b$; by a plane $z=0$, midway between an open space of width $2c$; and a plane $z=s$, $2s$ being the distance between centers of openings.

Taking ϕ as the potential function, V_a as the constant potential over the openings of the drain tube, and V_b the constant potential over the outer cylinder, the boundary conditions are—I: $\phi=V_a$, $r=a$, $0\leq z\leq c$; II: $\partial\phi/\partial r=0$, $r=a$, $c<z\leq s$; III: $\partial\phi/\partial z=0$, $z=s$; IV: $\phi=V_b$, $r=b$; V: $\partial\phi/\partial z=0$, $z=0$.

The exact solution of $\nabla^2\phi$ which satisfies the above conditions can be formulated. This exact solution, is not, however, tractable in calculations. Therefore, a simpler, approximate solution is sought. Simplification is looked for through substitution of approximately correct,

homogeneous boundary conditions at $r=a$, for the accurate, mixed boundary conditions, I and II. Homogeneous boundary conditions at $r=a$ can be realized in two ways: (1) by using the exact condition, $\phi=V_a$ for $0<z<c$ and finding by trial a ϕ for $c<z<s$ such that over $c<z<s$, $\partial\phi/\partial r=0$; or (2), by using the exact condition

$$\partial\phi/\partial r=0, \quad c<z<s, \quad r=a \tag{1}$$

and finding by trial a $\partial\phi/\partial r$ such that

$$\partial\phi/\partial r=f(z, r, b, s, c)=f(z), \quad 0\leq z<c, \quad r=a, \tag{2}$$

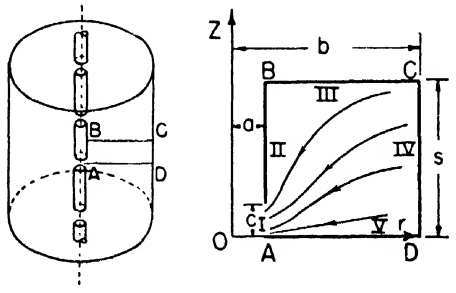

FIG. 1. Case of axially symmetric flow.

the ϕ in Eq. (2) satisfying simultaneously the relation

$$\phi=V_a, \quad 0\leq z<c, \quad r=a. \tag{3}$$

Because in practice one has $c\ll s$, with the consequence that $\partial\phi/\partial r$ is known exactly $(=0)$ over most of the boundary, it appears better to use the second method. Accordingly we attempt to satisfy Eqs. (1), (2) and (3).

As will appear, Eqs. (1) and (2) can, with the aid of Fourier series, be satisfied for an infinite number of values of $f(z)$. To satisfy, in addition, Eq. (3), however, there exists only one suitable value of $f(z)$, and to determine this value, by trial with accuracy, considerable labor would be required. A form of $f(z)$ which satisfies Eq. (3) for practical purposes can be determined by considering the two-dimensional case[2] into which Fig. 1 goes over when $a\to\infty$. Here with $b>s$, $s\gg c$, y replacing r, x replacing z, $z'=x'+iy'$, $i=(-1)^{\frac{1}{2}}$; one finds,[3] taking w for the complex potential,

$$\frac{dw}{dz'}=\frac{A\cos\pi(x'+iy')/2s}{[\sin^2\pi c/2s-\sin^2\pi(x'+iy')/2s]^{\frac{1}{2}}},$$

where A is a constant. Now, setting $y=0$, and observing that the x-component of dw/dz' over the opening is zero, there results

$$\left[\frac{\partial\phi}{\partial y}\right]_{y=0}=\frac{A\cos\pi x'/2s}{(\sin^2\pi c/2s-\sin^2\pi x'/2s)^{\frac{1}{2}}}, \quad 0<x'<c,$$

or, in notation corresponding to Fig. 1,

$$\left[\frac{\partial\phi}{\partial r}\right]_{r=a}=\frac{A\cos\pi z/2s}{(\sin^2\pi c/2s-\sin^2\pi z/2s)^{\frac{1}{2}}}, \quad 0<z<c,$$

that is with c, and hence z, small compared to s,

$$\left[\frac{\partial\phi}{\partial r}\right]_{r=a}\simeq A'[1-(z/c)^2]^{-\frac{1}{2}}, \quad c\ll s, \quad 0<z<c, \tag{4}$$

where A' is a constant $(A'=2sA/\pi c)$.

In order to evaluate the constant A' there is available the expression for the flux Q_1 entering the tube between $z=0$ and $z=c$. This flux is

$$Q_1=2\pi aK\int_0^c \partial\phi/\partial r\Big|_{r=a}\,dz,$$

where K is the soil permeability[4] (thermal conductivity in the heat problem, ϕ being then the temperature). Substituting Eq. (4) in the last expression and integrating, there results

$$Q_1=ac\pi^2A'K.$$

It is more convenient to consider the flow into unit length of drain tube including both the open and the impervious portions of surface. Let Q be this flux. Then, $Q=Q_1/s=ac\pi^2A'K/s$; that is

$$A'=Qs/ac\pi^2K \tag{5}$$

and Eq. (4) becomes

$$[\partial\phi/\partial r]_{r=a}\simeq(Qs/ac\pi^2K)[1-(z/c)^2]^{-\frac{1}{2}}, \quad 0<z<c. \tag{6}$$

This expression, since we took $b>s$, does not involve b.

As has been indicated, the right-hand sides of Eqs. (2) and (6) require development in a Fourier series. A cosine series is needed. It is

$$[\partial\phi/\partial r]_{r=a}=\sum_{n=1}^{\infty}A_n\cos n\pi z/s+A_0/2, \quad 0<z<s,$$

where the coefficients are found in the usual way to have the values,

$$A_0/2=Q/2a\pi K, \tag{7}$$

$$A_n=(2Q/a\pi^2K)\sin^{-1}[(s/n\pi c)\sin n\pi c/s]. \tag{8}$$

If we now define $R_0(n\pi r/s)$ by

$$R_0(n\pi r/s)=\frac{K_0(n\pi b/s)I_0(n\pi r/s)-I_0(n\pi b/s)K_0(n\pi r/s)}{K_0(n\pi b/s)I_1(n\pi a/s)+I_0(n\pi b/s)K_1(n\pi a/s)}, \tag{9}$$

in which I_0 and K_0 are modified Bessel functions of the

[2] Two-dimensional boundary conditions in solving problems of axial symmetry have recently been applied by W. R. Smythe, Rev. Mod. Phys. 20, 176 (1948).

[3] W. R. Smythe, *Static and Dynamic Electricity* (McGraw-Hill Book Company, Inc., New York, 1939), first edition, p. 89.

[4] Muskat (see reference 1, p. 294) uses the symbol k where we use K. K is the quantity of water seeping through a unit length of soil of unit cross section when the difference in hydraulic head across the unit length is unity. Our ϕ has the physical significance of hydraulic head and is equivalent to Muskat's Φ/k.

first, and second kind and zero order; and I_1, of the first kind and first order; we can write down a function ϕ which satisfies $\nabla^2\phi=0$ and conditions (II), (III), (IV), and (V) exactly, and (I) approximately. It is

$$\phi=\sum_{n=1}^{\infty}\frac{A_n s}{n\pi}R_0\left(\frac{n\pi r}{s}\right)\cos\frac{n\pi z}{s}+\frac{A_0}{2}a\ln\frac{r}{b}+V_b, \quad (10)$$

where the A_n and A_0 are given by Eqs. (7) and (8).

The right-hand side of Eq. (10) does not converge rapidly; nor has an analytic summation for it been found. Furthermore the flux values based on Eq. (10), as numerical calculations show, are not appreciably different for practical purposes, from the values resulting from a simpler expression obtained as follows.

SIMPLIFIED APPROXIMATE SOLUTION OF SPECIFIED UNCERTAINTY

Let (instead of Eq. (4))

$$[\partial\phi/\partial r]_{r=a}=B', \quad 0<z<c; \quad (11)$$

then, as Eq. (5) was determined, one finds

$$B'=Qs/2ac\pi K.$$

Also, developing the right-hand side of Eqs. (1) and (11) into a Fourier cosine series in the interval $0<z<s$, there results

$$[\partial\phi/\partial r]_{r=a}=\sum_{n=1}^{\infty}B_n\cos\frac{n\pi z}{s}+\frac{B_0}{2},$$

where

$$B_0/2=cB'/s,$$
$$B_n=(2B'/n\pi)\sin n\pi c/s.$$

Instead of Eq. (10) we now have

$$\phi=\sum_{n=1}^{\infty}(B_n s/n\pi)R_0(n\pi r/s)\cos n\pi z/s+(B_0/2)a\ln r/b+V_b;$$

or, in terms of the flux Q,

$$\phi=\frac{Q}{2\pi K}\left[\ln\frac{r}{b}-\frac{2s^2}{ac\pi^2}S(r,z)\right]+V_b \quad (12)$$

where

$$S(r,z)=-\sum_{n=1}^{\infty}\frac{1}{n^2}\sin\frac{n\pi c}{s}R_0\left(\frac{n\pi r}{s}\right)\cos\frac{n\pi z}{s}. \quad (13)$$

In Eq. (12) $\phi(r,z)$ is given in terms of supposedly known values of V_b and Q. If, however, $\phi(r,z)$ is known for some point (r,z), the flux Q may be considered as unknown and there results

$$Q=\frac{2\pi K[V_b-\phi(r,z)]}{\ln b/r+(2s^2/ac\pi^2)S(r,z)}. \quad (14)$$

We will now establish, referring to Fig. 2, lower and upper limits Q_l and Q_u for the flux. In the figure the line EF represents the equipotential passing through the point $(r,z)=(a,c)$, the point E being at higher potential than the point A. Now, since in the actual physical problem the potential along AE does not increase but has the constant value V_a, identification of V_a with $\phi(r,z)=\phi(a,0)$ in Eq. (12) establishes a lower limit Q_l of flow.

Suppose now that V_a is identified with the equipotential EF,[5] specified analytically by $\phi=\phi(a,c)$. Then, in order that the potential along AE be constant, a section AEF of soil must be removed. But with this soil removed the flow will be greater than if the potential V_a were applied along AE with no soil removed. Therefore, identification of $\phi(r,z)$ with $\phi(a,c)=V_a$ yields an upper limit of flow.

From the above considerations and Eqs. (13) and (14) we have then

$$Q_l=\frac{2\pi K(V_b-V_a)}{\ln b/a+(2s^2/ac\pi^2)S(a,0)}, \quad (15)$$

$$Q_u=\frac{2\pi K(V_b-V_a)}{\ln b/a+(2s^2/ac\pi^2)S(a,c)}; \quad (16)$$

and we define an average value of flux Q_{Av} by

$$Q_{Av}=(Q_l+Q_u)/2, \quad (17)$$

a value which should not be far in error.

Although Eqs. (15) and (16) are correct lower and upper limits of the flow for all values of a, b, c, and s, the expressions may be simplified. This is true, because for

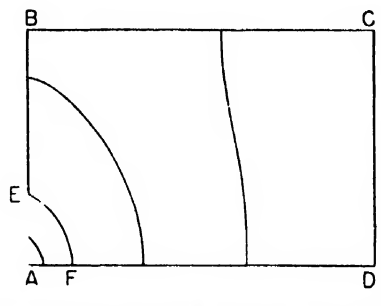

FIG. 2. Schematic equipotentials for the region $ABCD$ of Fig. 1 when the normal component of flux density across the stricture AE is constant.

the range of values of a, b, and s considered in the following, there is valid the approximation $R_0(n\pi a/s)=-K_0(n\pi a/s)/K_1(n\pi a/s)$ to better than 1 part in 10^8. (The approximation $R_0(n\pi r/s)=-K_0(n\pi r/s)/K_1(n\pi a/s)$ is correct to better than 1 part in 10^5, the worst case being for $n=1$ and $r=b$.) There results then, finally, for

[5] The distance AF in Fig. 2 has been computed, using Eq. (10). For $2a=19.2/\pi\simeq 6$, $b=48$, $2c=4/15\simeq\frac{1}{4}$, $s=6$, it is $AF=0.075$, where, for a practical example all units may be taken as inches. It will be shown that $b=48$ in. corresponds to a depth of 24 in. for a horizontally installed drain tube.

numerical calculations

$$Q_l=\frac{2\pi K(V_b-V_a)}{\ln b/a+(2s^2/ac\pi^2)S_1}, \tag{18}$$

$$Q_u=\frac{2\pi K(V_b-V_a)}{\ln b/a+(2s^2/ac\pi^2)S_2}, \tag{19}$$

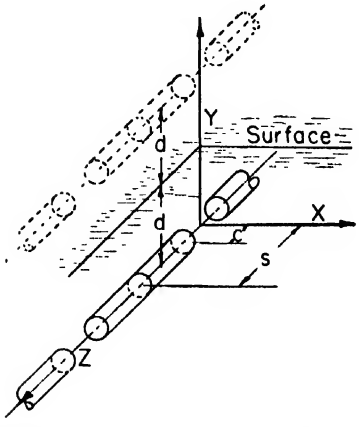

FIG. 3. Image case for a single drain tube. The semi-distance c between impermeable units is indicated larger than is found in practice.

where

$$S_1=S(a,0)=\sum_{n=1}^{\infty}\frac{1}{n^2}\sin\frac{n\pi c}{s}\frac{K_0(n\pi a/s)}{K_1(n\pi a/s)}, \tag{20}$$

$$S_2=S(a,c)=\sum_{n=1}^{\infty}\frac{1}{2n^2}\sin\frac{2n\pi c}{s}\frac{K_0(n\pi a/s)}{K_1(n\pi a/s)}. \tag{21}$$

A commonly recommended size of drain tube for laterals (as distinguished from mains) is 5 in. inside diameter. Smaller diameters, sometimes as small as 2 in. have been used. Unit lengths are almost invariably 1 ft., and wall thickness about $\frac{1}{2}$ in. In view of the above and in order to simplify computations the following values for geometrical quantities have been used: $a/s=0.8/\pi$ and $1.6/\pi$; $b/s=8$, 16 and 200; $c/s=1/1440$, $2/1440$, $\cdots$, $32/1440$. With $2s=1$ ft. the values of a/s and c/s correspond to $2a=3.06$ and 6.12 in., and $2c$ to approximately $1/128$, $1/64$, $\cdots$, $\frac{1}{4}$ in. The values chosen for b/s correspond (with $2s=1$ ft.) to $b=4$, 8 and 100 ft.

Numerical results for S_1 and S_2 are presented in Table I. The values were computed from Eqs. (20) and (21) by summing term by term, from $n=1$ to $n=44$ and using Euler-McLaurin[6] summation formulas for $n=45$ to ∞, taking for $n\geq 45$, $K_0(n\pi a/s)/K_1(n\pi a/s)=1$. Taking the latter ratio = 1 accounts for the uncertainty in the last place of decimals in Table I. In preparing Table I the relation $S_2[(1/2)c/s]=(1/2)S_1(c/s)$ was useful. There is a similar relation for Q_l and Q_u.

16/1440	0.13849 (2)	0.11455 (1)	0.12942 (4)	0.10572 (2)
8/1440	0.08128 (4)	0.06925 (1)	0.07668 (9)	0.06471 (2)
4/1440	0.04666 (4)	0.04066 (2)	0.04434 (9)	0.03834 (5)
2/1440	0.02634 (4)	0.02333 (2)	0.02517 (6)	0.02217 (4)
1/1440	0.01468 (2)	0.01317 (2)	0.01405 (4)	0.01259 (3)

[a] Numbers in parentheses indicate uncertainty (±) in the fifth decimal place.

Table II presents values of Q_l', Q_M' and Q_u', where,

$$\left.\begin{aligned} Q_l'&=Q_l/K(V_b-V_a),\\ Q_M'&=Q_M/K(V_b-V_a),\\ Q_u'&=Q_u/K(V_b-V_a).\end{aligned}\right\} \tag{22}$$

The uncertainty in Q_M' is greatest, $51/570=8.95$ percent for the values $b/s=8$, $a/s=0.8/\pi$ and $c/s=32/1440$; and (except for $c/s=1$ when the uncertainty is zero) is least, $14/437=3.20$ percent for the values $b/s=200$, $a/s=1.6/\pi$, and $c/s=1/1440$. The uncertainty in Q_M' increases with decreasing a/s and b/s and increasing c/s. The uncertainty 3.20 percent found for $c/s=1/1440$ is larger than was expected.

IMAGE CASE: A SINGLE DRAIN TUBE

Figure 3 represents the image case. The drain tube is buried horizontally (nearly, in practice) at depth d below a plane water table, here taken as the surface of

1/4	1.405	1.508	1.361	1.432
Inf.	3.268	4.425	2.809	3.846

[a] Crack widths, tube diameters and length of tube units are nominal. The entries in the table correspond actually (see Fig. 3) to $s=6$ in. (not $s-c=6$ in.) to $2c=1/120$, 1/60, 1/30, etc. in. and to $2a=19.2/\pi=6.06$ in. and $2a=9.6/\pi=3.03$ in. Infinite crack width corresponds to $c/s=1$. The depths 2 and 4 ft. are correct.

[b] For practical purposes in soil drainage, a drain tube embedded in gravel

the soil. The soil is of uniform permeability K and extends downward to great depth, the drain tube being the only exit for soil water. The fictitious image drain is distance d above the soil surface. With the coordinate axes as shown, and referring to Eq. (12), the potential θ may be written down by inspection and is

$$\theta=\frac{F}{2\pi K}\left\{\ln\frac{(x^2+y^2)^{\frac{1}{2}}}{[x^2+(2d-y)^2]^{\frac{1}{2}}}+\frac{2s^2}{ac\pi^2}\sum_{n=1}^{\infty}G_n n^{-2}\sin n\pi c/s\cdot\cos n\pi z/s\right\}+V_d, \quad (23)$$

where

$$G_n=R_0\left[\frac{n\pi}{s}(x^2+y^2)^{\frac{1}{2}}\right]-R_0\left\{\frac{n\pi}{s}[x^2+(2d-y)^2]^{\frac{1}{2}}\right\},$$

and where F, now used instead of Q, is the flux per unit length of drain tube, including the open and closed parts, and V_d is the hydraulic head at the surface of the soil.

We assume that the drain line is running full with zero back pressure or suction. Therefore, taking the axis of the drain tube as reference level for hydraulic head, the potential V_w over the inside of the tube is $V_w=a$; also $V_d=d$ if the soil is water-saturated to the surface; and $V_d=d+t$, if in addition there is a surface layer of water of thickness t.

Let us consider Eq. (23) for the case that $c=s$, that is, for the case that the summation is zero. Then, taking $x=0$ and $y=a$, there results $F=2\pi K(V_d-V_w)/\ln(2d-a)/a$; and taking $x=0$ and $y=-a$, there results $F=2\pi K(V_d-V_w)/\ln(2d+a)/a$. One of these values is too high and one too low.[7] A value which more nearly equals the actual flux is $F=2\pi K(V_d-V_w)/\ln 2d/a$.[8] Similarly, a best value for R_0-terms at the surface of the drain tube is

$$R_0(n\pi a/s)-R_0(2n\pi d/s)=-[K_0(n\pi a/s)/K_1(n\pi a/s)-K_0(2n\pi d/s)/K_1(n\pi a/s)],$$

very nearly, $=-[K_0(n\pi a/s)/K_1(n\pi a/s)]$, very nearly (for practical values of d, s and a). Therefore Eq. (23) may be written for the drain surface, upon solving for F,

$$F=2\pi K(V_d-V_w)\{\ln 2d/a+(2s^2/ac\pi^2)\sum_{n=1}^{\infty}n^{-2}\sin n\pi c/s\cdot\cos n\pi z/s\cdot K_0(n\pi a/s)/K_1(n\pi a/s)\}^{-1}.$$

Taking now, as was done in obtaining Eqs. (18) and (19), $z=0$ and then $z=c$, lower and upper limits, F_l and F_u, for the flux are found to be

$$F_l=\frac{2\pi K(V_d-V_w)}{\ln 2d/a+(2s^2/ac\pi^2)S_1}, \quad (24)$$

$$F_u=\frac{2\pi K(V_d-V_w)}{\ln 2d/a+(2s^2/ac\pi^2)S_2}, \quad (25)$$

where S_1 and S_2 are given by Eqs. (20) and (21). Also, as in Eq. (17), we define

$$F_{av}=(F_l+F_u)/2; \quad (26)$$

and as in Eq. (22),

$$\left.\begin{aligned}F_l'&=F_l/K(V_d-V_w)\\F_{av}'&=Q_{av}/K(V_d-V_w)\\F_u'&=F_u/K(V_d-V_w)\end{aligned}\right\}. \quad (27)$$

Comparing Eqs. (18) and (19) with Eqs. (24) and (25), and Eq. (17) with Eq. (26), it is now apparent that Table II gives values of F_l', F_{Av}' and F_u', if b is taken

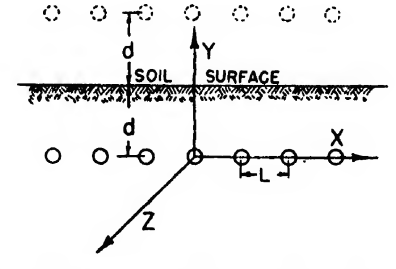

FIG. 4. A series of equally spaced drain tubes.

[7] The former value is too high, because the equipotential surface $\theta(0, a)$ lies outside the actual drain tube except at $(0, a)$; the latter, too small, because the equipotential $\theta(0, -a)$ lies inside the actual drain tube except at $(0, -a)$.

[8] The exact value (see reference 3, p. 77, Eq. 1) is $F=2\pi K(V_d-V_w)/\cosh^{-1}d/a$. The expression $\ln 2d/a$ approximates $\cosh^{-1}d/a$ to better than 1 part in 3400 for $d=4$ and $a=0.25$.

equal to $2d$, and if F's are substituted for Q's. With these considerations Table III has been prepared. The table brings out the fact that the width of opening between drain pipe units is an important factor in seepage calculations. For example, in a clay soil, where a crack width of $\frac{1}{4}$ in. may safely be used, flow to a 6 in. tube at 4 feet depth may be increased 36 percent over that achieved by putting the drain pipe units $\frac{1}{32}$ in. apart as is commonly done; while embedding the tubes in gravel may increase the flow 180 percent. In soils where gravel is not available and where wide drain tube openings might result in the entry of soil into the tubes, with possible clogging, screens could be placed over the openings. The soil would be stabilized by the time the screens deteriorate.

IMAGE CASE: MULTIPLE DRAIN TUBES

For a series of drain tubes equally spaced at distance L and at depth d (Fig. 4), the potential is, comparing Eq. (23),

$$\theta=\frac{F}{2\pi K}\sum_{m=-\infty}^{\infty}\left[\frac{1}{2}\ln\frac{(x+mL)^2+y^2}{(x+mL)^2+(2d-y)^2}+T_m\right]+V_d, \quad (28)$$

where

$$T_m=\frac{2s^2}{ac\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}\sin\frac{n\pi c}{s}\cos\frac{n\pi z}{s}\times\left(R_0\{(n\pi/s)[(x+mL)^2+y^2]^{\frac{1}{2}}\}-R_0\{(n\pi/s)[(x+mL)^2+(2d-y)^2]^{\frac{1}{2}}\}\right).$$

Now the first summation in Eq. (28) is[9]

$$(1/2)\ln(\cosh 2\pi y/L-\cos 2\pi x/L)/(\cosh 2\pi(2d-y)/L-\cos 2\pi x/L);$$

or putting $y=a$, $x=0$, it is

$$(1/2)\ln(\cosh 2\pi a/L-1)/[\cosh 2\pi(2d-a)/L-1]=\ln[(\sinh\pi a/L)/\sinh\pi(2d-a)/L].$$

The second summation in Eq. (28), when $y=a$ and $x=0$, reduces, since $d\gg s$, $L\gg s$, to the single summation $\sum_{n=1}^{\infty}[-K_0(n\pi a/s)/K_1(n\pi a/s)]n^{-2}\sin n\pi c/s\cdot\cos n\pi z/s$, in which $(-K_0/K_1)$ has been written, as before, for R_0. Therefore, Eq. (28) yields, taking first $x=0$, $y=a$, $z=0$, and then $x=0$, $y=a$, $z=c$, lower and upper limits for the flux as follows.

$$F_l=\frac{2\pi K(V_d-V_w)}{\ln[(\sinh 2\pi d/L)/(\sinh\pi a/L)]+(2s^2/ac\pi^2)S_1}, \quad (29)$$

$$F_u=\frac{2\pi K(V_d-V_w)}{\ln[(\sinh 2\pi d/L)/(\sinh\pi a/L)]+(2s^2/ac\pi^2)S_2}, \quad (30)$$

where the a in $\sinh\pi(2d-a)/L$ has been dropped for the same reason that the a in $(2d-a)$ was dropped in obtaining Eqs. (24) and (25).

It is apparent, comparing Eqs. (18), (19); (24), (25); and (29), (30), that the same two correction terms $(2s^2/ac\pi^2)S_1$ and $(2s^2/ac\pi^2)S_2$ will apply in a number of drainage problems.[10,11] These terms, multiplied by $1/2\pi K$, represent upper and lower limits of a resistance term which, in order to compute the flux, must be added to the resistance of the medium when calculated for completely open drain tubes. Stated in another way, the loss in hydraulic head due to strictures in a drain tube of the type shown in Fig. 1, whether there is a single tube or a number of tubes in an installation, will not exceed $(Q/2\pi K)(2s^2/ac\pi^2)S_1$; nor be less than $(Q/2\pi K)(2s^2/ac\pi^2)S_2$, where Q is the flow per unit length of tube.

Determination of Modified Index-of-Refraction over the Gulf of Mexico from Radio Data*

A. W. Straiton and A. H. LaGrone
The University of Texas, Austin, Texas
(Received November 21, 1949)

This paper presents the results of measurements of the signal strength and phase of 3.2-centimeter radio waves for a 26.5-mile path over the Gulf of Mexico under a variety of meteorological conditions. The radio data are used to determine the modified index-of-refraction as a function of height and the associated attenuation factor. The modified index-of-refraction curves are compared to those measured meteorologically.

I. INTRODUCTION

THE strength of radio waves received through the troposphere is influenced by the distribution of the index-of-refraction with height. For this work a modified index-of-refraction, M,** is used to permit the use of a plane earth representation. Numerous papers have described the theory and measurements from which the radio signal strength may be determined from a known distribution of index with height.

Macfarlane[1] pointed out the possibility of reversing the process so as to obtain the index distribution with height from radio data. His method requires a knowledge of the height-gain curve and additional data from which the wave attenuation with distance may be determined.

Macfarlane's method may be extended[2] to use as known data the phase distribution with height as well as the signal strength distribution. This eliminates the necessity of additional information from which the attenuation may be determined. This modified method is used in this paper to obtain the low level index-of-refraction distribution on a 26.5-mile over-water path using a wave-length of 3.2 centimeters. These data, taken during June and July, 1949, are associated with a variety of meteorological conditions ranging from an almost standard atmosphere to very strong ducts.

II. RADIO MEASUREMENTS

The radio path was over a section of the Gulf of Mexico adjacent to Bolivar Peninsula near Galveston, Texas as shown in Fig. 1. A 3.2-centimeter transmitter was located on a 50-foot tower on the mainland beach near High Island, Texas. A 2K39 Klystron supplied a continuous wave output of approximately 200 milliwatts. A picture of the transmitting tower is shown in Fig. 2.

Radio receivers were located on the northeast point of Galveston Island on two towers. The phase-difference equipment developed by the Electrical Engineering Research Laboratory of The University of Texas[3] was located on the elevator of a 60-foot tower with its base at 10 feet above mean sea level as shown in Fig. 3. This permitted measurements of the signal strength and phase difference from 15 to approximately 60 feet mean sea level. Three antennas were mounted on the elevator in a vertical line with a spacing of five feet between adjacent antennas. The signal strength was measured at the top and bottom antennas, and the phase difference was measured between the center and the two outside antennas. This permitted duplicate signal-strength and phase data over most of the height range obtained with the 60-foot tower. An auxiliary 16-foot tower with a movable elevator, as shown in Fig. 4, permitted measurement of signal strength from 2 to approximately 15 feet above the mean sea level. Horizontal polarization was used for the test.

III. METEOROLOGICAL MEASUREMENTS

Meteorological stations were set up at two points along the radio path. One station was located at a lighthouse, Station B in Fig. 1. Wet- and dry-bulb temperature soundings were made over a range of heights up to 60 feet, and wind speed and direction measurements were made at a height of about 70 feet.

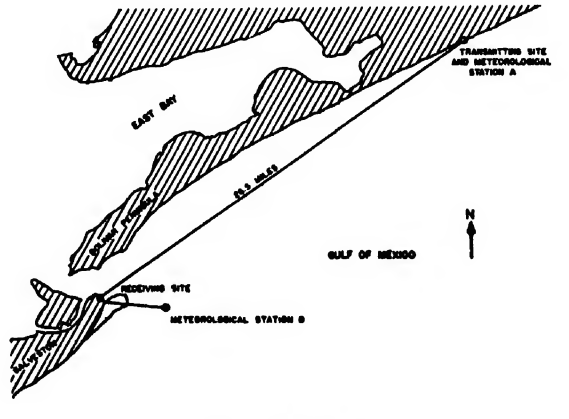

FIG. 1. Radio path.

* This work was sponsored by the ONR at The University of Texas under Contract N5ori-136, P.O.I.

** $M=(79/T)(P+4800e/T)+0.048h$, where T, P, e, and h are temperature in degrees Kelvin, atmospheric pressure in millibars, vapor pressure in millibars, and height in feet. This permits the use of a plane earth representation. For the standard atmosphere, $dm/dh=0.036$ M units per foot.

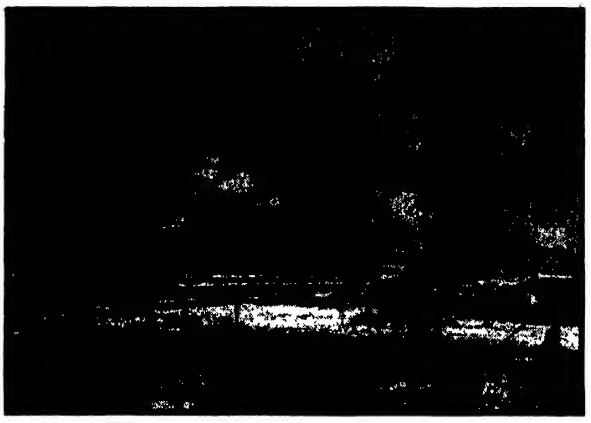

FIG. 2. Transmitting tower looking toward receiver.

The second meteorological station was on an oil drilling platform, Station A, approximately 50 feet off shore near the transmitter. Wet- and dry-bulb temperature measurements were made up to heights of 60 feet, and wind speed and direction were measured at the 10-foot platform level. A detailed description of the meteorological stations and the measurements is given elsewhere.[4] The meteorologically-measured modified index of refraction taken simultaneously with the radio data will be shown in this report for comparison with those determined from radio data.

IV. THEORETICAL CONSIDERATIONS

For radio propagation well beyond the line of sight, the electrical field vector, ψ, may be expressed as the sum of a number of normal modes[5] as follows:

$$\psi = e^{i\omega t - i\pi/4}(2\pi/kr)^{\frac{1}{2}} \sum_m e^{-\gamma_m r} U_m(h_1) U_m(h), \qquad (1)$$

where r is the distance around the earth's surface, k is 2π divided by the wave-length, γ_m is the propagation function for the mth mode, $U_m(h_1)$ and $U_m(h)$ are the height-gain function for the transmitter and receiver, respectively, for the mth mode.

For the distances and heights used in the measurement program, all modes higher than the first may usually be neglected.[6] The height-gain function is then given for the first mode by:

$$(d^2U_1/dh^2) + k^2[y(h) + \Lambda_1]U_1 = 0, \qquad (2)$$

where Λ_1 is characteristic value for the first mode.

V. MACFARLANE'S EQUATION

Macfarlane[1] expressed Eq. (2) as follows: Let

$$U_1 = Ae^{i\phi} \quad \text{and} \quad \Lambda_1 = a + ib.$$

Then

$$k^2(y+a) = (\dot{\phi})^2 - d^2A/dh^2/A \qquad (3)$$

and

$$\dot{\phi} = \frac{-k^2 b \int_0^h A^2 dh}{A^2} \qquad (4)$$

where the dots indicate derivatives with respect to h.

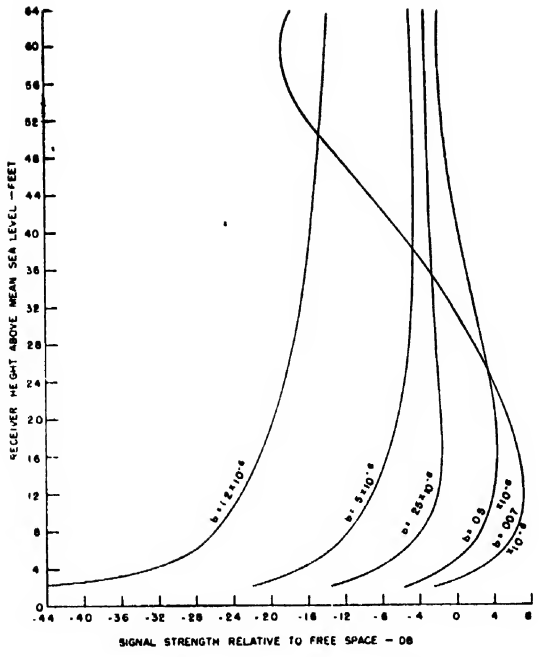

FIG. 5. Measured signal-strength curves on a db basis relative to free space.

Macfarlane replaced ϕ in Eq. (3) by the right side of Eq. (4). Then, if the attenuation factor b is known from measurements at other frequencies or distance, $(y+a)$ can be determined directly.

However, since the measurements made at the Electrical Engineering Research Laboratory were of A and $\dot{\phi}$, $(y+a)$ can be determined directly from (3), and b from (4).

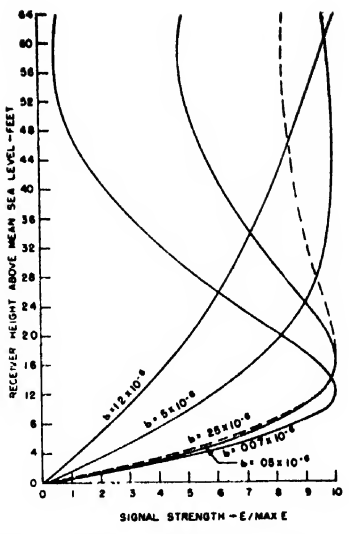

FIG. 6. Measured signal-strength curves relative to maximum signal in height interval.

VI. PROCEDURE FOR FINDING M CURVES

The procedure used was as follows:

1. The phase difference between the signals at the receivers and the signal strength at the receivers were obtained from the measurement charts. This provided the signal strength, A, and the phase difference, $\dot{\phi}$, both as a function of height.
2. The first derivative of A with respect to h was obtained graphically and plotted as a function of h. A smoothed first derivative was drawn and the original A curve was modified in accordance with the smoothed first derivative curve.
3. The second derivative with respect to h, was found graphically and divided by A.
4. A smooth curve was drawn through the values of ϕ as a function of height.
5. The values of $(y+a)=[2(M-M_0)\times 10^{-6}+a]$ were found from Eq. (3).
6. Curves of $\dot{\phi}$ for several assumed values of b were plotted

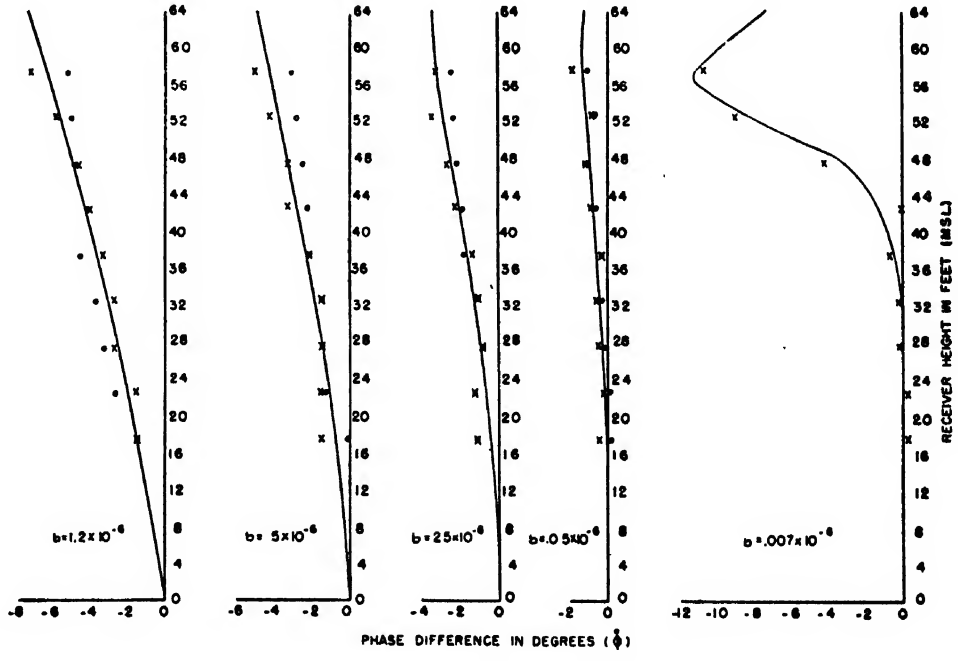

FIG. 7. Measured phase-difference curves.

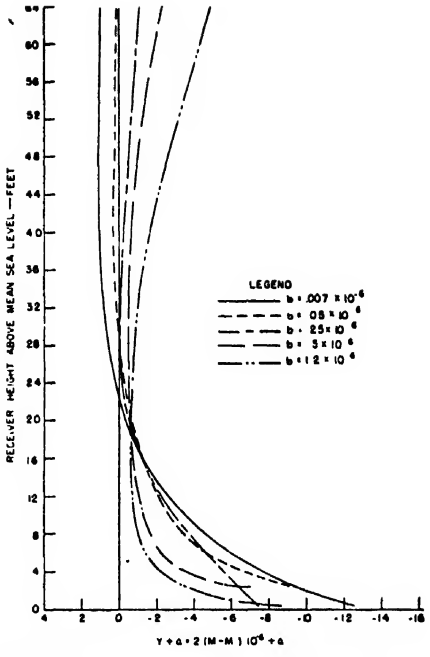

FIG. 8. M curves determined from radio data.

from Eq. (4). When the measured values of ϕ were superimposed on these curves, the value of b was chosen such that the measured curve coincided as nearly as possible with the one determined from the A data.

VII. HEIGHT-GAIN CURVES

In measuring the height-gain curves, data were taken in several ways. The receiver on the auxiliary 16-foot tower was moved up and down while its received signal was being recorded. The 16-foot tower receiver was then set at 15 feet and left there as a reference while the main receiver on the 60-foot tower was moved up continuously and down in five-foot steps. Since the signal was scintillating rapidly, averages of the various readings were taken to establish the height-gain curves shown. Fifty-two sets of such readings were taken and the height-gain or A curves were drawn. Many of the A curves were near duplicates and others were very similar. The entire group can be well represented by five samples which include the two extreme signals and three intermediate values. The signal strength-height curves for these five cases are shown on a db basis relative to free space in Fig. 5. The same curves are shown in Fig. 6 in terms of the field strength at a given height divided by the maximum field strength in the interval included. The curves representing the various examples are the ones which gave the smoothed first derivative curves. Seven intermediate values are added to increase to twelve the number used for the tabulation shown later.

VIII. PHASE DIFFERENCE-HEIGHT CURVES

The phase-difference curves corresponding to the signal-strength curves shown in Figs. 5 and 6 are shown in Fig. 7. The points indicated are the values measured between the center and each of the two outside antennas for the five-foot interval runs. The lines shown are the values of ϕ determined from the corresponding signal-strength curves by Eq. (4). Because of the physical location of the receivers, it was not convenient to use a reference angle. The reference angles were then chosen so that ϕ would fulfill the boundary condition of being zero at zero height.

IX. M CURVES FROM RADIO DATA

The A curves of Fig. 6 and the ϕ curves of Fig. 7 were used to determine $(y+a)$ from Eq. (3). The M curves thus obtained for the five cases considered are shown in Fig. 8. The inability to separate a from $2(M-M_0)$ is really no disadvantage. The reference value of index of refraction, M_0, is not of much significance and could, without harm, be increased or decreased. However, $(y+a)$ or $[2(M-M_0)\times10^{-6}+a]$ is the quantity that appears in the equations for the height-gain function given in reference 5. The degree to which $(y+a)$ goes negative is a measure of the amount of trapping and the points at which $(y+a)$ is zero are the "turning points," Z_0^m, of the W.K.B. approximation solution.

X. CHECK OF PHASE-INTEGRAL CONDITION

From reference 5, the phase-integral condition is known to be

$$\int_0^{z_{01}} (y+a+ib)^{\frac{1}{2}}dz=\frac{(m-\frac{1}{4})\pi}{k}=\frac{3\pi}{4k}. \qquad (5)$$

For the cases when $(y+a)$ becomes zero, (ib) may be neglected and the integral evaluated numerically from the measured data as the area beneath the portion of the $(y+a)$ curve below the first turning point. For the case when $(y+a)$ did not become zero, the curve was approximated by a linear-exponential expression and a complex turning point established. With this turning point, the integral of Eq. (5) may be evaluated. The value of the phase integral of Eq. (5) for twelve cases is compared with the theoretical value in Table I.

From Table I it is seen that the phase-integral condition is approximately satisfied.

XI. DETERMINATION OF WAVE ATTENUATION

As discussed in Section V, the wave-attenuation factor b may be determined from Eq. (4) by use of radio data. This attenuation is relative to the inverse square root relationship, and may be converted to decibels per mile as shown in Table II.

The attenuation factors may also be determined from the shape of the M curves which were obtained from radio data. The procedure used was to express the M curves from radio data in the form of a linear-exponential; and from the charts given by Pekeris and Ament,[7] values of b were obtained. A comparison of these values of b with those determined by Eq. (4) is also shown in

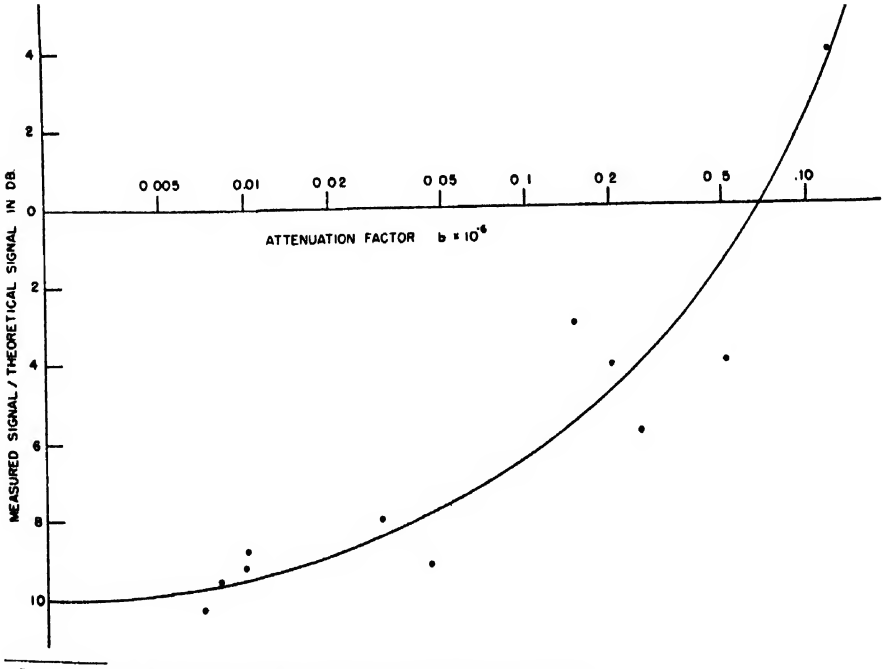

FIG. 9. Comparison of M curves from radio data with meteorological data.

[7] C. L. Pekeris and W. S. Ament, Phil. Mag. 38, 801–823 (1947).

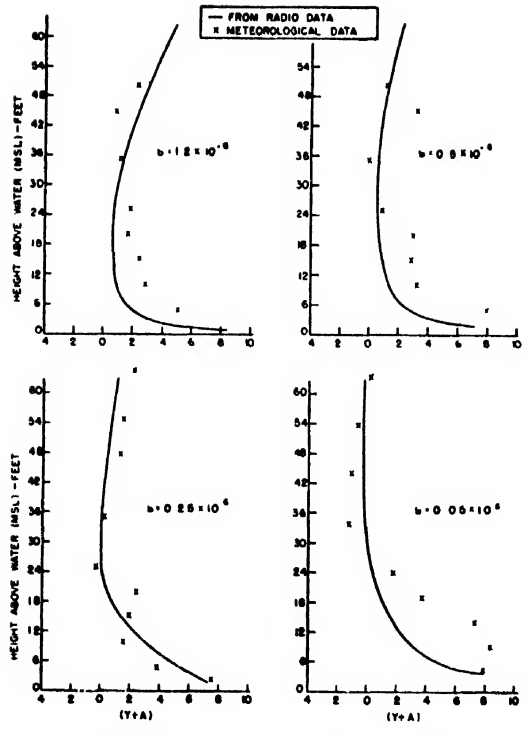

FIG. 10. Relationship between measured and theoretical signal strength.

Table II. The values of b obtained from the charts for cases 8 through 12 are shown as zero, since the scale of the charts was such that the values could not be distinguished from zero. There would, of course, be some attenuation, and the value obtained from radio data is thought to be fairly accurate.

XII. CHECK OF POSITIONING OF M CURVES

The form of linear exponential used by Pekeris and Ament[7] was

$$M-M_0=(0.036h+ge^{-ch}).$$

Then $(y+a)$ will be given by

$$(y+a)=[2(M-M_0)\cdot 10^{-6}+a]$$
$$=[(0.072h+2ge^{-ch})\cdot 10^{-6}+a].$$

The values of g, c, and a necessary to fit the linear exponential to M curves were determined. However, the value of a depends on g and c and may be determined from them by reference 7. In other words, a given shape of M curve must have a certain positioning with respect to the $(y+a)$ axis. Since the positioning is known from the measured data, a comparison may be made between the measured and theoretical position of the $(y+a)$ curve. Such a comparison is shown in Table III.

XIII. CHECK OF ABSOLUTE SIGNAL STRENGTH

The calculation of M curves from radio data requires a knowledge of the relative and not the absolute signal strengths. However, from the shape of the M curves determined from radio data, the signal strength relative to the free-space value may be determined. Using the measured signal strength, a theoretical value for the free-space signal was found for each case by the method of reference 5. Since the gains of the transmitting and receiving system were known as well as the power of the transmitter, a free-space value was established directly. The two values of the free-space signal are compared in Table IV.

From Table IV, it is noticed that the deviation between the theoretical and measured free-space signal strength is a function of the attenuation factor. This relationship is shown graphically in Fig. 9. For strong ducts in which the attenuation factor is low, the measured signal is considerably weaker than the theoretical value. However, for weaker ducts the measured signal strength approaches the theoretical value. It is thought that this deviation may be due to scattering by discontinuities in the atmosphere. For strong ducts, more signal is lost by scattering inside of the duct than is gained from scattering outside of the duct. However, when the signal is weak, the contribution from scattering outside of the duct is significant.

XIV. COMPARISON WITH METEOROLOGICALLY MEASURED M CURVES

As stated in Section III, meteorological data were taken at sites near both ends of the radio path. From the data taken at these sites simultaneously with the radio data, modified index-of-refraction distributions were obtained. For these curves, the measurements made at a given height at the two ends were averaged to obtain the value for that height. The M curves determined from radio data are compared with meteorological data in Fig. 10. From this figure, it is seen that general agreement exists between the M curves determined from radio data and meteorological data. However, it is noted that the meteorologically measured points are badly scattered. It is felt that it is difficult to determine the average M curve over a distance from the measurements at a single site since the meteorological parameters were fluctuating considerably. It seems, therefore, that the M curves may be obtained with a higher degree of accuracy from the radio data than from temperature and humidity measurements.

XV. CONCLUSIONS

It appears from this paper that for the conditions of the experiment, the modified index-of-refraction values as a function of height may be satisfactorily determined from signal-strength and phase-difference measurements. However, for very short distances, the method will fail since a single mode will not account for the signal distributions. For greater distances or very weak signals, the method may fail when an appreciable part of the signal is the result of scattering from elevated discontinuities in the index of refraction.

The Effective Permeability of an Array of Thin Conducting Disks

GERALD ESTRIN*
University of Wisconsin, Madison, Wisconsin
(Received December 5, 1949)

A three-dimensional array of thin conducting disks has found special application as an artificial refracting medium at microwave frequencies. Treatment of these refractive properties at oblique incidence requires specification of the dielectric and permeability coefficients of the medium.

When an alternating magnetic field is parallel to the disk faces, the field is undisturbed and the relative permeability coefficient is unity. When the alternating magnetic field is normal to the disk faces, circulating currents are induced on them. The boundary value problem of determining the current distribution on a single perfectly conducting disk is carried out in detail for the case where the disk diameter is small compared to the wave-length. This current distribution is found to be representable by a magnetic dipole. If the disks in an array are far enough apart to neglect interaction, a simple summation of the dipole moments shows the array to have a diamagnetic susceptibility in the direction normal to the disk faces.

Combining this result with an expression for the dielectric coefficient, which was developed earlier by Kock, the constants of the anisotropic array are completely specified.

INTRODUCTION

THE first part of this paper evaluates the steady state circulating current distribution induced in a thin conducting disk by a perpendicular time varying magnetic field whose wave-length is large compared to the disk diameter. The disk is treated as the limiting case of an oblate spheroid. The use of oblate spheroidal coordinates and the definition of a scalar potential function, $V=rE_\varphi$, lead to a Legendre Polynomial solution outside a conducting spheroid and to a general power series solution inside. Imposition of boundary conditions at the surface and far from the obstacle provides a simple relation for the surface current density distribution in the limit of a perfectly conducting disk.

In Part II, a magnetic dipole equivalent to the surface current distribution on the disk, is evaluated by integration of ring-shaped elements. For the case of a three-dimensional array in which the packing of the disks is small enough to neglect interaction, the dipole moment per unit volume leads to an expression for the magnetic susceptibility. The composite medium is observed to be diamagnetic in the direction normal to the disk faces and non-magnetic in directions parallel to them. There is a simple relation between the magnetic and electric susceptibilities of this array. Knowledge of the disk radius and the number per unit volume completely specifies the component constituitive equations which are necessary to determine the effect of the composite medium on an obliquely incident electromagnetic wave. The constituitive coefficients are calculated for two cases; one typical of microwave lens design and the other of a prism constructed at the University of Wisconsin.

PART I

As illustrated in Fig. 1, a conducting oblate spheroid is placed in a time varying magnetic field which is parallel to the axis of rotation of the spheroid. The applied field is given by $\bar{H}=\bar{\imath}H_a=\bar{H}_0\exp(-j\omega t)$. The diameter of the conducting body is assumed small compared to the wave-length and Maxwell's field equations for steady state become:

$$\nabla\times\bar{E}-j\omega\mu\bar{H}=0, \tag{1a}$$

$$\nabla\times\bar{H}-\sigma\bar{E}=0. \tag{1b}$$

Oblate spheroidal coordinates[1,2] provide a natural system for dealing with this problem. Using the notation defined in Appendix I, the component field equations separate into two independent sets. The set that must be solved in this case is given by:

$$\partial/\partial\eta(h_3E_\varphi)-j\omega\mu h_2h_3H_\xi=0, \tag{2a}$$

$$\partial/\partial\xi(h_3E_\varphi)+j\omega\mu h_1h_3H_\eta=0, \tag{2b}$$

$$\partial/\partial\xi(h_2H_\eta)-\partial/\partial\eta(h_1H_\xi)-\sigma h_1h_2E_\varphi=0. \tag{2c}$$

When the field equations in (1) are uncoupled they give

$$\nabla\times\nabla\times\bar{E}=j\omega\sigma\mu\bar{E}. \tag{3}$$

Since there is only a φ component of $\bar{E}$, (3) yields

$$\frac{\partial}{\partial\xi}\left[\frac{h_2}{h_1h_3}\frac{\partial}{\partial\xi}(h_3E_\varphi)\right]+\frac{\partial}{\partial\eta}\left[\frac{h_1}{h_2h_3}\frac{\partial}{\partial\eta}(h_3E_\varphi)\right]=-j\omega\sigma\mu h_1h_2E_\varphi. \tag{4}$$

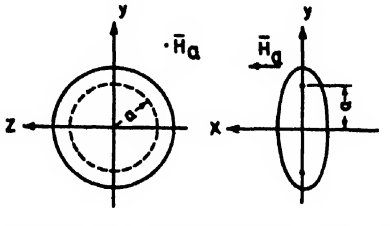

FIG. 1.

* RCA Research Fellow, Electrical Engineering Department.

[2] J. A. Stratton, *Electromagnetic Theory* (McGraw-Hill Book Company, Inc., New York, 1941).

If a potential function, $V \equiv rE_\varphi$, is now defined and substituted in (2) and (4), the following set of equations results.

$$H_\xi = \frac{-j}{\mu\omega h_2 h_3}\frac{\partial V}{\partial \eta}, \tag{5a}$$

$$H_\eta = \frac{j}{\mu\omega h_1 h_3}\frac{\partial V}{\partial \xi}, \tag{5b}$$

$$\frac{\partial}{\partial \xi}\left[\frac{h_2}{h_1 h_3}\frac{\partial V}{\partial \xi}\right]+\frac{\partial}{\partial \eta}\left[\frac{h_1}{h_2 h_3}\frac{\partial V}{\partial \eta}\right]+j\omega\sigma\mu\frac{h_1 h_2}{h_3}V=0. \tag{5c}$$

Separation of variables in (5c) is carried out in Appendix II yielding identical differential equations in the independent variables, η and $(j\xi)$ of the form,

$$(1-x^2)\partial^2 y/\partial x^2+(k^2x^2+D)y=0, \tag{6}$$

where $k^2=ja^2\omega\sigma\mu$ and a is defined in Appendix I.

Outside the conducting spheroid, $k^2=0$. Appendix III shows that with $D=l(l+1)$, Eq. (6) is then satisfied by a solution containing Legendre Polynomials of the first and second kind.

$$y=(1-x^2)d/dx[P_l(x)+Q_l(x)]. \tag{7}$$

Hence a set of solutions is obtained for the potential function, V, in the region outside the conducting spheroid.

$$V_0=\sum_{l=0}^{\infty} j(1-\eta^2)(1+\xi^2)\left[A_l\frac{d}{d\eta}P_l(\eta)+B_l\frac{d}{d\eta}Q_l(\eta)\right] \times\left[C_l\frac{d}{d\xi}P_l(j\xi)+D_l\frac{d}{d\xi}Q_l(j\xi)\right]. \tag{8}$$

The set of solutions, (8), must now be restricted by imposing the physical conditions of the problem.

(a) The field vectors are bounded. Therefore V_0 must be bounded for finite values of the coordinates. Since $Q_l(\pm 1)$ is unbounded, $B_l\equiv 0$ for all l.

(b) $H_\xi^2+H_\eta^2$ must reduce to the external field H_a^2 when $\xi\to\infty$. As shown in Appendix IV, this condition requires that

$$V_0\underset{\xi\to\infty}{\longrightarrow} j\omega\mu a^2(1-\eta^2)(1+\xi^2)H_a/2.$$

Since

$$Q_l(j\xi)\underset{\xi\to\infty}{\longrightarrow}0 \quad\text{and}\quad P_l(j\xi)\underset{\xi\to\infty}{\longrightarrow}\infty,$$

$$\sum_{l=0}^{\infty}\left[A_l\frac{d}{d\eta}P_l(\eta)\right]\left[C_l\frac{d}{d\xi}P_l(j\xi)\right]$$

may enter into the solution only as a constant. Hence $C_l\equiv 0$ for $l>1$.

(c) Symmetry considerations demand that $V(\xi,+|\eta|)=V(\xi,-|\eta|)$. Hence the solution may contain only even powers of η and $A_l\equiv 0$ for $l=2n$, where $n=0, 1, 2, \cdots$.

Thus the solution for V outside the spheroid reduces to

$$V_0=(1-\eta^2)(1+\xi^2)\left[\frac{j\omega\mu a^2}{2}H_a + \sum_{n=0}^{\infty}F_{2n+1}\frac{d}{d\eta}P_{2n+1}(\eta)\frac{d}{d\xi}Q_{2n+1}(j\xi)\right]. \tag{9}$$

Inside the conducting spheroid, the differential equation to be solved is of the form,

$$(1-x^2)d^2y/dx^2+[l(l+1)+k^2x^2]y=0. \tag{10}$$

A series solution in positive powers of x results in the recursion formula,

$$C_{s+2}=\frac{s(s+1)-l(l+1)}{(s+2)(s+1)}C_s-\frac{k^2}{(s+2)(s+1)}C_{s-2}. \tag{11}$$

The continuity of V at the surface requires that the solution contain only even powers of the independent variable. Hence

$$V_i=\sum_{n=0}^{\infty}G_{2n+1}\sum_s C_{2s}\eta^{2s}\sum_p C_{2p}(j\xi)^{2p}, \tag{12}$$

where the coefficients of (12) and (9) must be matched at the surface.[3]

CURRENT DISTRIBUTION ON A PERFECTLY CONDUCTING DISK

For a perfectly conducting spheroid, $V_i=0$. V must be continuous at the surface, $\xi=\xi_0$, for arbitrary values of η. This requires that

$$-j\mu\omega a^2H_a/2 = \left[\sum_{n=0}^{\infty}F_{2n+1}\frac{d}{d\eta}P_{2n+1}(\eta)\frac{d}{d\xi}Q_{2n+1}(j\xi)\right]_{\xi=\xi_0}. \tag{13}$$

This relation can hold only for $n=0$. Hence $F_{2n+1}\equiv 0$ for $n\neq 0$ giving

$$-j\mu\omega a^2H_a/2=F_1[\cot^{-1}\xi-\xi/(1+\xi^2)]_{\xi=\xi_0}. \tag{14}$$

The spheroid reduces to a thin disk as $\xi\to 0$. In that case (14) yields $F_1=-j\mu\omega a^2H_a/\pi$ and

$$V_0=j(1-\eta^2)(1+\xi^2)\omega\mu a^2H_a \times\{1-2/\pi[\cot^{-1}\xi-\xi/(1+\xi^2)]\}/2. \tag{15}$$

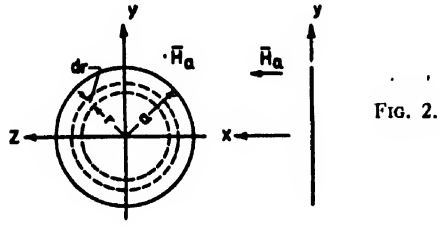

FIG. 2.

[3] Extensive treatment of this type of solution is given by R. C. Maclaurin, Trans. Camb. Phil. Soc. 17, 41-108 (1899).

The surface current density distribution is evaluated from the discontinuity in the tangential component of $\bar{H}$ at the double layer obtained when $\xi \to 0$. Using the relation (5b), the surface current density, i_φ, is

$$i_\varphi = 2[H_\eta|_{\xi=0}] = \frac{2j}{\mu\omega h_1 h_3}\frac{\partial V_0}{\partial \xi}\bigg|_{\xi=0}. \tag{16}$$

When the values of the metric coefficients are substituted, (16) reduces to

$$-i_\varphi = [4a(1-\eta^2)H_a/\pi\eta r]_{\xi=0}. \tag{17}$$

However $(1-\eta^2)/\eta \xrightarrow[\xi\to 0]{} r^2/a(a^2-r^2)^{\frac{1}{2}}$, resulting in the final simple expression,[4]

$$-i_\varphi = 4H_a r/\pi(a^2-r^2)^{\frac{1}{2}}. \tag{18}$$

PART II

The circulating current, I, flowing in the ring element of Fig. 2 is given by

$$I = i_\varphi dr = -4H_a r dr/\pi(a^2-r^2)^{\frac{1}{2}}. \tag{19}$$

The effect of this circulating current may be represented by an elementary magnetic dipole, defined by

$$dm = \pi r^2 I = -4H_a r^3 dr(a^2-r^2)^{-\frac{1}{2}}. \tag{20}$$

Integration over the face of the disk [Dwight 323.01] then provides an expression for a magnetic dipole equivalent to the entire current distribution.

$$m = -(8/3)a^3 H_a. \tag{21}$$

A three dimensional array of thin conducting disks is illustrated in Fig. 3. If the number of disks per unit volume is small enough to neglect interaction between them, the magnetization of the composite medium is given simply by

$$M = Nm. \tag{22}$$

N is the number of disks per unit volume and m is given by (21). Since the ratio of the magnetization, M, to the applied field, H_a, is defined as the magnetic susceptibility x_m,

$$x_m = M/H_a = -8Na^3/3. \tag{23}$$

The negative susceptibility of (23) is a characteristic of diamagnetic media. The relative permeability is then evaluated from the relation,

$$k_m = 1 + x_m = 1 - 8Na^3/3. \tag{24}$$

The positive definite form of the expression for the energy stored in the magnetic field does not permit k_m to be negative. This limitation is implicit in the assumption that N is small.

Up to this point the obvious anisotropy of the composite medium has not been mentioned. For the cartesian coordinates shown in Fig. 3, (24) holds for an applied magnetic field in the x direction, normal to the disk faces. In directions parallel to the disk faces, the thin disks do not disturb the applied field and $k_{my} = k_{mz} = 1$. Thus the constituitive equations for the magnetic vectors take the form,

$$\begin{bmatrix} B_x \\ B_y \\ B_z \end{bmatrix} = \mu_0 \begin{bmatrix} 1-8Na^3/3 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} H_x \\ H_y \\ H_z \end{bmatrix}. \tag{25}$$

The electric susceptibility, x_e, for this type of array has previously been evaluated for the case of an external electric field parallel to the disk faces,[5] yielding

$$x_e = 16Na^3/3. \tag{26}$$

When the anisotropy is considered, the constituitive equations for the electric vectors become

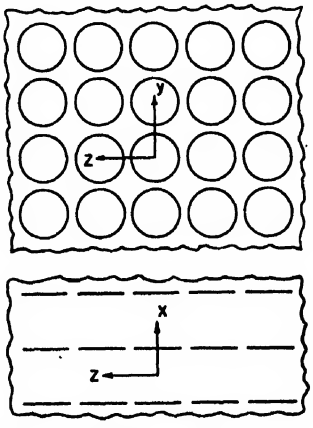

FIG. 3.

$$\begin{bmatrix} D_x \\ D_y \\ D_z \end{bmatrix} = \epsilon_0 \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1+16Na^3/3 & 0 \\ 0 & 0 & 1+16Na^3/3 \end{bmatrix} \begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix}. \tag{27}$$

The relations in (25) and (27) now completely specify the characteristics of the composite medium, which was originally developed for use in focusing microwaves. Past analyses of this medium have assumed normal incidence of a plane wave, thereby neglecting the anisotropic characteristics. These results now permit extension to the case of oblique incidence.

A typical value for the relative dielectric constant in arrays designed for microwave lenses is $k_e = 2.25$. The constituitive equations for this case then become:

$$\begin{bmatrix} D_x \\ D_y \\ D_z \end{bmatrix} = \epsilon_0 \begin{bmatrix} 1 & 0 & 0 \\ 0 & 2.25 & 0 \\ 0 & 0 & 2.25 \end{bmatrix} \begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix}. \tag{28a}$$

$$\begin{bmatrix} B_x \\ B_y \\ B_z \end{bmatrix} = \mu_0 \begin{bmatrix} 0.375 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} H_x \\ H_y \\ H_z \end{bmatrix}. \tag{28b}$$

An experimental prism, constructed at the University of

[4] This result differs by a factor of 2 from that reported by M. Marc Jouguet in an abstract in Comptes Rendus 216, 523 April, 1943. The discrepancy is apparently due to his neglect of the double layer of surface current on the disk.

[5] W. E. Kock, "Metallic delay lenses," Bell Sys. Tech. J. 27, 58 (January, 1948).

Wisconsin displays the following characteristics:

$$\begin{bmatrix} D_x \\ D_y \\ D_z \end{bmatrix} = \epsilon_0 \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1.21 & 0 \\ 0 & 0 & 1.21 \end{bmatrix} \begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix}. \quad (29a)$$

$$\begin{bmatrix} B_x \\ B_y \\ B_z \end{bmatrix} = \mu_0 \begin{bmatrix} 0.895 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} H_x \\ H_y \\ H_z \end{bmatrix}. \quad (29b)$$

ACKNOWLEDGMENT

The author would like to acknowledge the support given to this research project by the Radio Corporation of America since July, 1949 and by the Wisconsin Alumni Research Foundation from February, 1948 to June, 1949. In addition the author is indebted to the guidance of Professor V. C. Rideout of the University of Wisconsin Electrical Engineering Department.

APPENDIX I

Oblate spheroidal coordinates are defined by the following relations:

$$y = r\cos\varphi; \quad z = r\sin\varphi, \quad (1a)$$

$$\frac{x^2}{a^2\xi^2} + \frac{r^2}{a^2(1+\xi^2)} = 1 \quad (0 \leq \xi \leq \infty), \quad (1b)$$

$$\frac{x^2}{-a^2\eta^2} + \frac{r^2}{a^2(1-\eta^2)} = 1 \quad (-1 \leq \eta \leq +1), \quad (1c)$$

ξ = constant describes a family of confocal oblate spheroids where (2a) is the distance between the foci in any plane through the x-axis. η = constant describes a family of confocal hyperboloids of one sheet, orthogonal to the spheroids. φ measures the azimuth angle in the meridian plane.

An element of arc length in this system is given by:

$$\begin{aligned} (ds)^2 &= h_1^2(d\xi)^2 + h_2^2(d\eta)^2 + h_3^2(d\varphi)^2, \\ h_1 &= a(\xi^2+\eta^2)^{\frac{1}{2}}(1+\xi^2)^{-\frac{1}{2}}, \\ h_2 &= a(\xi^2+\eta^2)^{\frac{1}{2}}(1-\eta^2)^{-\frac{1}{2}}, \\ h_3 &= r = a[(1+\xi^2)(1-\eta^2)]^{\frac{1}{2}}. \end{aligned} \quad (2)$$

If the field vectors have no φ dependence, the component field equations are given by (2) of Part I along with the following:

$$\partial(h_3H_\varphi)/\partial\eta - h_2h_3\sigma E_\xi = 0, \quad (3a)$$

$$\partial(h_3H_\varphi)/\partial\xi + h_1h_3\sigma E_\eta = 0, \quad (3b)$$

$$\partial(h_2E_\eta)/\partial\xi - \partial(h_1E_\xi)/\partial\eta - j\omega\mu h_1h_2H_\varphi = 0. \quad (3c)$$

APPENDIX II

In (5c) of Part I, substitution of the metric coefficients gives

$$\frac{\partial}{\partial\xi}\left(\frac{1}{a(1-\eta^2)}\frac{\partial V}{\partial\xi}\right) + \frac{\partial}{\partial\eta}\left(\frac{1}{a(1+\xi^2)}\frac{\partial V}{\partial\eta}\right) + j\omega\sigma\mu a\left(\frac{\xi^2+\eta^2}{(1+\xi^2)(1-\eta^2)}\right)V = 0. \quad (1)$$

Let $V = V_1(\xi)V_2(\eta)$ and multiply through by $a(1-\eta^2)(1+\xi^2)/V_1V_2$.

$$\frac{(1+\xi^2)}{V_1}\frac{d^2V_1}{d\xi^2} + \frac{(1-\eta^2)}{V_2}\frac{d^2V_2}{d\eta^2} + ja^2\omega\mu\sigma(\xi^2+\eta^2) = 0. \quad (2)$$

Introducing the separation constant D, and making the substitutions, $\xi' = j\xi$ and $k^2 = j\omega\sigma\mu a^2$ gives

$$(1-\eta^2)d^2V_2/d\eta^2 + (k^2\eta^2+D)V_2 = 0, \quad (3a)$$

$$(1-\xi'^2)d^2V_1/d\xi'^2 + (k^2\xi'^2+D)V_1 = 0. \quad (3b)$$

APPENDIX III

Outside the spheroid,

$$(1-x^2)d^2y/dx^2 + Dy = 0. \quad (1)$$

Consider the equation satisfied by the Legendre Polynomials, $P_l(x)$.

$$(1-x^2)d^2y/dx^2 - 2xdy/dx + l(l+1)y = 0 \quad (2)$$

Differentiate (2) with respect to x and substitute $y = P_l(x)$.

$$(1-x^2)d^2/dx^2[d/dxP_l(x)] - 4xd/dx[d/dxP_l(x)] + [l(l+1)-2][d/dxP_l(x)] = 0. \quad (3)$$

Try the solution $d[P_l(x)]/dx = (1-x^2)^{-r}y$ in (3) and multiply through by $(1-x^2)^r$. This results in

$$(1-x^2)d^2y/dx^2 + 4x(r-1)dy/dx + \{(1-x^2)^{-1}[4x^2r(r-1)] + l(l+1) + 2(r-1)\}y = 0. \quad (4)$$

Let $r = 1$ in (4) giving

$$(1-x^2)d^2y/dx^2 + l(l+1) = 0. \quad (5)$$

Hence $y = (1-x^2)d[P_l(x)]/dx$ is a solution of (1).

A similar procedure shows that $y = (1-x^2)d[Q_l(x)]/dx$ is also a solution.

APPENDIX IV

From (5a, 5b) of Part I and the relation $\partial V/\partial\eta = (\partial V/\partial r)(\partial r/\partial\eta)$,

$$[H_\xi^2 + H_\eta^2] = -1/\omega^2\mu^2r^2[1/h_2^2(\partial r/\partial\eta)^2 + 1/h_1^2(\partial r/\partial\xi)^2](\partial V/\partial r)^2. \quad (1)$$

Introducing the expressions for the metric coefficients given in Appendix I, (1) reduces to

$$[H_\xi^2 + H_\eta^2] = -1/\omega^2\mu^2r^2(\partial V/\partial r)^2. \quad (2)$$

Hence[6]

$$\partial V/\partial r \xrightarrow[\xi\to\infty]{} j\omega\mu rH_\varphi$$

resulting in

$$V_0 \xrightarrow[\xi\to\infty]{} j\omega\mu a^2H_\varphi/2 = j\omega\mu a^2(1-\eta^2)(1+\xi^2)H_\varphi/2. \quad (3)$$

[6] Physical consideration of the final direction of induced current demands the positive root.

Stress Analysis for Compressible Viscoelastic Materials

W. T. Read, Jr.
Bell Telephone Laboratories, Murray Hill, New Jersey
(Received January 11, 1950)

Mathematical methods of stress analysis are presented for linear, compressible, viscoelastic, or anelastic, materials such as metals at high temperatures or high polymers with small strains. For such materials stress, strain and their time derivatives of all orders are related by linear equations with coefficients which are material constants. Fourier integral methods are used to show that static elasticity solutions can be used to determine the time dependent stresses in viscoelastic bodies with any form of boundary conditions.

If stress and double refraction and their time derivatives are also linearly related, the standard photoelastic techniques can be used to determine the directions and difference in magnitude of the time dependent principal stresses, even though the principal stress axes do not coincide with the polarizing axes and both vary with time. When viscoelastic models are used in photoelastic studies, the time variation of the stress distribution in the model represents a first approximation to the dependence of the stress in the elastic prototype on Poisson's ratio.

INTRODUCTION

MANY efforts have been made to extend the standard methods of stress analysis to non-elastic materials. One approach has been to consider the general linear solid, defined as a material in which the stress-strain behavior can be represented by linear relations involving not only stress and strain but also their time derivatives of all orders. An elastic material represents the special case of a linear material in which the time derivatives can be neglected for the range of frequencies involved. Phenomena which are linear but time dependent have been called "viscoelastic" in the case of high polymers[1] and "anelastic" in the case of metals.[2] It has been shown that both the solutions of problems in elasticity and the standard photoelastic techniques can be applied to a linear incompressible solid when the forces and displacements given on the boundary vary uniformly with time and slowly enough that inertial effects can be neglected.[3,4] The present paper extends these results to the general, compressible, linear solid with any form of boundary conditions. The analysis makes use of the standard Fourier integral and operator methods. For simplicity the derivation considers only isotropic materials, but the results are readily generalized to the anisotropic case.

1. STRESS-STRAIN RELATIONS

In this section we show by use of Fourier integral methods that the time dependent stress-strain relations for the general linear solid can be transformed to static relations between the Fourier transforms of stress and strain, these relations having the same form as the elastic stress-strain relations except that the elastic constants are complex functions of frequency, readily determined from a simple tension test. We shall follow the conventional engineering notation, using σ's and ϵ's for normal components of stress and strain respectively and τ's and γ's for shearing components.

The most general linear isotropic stress-strain relations can be expressed in terms of three linear differential operators H, K and L by

$$H(\partial)/(\partial t)\sigma_x = K(\partial)/(\partial t)e + 2L(\partial)/(\partial t)\epsilon_x, \quad (1.1)$$

$$H(\partial)/(\partial t)\tau_{xy} = L(\partial)/(\partial t)\gamma_{xy} \quad (1.2)$$

where $e = \epsilon_x + \epsilon_y + \epsilon_z$ with four similar relations obtain by rotating subscripts. The operators have the form

$$H(\partial)/(\partial t) = H_0 + H_1(\partial/\partial t) + H_2(\partial^2)/(\partial t^2)\cdots H_n(\partial^n)/(\partial t^n)\cdots \quad (1.3)$$

the coefficients being constants of the material. By operating on (1.1) and (1.2) with $[1/H(\partial)/(\partial t)]$, the relations involve only two linear integro-differential operators and have the same form as in the elastic case, the two operators replacing the two independent elastic constants λ and G.

The number of terms in the operators required to adequately represent the stress-strain relation depends on the material. In general an infinite number will be required for an exact representation. It is customary to represent the solid by a mechanical model consisting of springs and dashpots having constants which determine the constants in the stress-strain relations. However, when many derivatives are required in the stress-strain relations, it is not practical to determine the operators. In the general case a more practical approach is to determine two complex elastic constants $G(i\omega)$ and $\lambda(i\omega)$ which are functions of frequency ω and may be determined from a simple experiment and used to express the stress-strain relations in the following way: We represent the time dependence of $\tau_{xy} = \tau_{xy}(t)$ by a Fourier integral

$$\tau_{xy}(t) = \int_{-\infty}^{\infty} \tau_{xy}(\omega) e^{i\omega t} d\omega, \quad (1.4)$$

[4] R. D. Mindlin, "A mathematical theory of photo-viscoelasticity," J. App. Phys. 20, 206 (1949).

where

$$\bar{\tau}_{xy}(\omega)=\frac{1}{2\pi}\int_{-\infty}^{\infty}\tau_{xy}(t)e^{-i\omega t}dt \tag{1.5}$$

is the Fourier transform of $\tau_{xy}(t)$. Expressing γ_{xy} also as a Fourier integral, substituting into (1.2), and considering that the relation must hold for all values of time, we have

$$\bar{\tau}_{xy}(\omega)=G(i\omega)\bar{\gamma}_{xy}(\omega), \tag{1.6}$$

where $\bar{\gamma}_{xy}(\omega)$ is the Fourier transform of $\gamma_{xy}(t)$, and the complex modulus

$$G(i\omega)=\frac{L(\partial)/(\partial t)e^{i\omega t}}{H(\partial)/(\partial t)e^{i\omega t}}=\frac{L(i\omega)}{H(i\omega)}. \tag{1.7}$$

Defining another complex modulus,

$$\lambda(i\omega)=[K(i\omega)]/[H(i\omega)], \tag{1.8}$$

the relation (1.1) is transformed to

$$\bar{\sigma}_x(\omega)=\lambda(i\omega)\bar{e}(\omega)+2G(i\omega)\bar{e}_x(\omega), \tag{1.9}$$

where as before the bars denote Fourier transforms. Thus the time dependent stress-strain relations (1.1) and (1.2) are replaced by static relations between the Fourier transforms of stress and strain. The stress-strain relations can also be stated in terms of the complex Young's modulus and Poisson's ratio $E(i\omega)$ and $\nu(i\omega)$, which are related to $\lambda(i\omega)$ and $G(i\omega)$ by the same relations as in the elastic case. For an experimental determination of the two complex elastic constants, it is convenient to perform a simple tension test in which the tension $\sigma_x(t)$ varies with time in any convenient manner. By measuring the strain $e_x(t)$ along, and $e_y(t)$ at right angles to the tension, and taking the Fourier transforms of the three known functions of time, we can calculate

$$E(i\omega)=[\bar{\sigma}_x(\omega)]/[\bar{e}_x(\omega)]$$

and

$$\nu(i\omega)=-[\bar{e}_y(\omega)]/[\bar{e}_x(\omega)]. \tag{1.10}$$

For an anisotropic material the same results hold except that additional complex elastic constants are required.

2. DIFFERENTIAL EQUATIONS AND BOUNDARY CONDITIONS

The differential equations, to be satisfied are the compatibility equations for the strains and the equilibrium equations, which involve the stresses, body forces and inertial terms. Whether we formulate the problem in terms of stress or displacement, we obtain equations which are the same as in the elastic case except that the elastic constants λ and G are replaced by the corresponding operators

$$\frac{K(\partial)/(\partial t)}{H(\partial)/(\partial t)} \quad \text{and} \quad \frac{L(\partial)/(\partial t)}{H(\partial)/(\partial t)}.$$

These equations can be treated in the same way as the stress-strain relations, all quantities including the body forces being expressed as Fourier integrals. This gives equations for the Fourier transforms which are the same as the static elasticity equations except that the elastic constants are replaced by the complex functions of frequency $\lambda(i\omega)$ and $G(i\omega)$. The boundary conditions on the Fourier transforms are the Fourier transforms of the actual time dependent boundary conditions. Thus every stress analysis problem involving the general linear solid can be reduced to a static elasticity problem and the extensive known solutions of elasticity used. When the Fourier transforms have been obtained, by substituting complex elastic constants and boundary values into the elasticity solution, the actual time dependent solution is obtained from the Fourier transforms, using relations of the form (1.4).

3. SPECIAL CASES AND APPROXIMATIONS

In this section we assume that inertial effects and body forces can be neglected, and that the boundary conditions vary uniformly with time. Let the time dependence of the applied forces and displacements be given by an arbitrary function $F(t)$. If the static elasticity solution for $F(t)=\text{constant}=\text{unity}$ is $S_e[x, y, z, \lambda, G]$, then the solution for the general linear solid is

$$S(x, y, z, t)$$

$$=\int_{-\infty}^{\infty}\bar{F}(\omega)S_e[x, y, z, \lambda(i\omega), G(i\omega)]e^{i\omega t}d\omega, \tag{3.1}$$

where

$$\bar{F}(\omega)=\int_{-\infty}^{\infty}F(t)e^{-i\omega t}dt \tag{3.2}$$

is the Fourier transform of $F(t)$, and S may be any component of stress, strain or displacement. When $S_e[x, y, z, \lambda, G]$ is a rational algebraic function of λ and G, Eq. (3.1) can be transformed to the operator equation

$$S(x, y, z, t)$$

$$=S_e\left[x, y, z, \frac{L(\partial)/(\partial t)}{H(\partial)/(\partial t)}, \frac{K(\partial)/(\partial t)}{H(\partial)/(\partial t)}\right]F(t). \tag{3.3}$$

Thus in problems of this type, which include the greater part of practical cases, the procedure is to replace the elastic constants in the elasticity solution for $F(t)=1$ by the corresponding operators. The elasticity solution in operator form acting on the actual $F(t)$ then gives the time dependent solution for the general linear solid. Since the operators are rational algebraic functions of $\partial/\partial t$, the solution can be expressed as a sum of partial fractions of the form

$$\frac{1}{\beta+(\partial/\partial t)}F(t)=e^{-\beta t}\int_{-\infty}^{t}e^{\beta t'}F(t')dt'. \tag{3.4}$$

In cases where the operators are known this is frequently the most practical method of solution.

When the elasticity solution involves only the ratio of elastic moduli, conveniently expressed by the dimensionless quantity ν, special methods and simple approximate procedures can be used. For example, if loads are suddenly applied and held constant, the initial state of stress will be the same as that in an elastic body with Poisson's ratio equal to the Poisson's ratio of the instantaneous elastic response. Then, if the loads are held constant until a steady state is reached, the state of stress approaches that in an elastic body having the Poisson's ratio characteristic of the steady state. This suggests that a general linear solid is equivalent to an elastic solid with a time variable Poisson's ratio. To show that this is true to a first approximation, we expand the static elasticity solution $S_e[x, y, z, \nu]$, for $F(t)=1$, in a Taylor's series about some average value of ν. Then, using a relation of the form (3.1) and neglecting second and higher order terms in the Taylor's series, we find

$$S[x, y, z, t]=S_e[x, y, z, \nu(t)]F(t), \qquad (3.5)$$

where $\nu(t)$ is determined in terms of $F(t)$ by a simple tension test in which the strain e_x in the direction of tension is $F(t)$, and $\nu(t)=-e_y(t)/F(t)$, $e_y(t)$ being measured at right angles to the tension Equation (3.5) gives a first approximation to the time variation of the solution, and is exact in the special case where $\nu(t)$ = constant. The incompressible case is a special case of this special case, and corresponds to $\nu(t)=\frac{1}{2}$.

Another simple case occurs in problems of plane strain where the boundary conditions are on stress and there is no resultant force on an internal boundary; then the elasticity solution for the stress distribution is independent of the elastic constants, and the stress distribution in the general case is $F(t)$ times the static elasticity solution.

4. OPTICAL METHODS

In this section we consider transparent materials in which the stress-optical relations are of the same form as the stress-strain relations, and can be expressed by linear differential equations with constant coefficients. Although operator methods are used in the derivation, the parallel Fourier integral treatment is evident. It is also known that the standard techniques used in photoelasticity can be employed to determine the directions of the secondary principal axes of stress in the plane of the wave front and the secondary principal stress difference. No restrictions on the boundary conditions are involved.

The stress optical effect involves the relation between the stress and velocity tensors, the latter being simply related to the dielectric constant tensor.* We let V_{xx}, V_{xy}, $\cdots V_{zz}$ be the components of the velocity tensor. Since this tensor is symmetric, it can be represented by an ellipsoid, called the velocity ellipsoid, which provides a graphic means of describing the polarizing axes and wave velocities for plane polarized light. If the xy plane is the plane of the wave front, then the polarizing axes are the axes of the ellipse formed by the trace of the ellipsoid in the xy plane and the wave velocities, V_1 and V_2, are inversely proportional to the squares of the major and minor axes of the ellipse. The standard photoelastic techniques give the difference V_1-V_2 and the angle φ between the polarizing axes and the fixed x and y axes. The difference $V_{xx}-V_{yy}$ is given by the tensor relation

$$V_{xx}-V_{yy}=(V_1-V_2)\cos 2\varphi, \qquad (4.1)$$

where all quantities vary with both time and position in the specimen.

For an isotropic viscoelastic material the most general linear differential equations for the time dependence of the stress-optical effect give

$$X(\sigma_x-\sigma_y)=Y(V_{xx}-V_{yy}), \qquad (4.2)$$

where X and Y are linear differential operators which may have any number of terms. Combining (4.1) and (4.2) gives

$$\sigma_x-\sigma_y=\frac{Y}{X}(V_1-V_2)\cos 2\varphi, \qquad (4.3)$$

from which the stress difference $\sigma_x-\sigma_y$ can be calculated as a function of time for all points, where V_1-V_2 and φ have been measured.

The choice of the fixed axes x and y is arbitrary. The stress difference $\sigma_x'-\sigma_y'$ referred to axes x' and y' at an angle θ to the x and y axes is given by (4.3) with φ replaced by $\varphi-\theta$. Maximizing this with respect to θ gives the secondary principal stress difference in the plane of the wave front, the value of θ giving the direction of the secondary principal axes. Thus, as in photoelasticity, the optical measurements give the directions and difference in magnitude of the secondary principal stresses. In the general viscoelastic case the principal axes of stress are not parallel to the polarizing axes.

In the special cases of Section 3 where the state of stress is known to be the same as the stress in an elastic body, (4.3) takes the simple form

$$\sigma_1-\sigma_2=K(t)(V_1-V_2), \qquad (4.4)$$

where

$$K(t)=\frac{1}{F(t)}\frac{Y}{X}F(t)$$

and σ_1 and σ_2 are the secondary principal stresses and

* The principal axes of the velocity tensor coincide with the principal axes of the dielectric constant tensor and the principal velocities are inversely proportional to the square roots of the principal dielectric constants: G. Joos, *Theoretical Physics* (G. E. Stechert and Company, New York, 1934), p. 349.

act in the directions of the polarizing axes. A simple tension experiment gives $K(t)$.

When viscoelastic materials are used for models in optical stress studies, and the Poisson's ratio has been measured for the instantaneous elastic deformation under constant load and also for the final steady state deformation, then the photoelastic analysis gives the stress distribution in the elastic prototype for two values of Poisson's ratio. As was discussed in the last section, the intermediate stress distributions are the first approximations to the stresses in an elastic prototype with a time variable Poisson's ratio. The viscoelastic model therefore gives information about the dependence of the stress distribution on Poisson's ratio.

Electrolytic-Tank Measurements for Microwave Metallic Delay-Lens Media*

SEYMOUR B. COHN
Sperry Gyroscope Company, Great Neck, New York
(Received December 15, 1949)

In this paper it is shown how the low frequency index of refraction of a metallic delay-lens medium may be calculated from electrolytic-tank measurements on individual metallic elements of the medium. The proximity between adjacent elements is taken exactly into account for low frequencies. The test apparatus is described, and measured results are presented for three kinds of delay-lens structures.

I. INTRODUCTION

IT has been shown by W. E. Kock that an array of discrete metallic obstacles in free space (Fig. 1) has an index of refraction greater than unity, and hence is a suitable lens medium for microwaves.[1] In his article Kock gives approximate index-of-refraction formulas, surface-shape relations, and practical methods of construction.

Kock's analysis for thin-strip and thin-circular-disk obstacles assumes the dimensions of the obstacles to be small compared to their spacings. Because of this assumption, substantial errors exist in practical delay-lens media for which rather close spacings are required in order to obtain a reasonably high index of refraction. In the case of the metallic-strip structure, the writer has presented accurate theoretical relations and graphs for the index of refraction and image admittance with proximity between the strips and the effect of frequency taken into account.[2] For other obstacle shapes an exact theoretical solution appears to be exceedingly difficult, and therefore experimental methods of acquiring index-of-refraction data are necessary. One possible method calls for direct index-of-refraction measurements in the microwave range on delay-medium samples. Another method, which is described in this paper, utilizes indirect measurement of the capacitance of individual obstacles with the aid of an electrolytic-tank analogy. Since promixity is taken fully into account, the index of refraction computed with the electrolytic-tank analogy is exact if the wave-length is much greater than the size and spacing of the obstacles.

The writer has shown how the problem of a metal-strip delay-lens medium may be reduced to that of a parallel-plane transmission line containing uniformly spaced obstacles, and has given formulas by which the parameters of the medium may be calculated from the equivalent circuit of the transmission line.[2] The same

reduction may be made with many other kinds of delay-lens media (for example, those of Fig. 1) and the same formulas apply. The purpose of the electrolytic-tank measurements is to provide quantitative values of the shunt capacitance introduced by each obstacle in the equivalent circuit.

II. THE EQUIVALENT CIRCUIT

The procedure by which an equivalent transmission line may be obtained for the two configurations of Fig. 1 will now be explained. Assume a plane wave in

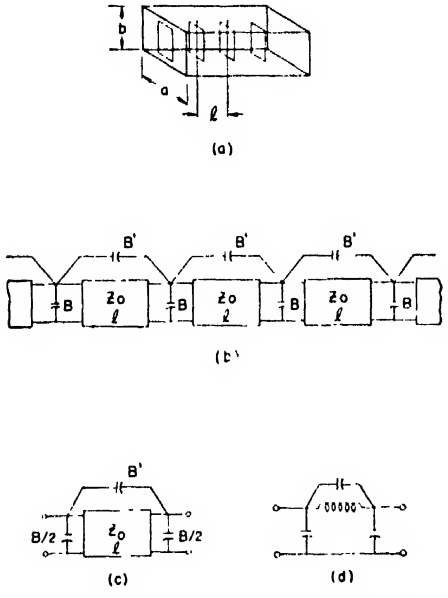

FIG. 2. Equivalent circuit of obstacles in a parallel-plane line.

the medium traveling in the z direction with the average electrical polarization in the y direction. Then with no disturbance to the electromagnetic field, thin "electric" walls may be inserted horizontally in planes y_1, y_2, $y_3 \cdots$ and thin "magnetic" walls vertically in planes x_1, x_2, $x_3 \cdots$ (an electric wall is a conducting sheet, while a magnetic wall is a hypothetical surface on which only tangential-electric and normal-magnetic field components can exist. Such a surface does not occur in nature, but is a useful tool for theoretical analysis). In this way a single channel through the medium such as that in Fig. 2a has been isolated. Since the top and bottom surfaces are conductors while the sides are nonconductors, the channel is in reality a parallel-plane transmission line shunted at uniform spacings by capacitive metallic obstacles. The wave velocity and the normalized image impedance of the transmission line is the same as that of the corresponding lens medium.

For the hexagonal distribution shown in Fig. 1b, the same procedure applies for obtaining the equivalent transmission line. Note that electric and magnetic planes may be passed through the center of each circular obstacle without altering the field, and hence a parallel-plane line having the cross-sectional dimensions $a/2$ and $b/2$ may be used.

The equivalent circuit for the basic transmission line of the metal-strip delay medium has been found in reference 2 to be that of Fig. 2b. The shunt capacitive susceptances represent the shunting effect of the obstacles in the transmission line, while the bridging capacitive susceptances B' represent a proximity effect between adjacent obstacles in the line. Proximity effects between nonadjacent obstacles are neglected, since they are not believed to be of appreciable magnitude in delay-media computations. A second effect of proximity is a reduction in the magnitude of B. Experience with the metal-strip medium has shown that B' is negligible when the obstacle spacing l is large enough to make B constant. This condition occurs for l/b greater than approximately 0.75.

The boxes in Fig. 2b represent sections of transmission line of length l and characteristic impedance Z_0. A single section of the line is shown in Fig. 2c. When the Pi equivalent circuit of the length l of uniform line is substituted for the box and combined with the obstacle susceptances, one obtains the circuit shown in Fig. 2d, which may be recognized as an m-derived low pass filter section. Consequently, the delay lens may be expected to transmit waves freely up to a definite cut-off frequency and to have an opaque band above that. For lens applications only the band below this cut-off frequency is useful, and all discussion in this paper will be limited to this range. Even within this range, however, the capacitances and inductances of the equivalent circuit are not constants, but vary somewhat with frequency.

Note in Fig. 2d that the bridging susceptance B' is shunted by an inductive element. At low frequencies B' is almost zero while the inductive susceptance is very large, and therefore it may be seen that B' can have no effect on the low frequency behavior of the delay medium. Consequently, the electrolytic-tank method can give precise values of the index of refraction at low frequencies even though it is incapable of measuring B'.

The formulas for the index of refraction and image

admittance for the case of B' negligible are:[2]

$$\eta=\frac{\lambda}{2\pi l}\cos^{-1}\left(\cos\frac{2\pi l}{\lambda}-\frac{B}{2Y_0}\sin\frac{2\pi l}{\lambda}\right), \tag{1}$$

$$y_I=\frac{Y_I}{Y_0}=\left[1+(B/Y_0)\cot\frac{2\pi l}{\lambda}-(B/2Y_0)^2\right]^{\frac{1}{2}}, \tag{2}$$

where η is the index of refraction, λ the wave-length in free space, Y_0 the characteristic admittance of the parallel-plane transmission line, Y_I the image admittance of the line loaded by the obstacles, y_I the normalized image admittance, and l the spacing shown in Fig. 1. Equations (1) and (2) are correct only for a plane wave traveling normal to the obstacle planes. The surfaces of the lens should therefore be shaped in a given application so as to obtain this condition inside the lens. For this purpose, the index of refraction given by Eq. (1) may be correctly used with Snell's law of refraction. This was done by Kock in deriving his lens-surface formula for a "pencil-beam" lens.[1]

Figure 3 shows a sketch of η and y_I. Note that at low frequencies these functions are essentially constant and equal to each other. At higher frequencies η bends upward and y_I downward. When B' is neglected they bend less sharply than when it is taken into account. The limiting value of η and y_I at zero frequency is given by

$$\eta_0=y_{I0}=(1+B\lambda/2\pi lY_0)^{\frac{1}{2}}. \tag{3}$$

Since the construction and test of microwave delay-lens models are difficult and expensive, a static method of obtaining the lens parameters is desirable, even though it is accurate only at a low enough frequency or for a large enough l/b ratio so that B' is negligible. Direct measurements on a single obstacle are impossible in free space, since the necessary magnetic-wall boundary conditions are physically nonrealizable. Such measurements are feasible in an electrolytic tank, however, as will be apparent from the following discussion.

III. PRINCIPLE OF THE ELECTROLYTIC-TANK METHOD

If a static potential is impressed between two conductors, the electric field lines will follow the same paths whether the conductors are immersed in free space or in a conducting solution. In Fig. 4 the analogy between various free-space quantities and electrolytic-tank quantities is brought out. The electric field and the potential in space are analogous to the same quantities in the tank, the displacement flux $D=\epsilon E$ in space is analogous to the current density $i=\sigma E$ in the tank, the charge on a conducting surface in space is analogous to the total current flowing through the surface in the tank, and the capacitance between two surfaces in space is analogous to the conductance between surfaces in the tank. In addition, an electric wall in space is the analog of a conducting wall in the tank, while a magnetic wall in space is the analog of a non-conducting wall in the tank. The latter point is of extreme importance, since it shows that the boundary conditions for the equivalent transmission line may be correctly simulated in the tank, thus permitting a precise low frequency determination of the delay-medium parameters with proximity taken completely into account.

It will now be shown that it is only necessary to make measurements on a length $l/2$ of the transmission line in order to determine B correctly. Consider a static potential impressed between the top and bottom surfaces of the line of Fig. 2a. Then without disturbing

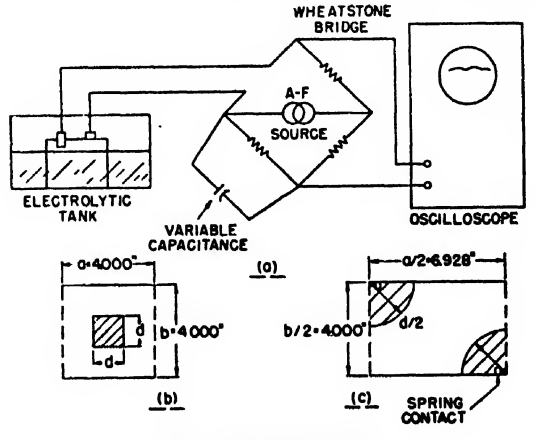

FIG. 5. Test equipment.

the electric field, magnetic walls may be inserted across the line in the obstacle planes and also halfway between the obstacles. The cell in Fig. 4 shows the electrolytic analog of the space between two magnetic walls. The obstacle and the two vertical walls of length a are conductors. The two vertical walls of length b, the surface of the solution, and the bottom of the cell (except for the obstacle) are all non-conductors, simulating the magnetic walls of their free-space counterparts. In order to determine the capacitance of the obstacle, the conductance between the metallic sides

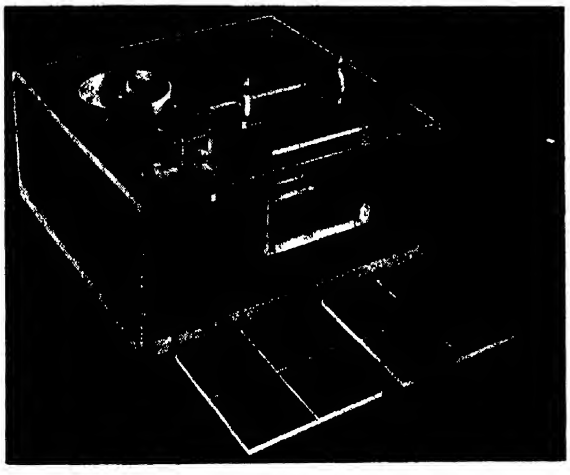

FIG. 6. Photograph of electrolytic-tank apparatus.

of the cell is measured with and without the obstacle present. The apparatus and techniques of the test will now be described.

IV. THE APPARATUS

Figure 5 shows a block diagram of the test equipment. The cell conductance is measured by means of a Wheatstone bridge. The arms of the bridge consist of precision decade resistance boxes having a range of 1 to 111,110 ohms in one-ohm steps. The signal source operates at 1000 cycles and has a balanced ungrounded output. The detector is a high gain oscilloscope. the variable capacitance across one of the bridge arms serves to balance out stray circuit capacitances and a small series reactance which occurs at the contact between electrolyte and metal. The sensitivity of the circuit is such that a change in a bridge arm of one part in five thousand is easily discernible.

Rhodium plating is used on all conducting surfaces in contact with the liquid, since rhodium is highly inactive chemically and electrolytically. The electrolyte is a dilute solution of potassium chloride in distilled water. The concentration was chosen so that measured resistances would lie in the range of about 1500 to 9000 ohms. These resistances are too low for stray shunt capacitances to cause significant error and too high for circuit resistance and inductance to affect the accuracy.

A photograph of the tank apparatus appears in Fig. 6. The tank is made of Lucite and has internal dimensions of 12×12×5 in. The cell, which has dimensions of 4×4×3 in., has four vertical Lucite walls and no top or bottom. One opposite pair of walls is rhodium plated on the inside, and terminals connect to each of these surfaces. The obstacles are cut from thin copper sheets 0.0015 in. thick and are rhodium plated and cemented onto Lucite plates. Grooves are cut in the Lucite on the opposite side so that the plates will flatten readily with pressure when in use. The coaxial cylinders shown in the photograph are used to calibrate the conductivity of the solution. Although it is theoretically possible to obtain this calibration with the cell with the obstacle removed, it has been found that small but not negligible leakage currents escape from the interior of the cell through the cracks between the cell and the bottom plate, thus adding an unknown but constant conductance to the readings with and without the obstacle in place. The coaxial cylinders are by nature self-shielding, and leakage currents cannot exist. Hence, they may be expected to provide an accurate conductivity calibration. A depth gauge is also visible in Fig. 6. By means of this, the height of the electrolyte may be measured to an accuracy of about 0.002 in.

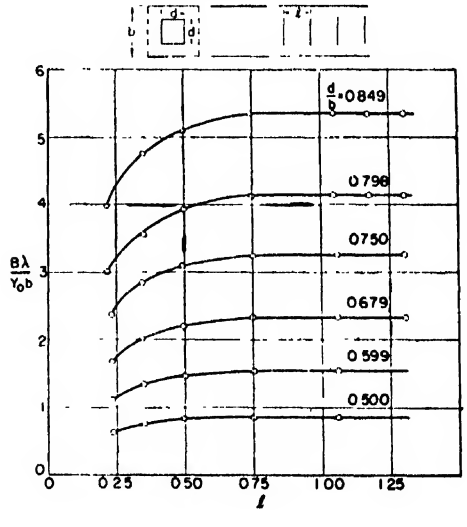

FIG. 7. Susceptance of thin square obstacles.

In performing a test, resistance measurements are made on the coaxial cylinders and on the cell with and without an obstacle in position. For the measurements without the obstacle, a blank Lucite plate having the same thickness as the obstacle plate is used in order to maintain a constant solution height. The susceptance of the obstacle may then be calculated from the following formula which is derived in the Appendix.

$$\frac{B\lambda}{Y_0 b} = \frac{4\pi h}{a}\left(\frac{376.6}{Z_{0\,\mathrm{coax}}}\right)\frac{R_3(R_2-R_1)}{R_1R_2}, \qquad (4)$$

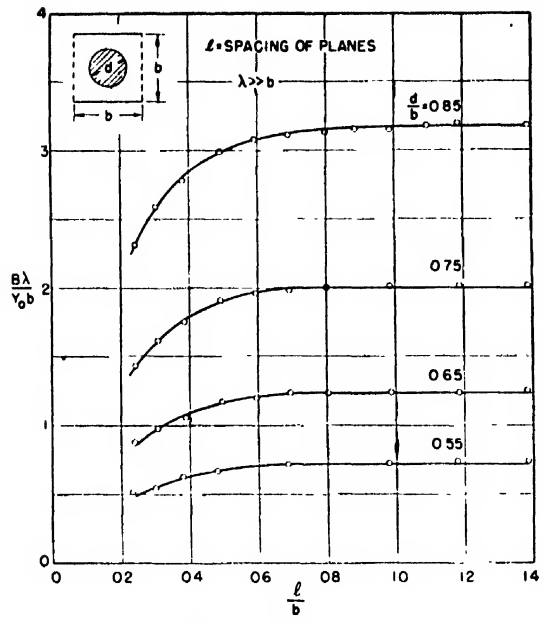

FIG. 8. Susceptance of thin circular obstacles, square distribution.

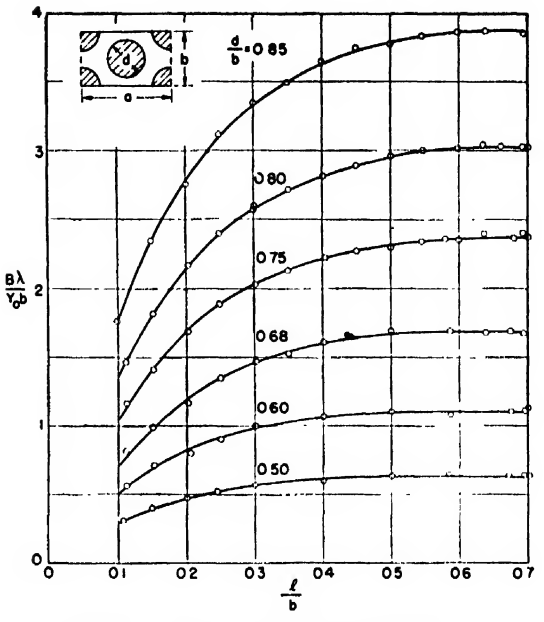

FIG. 9. Susceptance of thin circular obstacles, hexagonal distribution.

where B = shunt susceptance of obstacle ($=\omega C$); $Y_0 = 1/Z_0$ = characteristic admittance of parallel-plane line ($=a/376.6b$); λ = wave-length; b = distance between metal plates of line; a = width of metal plates; h = height of water ($=l/2$); $Z_{0\,coax}$ = characteristic impedance of coaxial cylinders ($=60 \ln r_2/r_1$); R_3 = resistance of coaxial cylinders; R_2 = resistance of cell without obstacle; R_1 = resistance of cell with obstacle.

Three kinds of configurations were measured, square obstacles having square distribution (Fig. 1a), circular obstacles having square distribution, and circular obstacles having hexagonal distribution (Fig. 1b). A top view of the cell for the first two is shown in Fig. 5b (with a square obstacle in place). A top view of the cell for the hexagonal distribution is shown in Fig. 5c. In this case it is necessary to have a low resistance contact between each obstacle quadrant and the adjacent conducting wall. This is obtained by means of a small leaf spring soldered to the wall. Since the spring is small and in a region of negligible current flow, its presence causes no appreciable error.

V. EXPERIMENTAL DATA

The measured shunt-susceptance data for the three configurations are shown in Figs. 7–9. Also, a table of values taken from accurately drawn curves plotted from the data is given in the Appendix. Notice that for l/b greater than approximately 0.75 the obstacle susceptances are independent of l. In practical delay media, however, it is generally necessary to have l/b less than 0.75 in order to have a large enough index of refraction, and hence the non-constant portions of the graphs are the most useful. The data of Figs. 7, 8, and 9 are valid only if $\lambda \gg b$, since for shorter wave-lengths the obstacle susceptance does not have the frequency dependence of a constant capacitance. Some experimental r-f data now available indicate that the frequency error is very small if $b/\lambda \leq 0.25$.

The following theoretical formula gives the low frequency susceptance in a parallel-plane line of one or more thin circular disks having a diameter much smaller than the spacings to surrounding walls and having $l/b > 0.75$.

$$B/Y_0 = 4\pi n d^3/3\lambda ab. \tag{5}$$

This formula may be derived very easily from a relation given by W. E. Kock for the average dielectric constant of a medium containing a uniform distribution of circular disks (Eq. (22), reference 1). The symbol n in Eq. (5) is the total number of obstacles in a cross section of the equivalent transmission line of sides a and b. It is equal to one for the square distribution and two for the hexagonal distribution. Equation (5) is plotted in Fig. 10 along with the experimental data for circular disks ($l/b > 0.75$). The agreement between experiment and simple theory is very good for d/b less than 0.5. This result checks the experimental method and also shows that Kock's low frequency formula for index of refraction is accurate provided that d/b is less than 0.5 and l/b greater than 0.75.

Another check between experiment and theory was obtained with a metal-strip obstacle which extended the full width of the cell and which had a ratio of 0.6 between the width of the strip and the spacing of the conducting plates. In this case the measured data are within one percent of the exact formula.

In Figs. 11–13 are plotted low frequency index-of-refraction curves calculated by Eq. (3) from the ex-

perimental curves of Figs. 7, 8, and 9. Notice that for given obstacle spacings the square obstacles have the highest index of refraction, the circular obstacles with hexagonal distribution the next highest, and the circular obstacles with square distribution the least. Consequently, the first two structures are likely to be more useful than the third.

The curves of Figs. 11–13 are accurate for b/λ up to approximately 0.1. For b/λ up to approximately 0.2, Eq. (1) may be used. For larger b/λ it is necessary to take account of B', which cannot be determined directly by any static method. The writer believes that a judicious estimate of B' may be made based on the measurements of B, but a discussion of this possibility will be postponed, since experimental verification is thus far lacking.

Although the measurements on the hexagonal distribution were made with the incident electric field parallel to the y axis (Fig. 1b), the index of refraction of a normally incident wave is the same for any polarization. This statement is obvious from the fact that three polarizations of a normal wave exist for which the field distributions are identical (except for 120 degree rotations), and that a normal wave of any other polarization may be represented by the sum of components polarized on two of these three axes. In a similar manner, it may be seen that the index of refraction of the square distributions is independent of the polarization of a normally incident wave. In addition, the normalized susceptance B'/Y_0' of the hexagonal distribution for the electric field parallel to the x axis is identical to B/Y_0 computed from Fig. 9 for the y axis polarization, and the normal susceptance of the square distributions for polarizations of ± 45 degrees from the x or y axis is identical to B/Y_0 computed from Figs. 7 and 8.

The writer wishes to thank his colleagues, H. L. Busching, R. Reisley, and R. C. MacVeety, who assisted in perfecting the measurement apparatus and techniques and in taking the data.

APPENDIX I

1. Derivation of Eq. (4)

Let the capacitance introduced by the obstacle be C_{obst} and that of the coaxial line C_{coax}. The corresponding conductances in the tank are G_{obst} and G_{coax}. Because of the analogy between capacitance and conductance

$$C_{obst}/C_{coax}=G_{obst}/G_{coax}.$$

The capacitance of the coaxial line is

$$C_{coax}=h/cZ_{0\,coax}\text{ farads},$$

where c is the velocity of propagation in free space. The conductances are obtained from the measured resistances by

$$G_{coax}=1/R_2$$
$$G_{obst}=1/R_1-1/R_2=(R_2-R_1)/(R_1R_2).$$

In the described test method, the obstacle is cemented on a flat plate, and hence only half of the total obstacle capacitance C is measured. Therefore

$$C=2\left[\frac{h}{cZ_{0\,coax}}\right]\frac{R_2(R_2-R_1)}{R_1R_2}.$$

When this is combined with $B=\omega C=2\pi cC/\lambda$ and $Y_0=a/376.6b$ one obtains Eq. (4).

The Role of Cathode Temperature in the Glow Discharge

HAROLD JACOBS AND JACK MARTIN
Signal Corps Engineering Laboratories, Fort Monmouth, New Jersey
(Received March 24, 1950)

Experiments were conducted to study the role of the temperature of oxide-coated cathodes in the glow discharge of argon, neon, and mixtures of neon and argon, and mercury vapor and argon.

It was found that for tubes without mercury present, in the region of cathode temperature between 300°K and 750°K: (1) The sparking potential falls with increasing cathode temperature. (2) The regulation voltage rises with increasing cathode temperature. For argon and mercury vapor, the regulation voltage falls with increasing cathode temperature. The action here is attributed to metastable states of inert gas. (3) The current density in the glow discharge decreases with increasing cathode temperature. This, too, is attributed to the action of metastable states. (4) The minimum sustaining current in a glow discharge is found to decrease with increasing cathode temperature and rise with increasing pressure. (5) The current density in the glow discharge varies roughly linearly with pressure, or at a slightly higher rate, in contrast with the space-charge derivations which claim a variation with pressure squared. (6) The regulation voltage tends to rise very slightly at lower pressures.

I. INTRODUCTION

COLD cathode behavior in the glow discharge region has received more interest in recent years due to its applications to electronic devices such as thyratrons, voltage regulators, lighting tubes, and switching devices. In the utilization of a glow tube in an electronic circuit a considerable amount of fundamental information must be integrated. For instance, variations of the cathode fall in potential is one type of problem which must be appreciated in designing a voltage regulator. The sparking potential values and relative stability of sparking potentials is important in switching devices and some thyratron control circuits. In the design of glow tubes, the current densities are of importance in order to calculate wattage dissipations at the cathode.

In reference to the stability of electrical performance of glow tubes, there is little or no fundamental information concerning the materials being used in modern tube fabrication techniques such as tubes with oxide-coated and inert gases. There is some general information, however, which is of interest and use in discussing these matters. For instance, the cathode fall in potential has been found to be related to the chemistry of the cathode surface. Bär[1] has shown that a lower work function will generally indicate a lower cathode fall in potential, for a given gas. Loeb[2] points out some early work in which analytic expressions were derived for current density in a glow discharge and cathode fall in potential.

In all of these calculations and in the derivations of most other investigators, the physical processes occurring in the glow are described as follows.

The mechanism of liberation of electrons from the cathode by positive ions or excited atoms is supposed to occur primarily in three ways. (a) Liberation of electrons by positive ion bombardment. (The exact mechanism is not yet understood.) (b) The freeing of electrons by photons produced in the gas. (c) Electron emission due to the effects of metastable atoms releasing energy to the cathode surface.

The electrons liberated from the cathode will, when accelerated, collide with the gas causing ionization and metastable states. These will, in turn, produce more electrons at the cathode. Most of these gas excitation processes are assumed to occur in the region of the cathode glow. For glow tubes where the current density is low and adequate anode area available, the cathode fall in potential is nearly equal to the total voltage across the tube.

In almost all of the reported experimental work with glow discharges and cathode effects, the tubes studied utilized metallic cathodes. In addition, for the case of these metallic surfaces, temperature changes were generally not regarded as important, until the higher temperatures were reached.[3]

II. STATEMENT OF THE PROBLEM

The purpose of the investigation was to describe the action of the glow discharge for the case of an oxide-

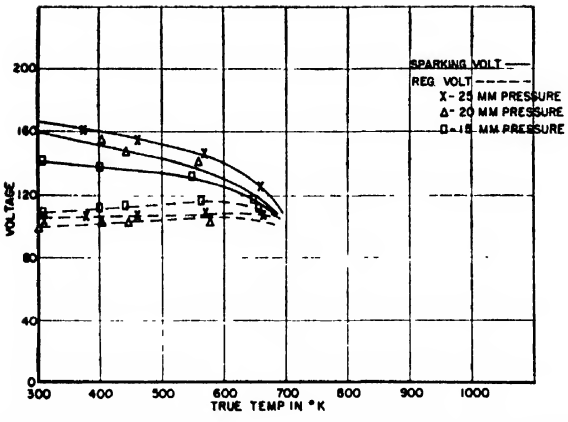

FIG. 2. Sparking potentials and regulation voltages as a function of temperature for neon gas and (BaSrCa)O cathodes.

coated cathode and an inert gas. Specifically, the following factors were studied as a function of cathode temperature and gas pressure: (a) sparking potential, (b) tube voltage drop, (c) current density, and (d) minimum current necessary to sustain a glow discharge. It was hoped, in this manner, that some of the causes of variations of the electrical characteristics in a glow discharge would be revealed.

III. EXPERIMENTAL TECHNIQUE

Tubes were constructed as in Fig. 1; the test circuit is sketched next to the design of the tube.

All tubes were constructed with trap-door anodes. The purpose here was to provide uncontaminated anodes and to facilitate cathode temperature measurements. During exhaust, when the cathode was activated, the trap was in an upright position. After cathode activation, the trap door was dropped and processing continued.

It is to be noted that all temperatures were measured on the cathode base metal. Thus the cathode surface was estimated to be from 0 to 50 degrees cooler than the temperature of the base metal. For the experiments to be described, extreme exactness of temperature measurement at the cathode surface was not required.

The following procedure was established for testing. After aging, the sparking potential was measured and the temperature of the base metal recorded. By means of adjusting the power supply voltage the glow was brought so that it just covered the cathode surface, and did not flow down the sides of the cylinder. The area was taken as the area of the cathode, the current was measured and the current density calculated. The normal glow voltage was recorded by taking the fall in potential across the tube at this point. It was noted that the tube drop changed very little by varying the area of cathode covered by the glow discharge. After the normal glow tube drop was recorded, the current was decreased in the tube until the glow was extinguished. This was a rather abrupt point. Sometimes a

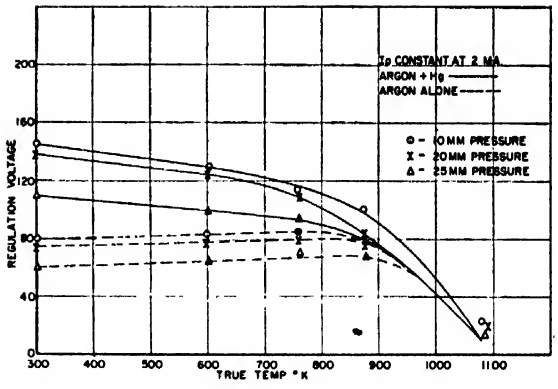

FIG. 3. Regulation voltages as a function of temperature for argon and argon contaminated with mercury.

sudden surge of current appeared as the glow was extinguished. The meaning here is not clear. Generally the current was decreased to the microampere region before it was extinguished. The minimum current refers to the lowest current that could be drawn before the glow became non-self-sustaining. The pressure of each tube was also recorded.

IV. DATA AND DISCUSSION CONCERNING SPARKING POTENTIALS AND REGULATION VOLTAGES

For each tube, a determination was made of sparking potentials, and regulation voltage, as a function of the temperature of the base metal. Some sample curves are to be found in Figs. 2 and 3. It is of interest to note that as the cathode temperature increases, the sparking potential decreases. This is to be expected to some extent. However, for argon, as the cathode temperature increases, from 300°K to about 750°K the regulation voltage does not fall, but, in fact, tends to show a slight rise. The general tendency or rising regulation voltage with rising cathode temperature was noted for all the tubes with the (BaSrCa)O cathodes and pure argon gas. Actually 19 tubes with this combination were tested and all showed the same tendency. Tubes made with neon gas and argon-neon mixture behaved similarly.

A question arises as to why the regulation voltage increased as the cathode temperature went from 300°K to about 750°K. By the accepted concepts, as the cathode becomes more efficient, liberating more electrons, the necessary ionization of the gas for a self-sustained discharge should be produced by a lower

0.08	0.06	5
0.22	0.11	10
0.37	0.16	15
0.48	0.20	20
0.62	0.25	25
0.75	0.29	30

field. Yet, experimentally this was not the case. One might suspect further that electron liberation just prior to the spark has a different mechanism from electron liberation due to the glow, since in the glow there is an increase in the number of metastables and photons close to the cathodes.

Another experiment was then performed where tubes were made up with argon gas and (BaSrCa)O cathodes, but this time a droplet of mercury was added prior to exhaust. After exhaust a portion of the mercury was still present as a droplet. During testing it was apparent that the presence of mercury vapor at room temperature had changed the characteristics of the tubes markedly, in the color of the glow, in the electrical properties, and in the cathode activity. During testing it was noted that the Hg greatly deactivated the (BaSrCa)O. Sometimes, as a cold cathode, the spark and glow would occur from the nickel instead of the cathode. Sometimes, only a part of the cathode was covered by the glow. In the following data only those tubes were used in which the glow was on the oxide-coated cathode surface. It was found, for mercury contaminated tubes, that as cathode temperature was increased, the regulation voltage decreased. This effect was in contrast to pure argon or neon where with increasing temperature the regulation voltage increased. As a matter of side interest the regulation voltage was higher for the argon and Hg tubes. The actual data are shown in Fig. 3.

The experiment with Hg vapor indicated the marked effect of Hg vapor in changing the glow characteristics. But more than this, it offers a possible explanation for the rather anomalous behavior of the regulation voltage in pure argon. In the glow discharge the liberation of electrons is aided not only by positive ions striking the surface but largely by photons and metastables. The effects of metastable atoms is greater in the glow than in the conditions leading to the spark. As the cathode in a glow discharge is heated, one might expect the gas in the cathode vicinity to have an increased kinetic energy. It seems reasonable to expect that a metastable atom can lose its energy by collision with a neutral atom, with the excess energy given off by the kinetic energy of the particles involved. If the kinetic energy of the gas particle is increased, one might expect the metastables to be decreased, thus the process of liberation of electrons from the cathode would be less efficient and a higher field would be necessary to maintain the discharge. One might expect that for pure argon the regulation voltage would rise with cathode temperature until the temperature rose enough to emit sufficient electrons for the tube to go into an externally sustained arc. The presence of the mercury in argon would effectively reduce the metastable argon atoms by ionization of the mercury. Without the metastables being present, the regulation voltage should drop with increasing cathode temperature and this is what has been observed.

Another point of interest is the determination of sparking potentials and regulation voltages at various pressures. For the case of (BaSrCa)O cathodes, it was found that the curves for sparking potential *versus* pressure×distance were very similar to those determined with barium metal cathodes in the same gas[4] (Table I).

It has been found, experimentally, that the regulation voltage, at constant temperatures, changes very slightly with pressure. In some cases, there is a slight increase of regulation voltage at reduced pressures.

V. CURRENT DENSITY AND MINIMUM SUSTAINING CURRENT

The current density in a glow discharge has been studied theoretically and the following equation[5] is most often quoted to describe it:

$$_n = 5.92\times10^{-14}\frac{AB^2(k_+p)(1+\gamma)}{\log(1+1/\gamma)}p^2\frac{\text{amp}}{\text{cm}^2}. \qquad (1)$$

In the experiments performed, current density measurements were made with respect to pressure and cathode temperature. The current density was actually found to decrease with increasing temperature up to about 700°K. Above this temperature the current density would start to rise very rapidly. The data reveals

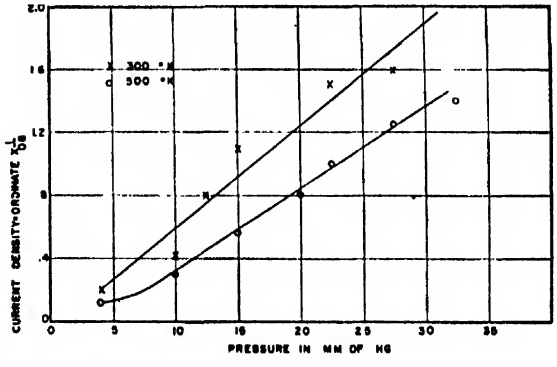

FIG. 4. Current density and pressure for argon-filled tubes and (BaSrCa)O cathodes. (Legend to the left of the figure should read: current density = ordinate × 1/0.08 ma/cm².)

[4] H. Jacobs and A. P. LaRocque, J. App. Phys. 18, 199–203 (1947).
[5] See reference 2, p. 584.

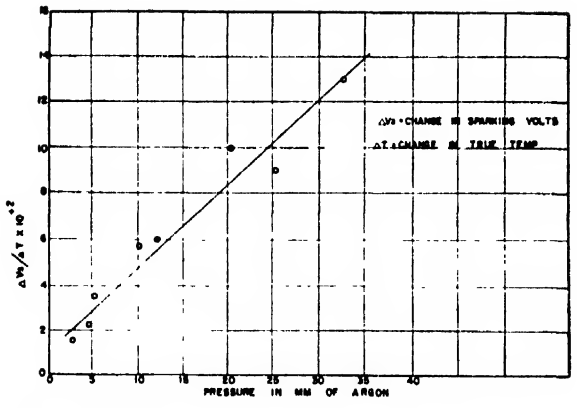

FIG. 5. The role of pressure on the change of sparking potential with respect to temperature (volts/°K) for argon gas and (BaSrCa)O cathodes.

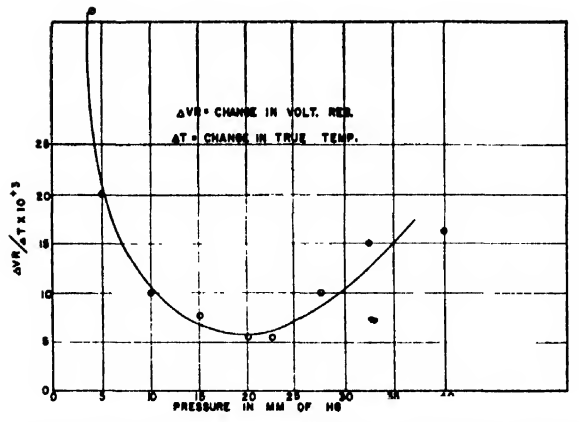

FIG. 6. The role of pressure on the change of regulation voltages with respect to temperature (volts/°K), for argon gas and (BaSrCa)O cathodes.

that as the cathode rises in temperature, the regulation voltage rises and the current density diminishes, until the region of the arc is approached, where the voltage drops rapidly and the current density rises rapidly.

Referring to Eq. (1) again, which was derived on space-charge considerations of positive ions, as p^2 increases, j_n should increase. In Fig. 4 we find the current density *vs.* pressure at 300°K temperature and at 500°K, for argon. This indicates two factors. (a) Current density decreases with increasing temperatures in this range. (b) Current density is almost a linear function of pressure. (For the mixtures of neon and argon, the current density was found to increase at a slightly higher rate as the pressure was increased.)

At the same period of measurement the minimum sustaining current was measured and found to decrease with increasing temperature (Table II).

VI. FURTHER CONSIDERATIONS

Upon study, the experiments with uncontaminated tubes indicated rather definite relationships between the change in sparking potential with respect to cathode temperature, dV_s/dT, and pressure. The change in regulation voltage with respect to pressure, dV_R/dT, was also found to be a function of pressure. As indicated in Fig. 5, dV_s/dT was found to be a constant as the pressure was increased.[6] Similarly (see Fig. 6) dV_R/dT was found to be a function of pressure—although not a constant.

The question then arises as to whether or not these experiments can give us a physical insight as to the mechanism in the spark. For instance, it has not been shown in what manner γ, the second Townsend coefficient, varies with cathode temperature for these particular cases. From Fig. 5, we can set up the following relation:

$$-dV_s/dT = Cp, \tag{2}$$

dV_s = change in sparking potential (volts), dT = change in cathode temperature (°K), C = constant, p = pressure in mm of mercury.

Using the Townsend criterion for sparking, Eq. (3) can be shown to be the equation for sparking.[7]

$$V_s = \frac{Bpd}{\ln[Apd/\ln(1/\gamma)]}, \tag{3}$$

where V_s = sparking potential, p = pressure, d = distance, γ = largely secondary emission on positive ion bombardment. This quantity, in addition, contains electrons liberated by photons and metastables. A and B = empirical constants.

Integrating Eq. (2),

$$-V_s = CpT + V_0. \tag{4}$$

V_0 is the extrapolated hypothetical sparking potential near 0°K for a given pressure and distance. We are now in a position to discuss the manner in which γ varies with cathode temperature. Substitute Eq. (3) in Eq. (4):

$$-\frac{Bpd}{\ln[Apd/\ln(1/\gamma)]} = CpT + V_0. \tag{5}$$

The following factors are assumed constant: B, p, d, A, C, and V_0. γ is the remaining factor varying with T.

$$T = -\frac{Bpd}{Cp\ln[Apd/\ln(1/\gamma)]} + \frac{V_0}{Cp}. \tag{6}$$

T varies as $K\{1/\ln[\ln(1/\gamma)]\}$, K = constant; $\ln[\ln(1/\gamma)]$ varies as K/T.

We can conclude: $\exp(e^{1/T})$ varies as $1/\gamma$ times a constant, for sparking.

Now let us refer to Fig. 6 which shows the increase of regulation voltage per change in cathode temperature as a function of pressure. We notice that at about 20

[6] $\Delta V_s/\Delta T$ is a negative quantity in Fig. 5.

[7] J. D. Cobine, *Gaseous Conductors* (McGraw-Hill Book Company, Inc., New York, 1941), p. 163.

mm, dV_R/dT is a minimum. The behavior here is not readily explained at the present time.[8]

VII. CONCLUSIONS

It was found that for experimental glow discharge tubes without mercury contaminations, and in the cathode temperature regions of from 300°K to 750°K, using oxide cathodes and inert gases:

1. The sparking potentials fall with increasing cathode temperatures.
2. The regulation voltage rises slightly with increasing cathode temperature. (For mercury vapor and argon, the regulation voltage falls with increasing cathode temperature.)
3. The current density decreases with increasing cathode temperature. This takes place concurrently with the increase in regulation voltage.
4. The minimum sustaining current in a glow discharge decreases with increasing cathode temperature, and rises with increasing pressure.
5. For the case of argon, the current density in the glow discharge varies roughly linearly with pressure in contrast with the space charge derivations which predict a variation with pressure squared. For the case of the neon, argon mixtures, the rate of increase in current density is not quite linear but slightly greater.
6. The decrease in sparking potential with respect to temperature diminished linearly with lower pressures. The change of regulation voltage with respect to temperature is related to pressure, but not in any simple manner.

[8] T. Jurrianse, Philips Res. Rep. 1, 407 (1946). For the case of neon gas and a molybdenum cathode, it was found that dV_R/dT was a negative quantity.

VIII. ACKNOWLEDGMENT

We wish to thank Mr. K. M. McLaughlin and the Radio Corporation of America Development Group at Harrison, New Jersey, for their suggestions in the tube design and for the construction of the experimental tubes.

The Emission of Radiation from Diatomic Gases. I. Approximate Calculations*

S. S. Penner
Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California
(Received February 6, 1950)

An approximate method for estimating radiant heat transfer from gaseous emitters is proposed. An average absorption coefficient is used for the effective width of an entire vibration-rotation band. The procedure for determining an average absorption coefficient in terms of the integrated absorption is justified, approximately, for very small optical densities and also for large total pressures where the spectral half-width is no longer small compared with the rotational spacing. Because of these limitations it is to be expected that the procedure proposed here will be particularly useful only in estimating gaseous emissivities for emitters in high-pressure combustion chambers. A preliminary compilation is given of the theoretical results which are necessary for making rapid estimates of the emissivities, over a wide temperature range, for CO, HI, HBr, HCl, and HF.

I. INTRODUCTION

PROBLEMS concerned with the emission of radiant energy from an assembly of gaseous emitters which are in thermal equilibrium have formed the subject for theoretical and experimental investigations by two essentially distinct groups.

The members of one group, the theoretical physicists, have attacked the fundamental atomistic problem in an effort to evolve relations, based on quantum-mechanical considerations, which permit a rigorous solution of the problem, at least in principle. The basic relations between the various factors contributing to radiant heat transfer are correlated by the well-known relations between the coefficients of induced and spontaneous emission and induced absorption developed by Einstein in 1917.[1] Theoretical efforts to derive relations for the Einstein coefficients from first principles have culminated in Dirac's treatment of the interaction of radiation and matter, numerical application of which to specific problems usually involves formidable computational difficulties. Excellent reviews from the fundamental point of view of the work of Dirac, Born, Slater, and others have been given by Fermi[2] and Breit.[3] The subject of the interaction of radiation and matter is still far from solved, as is evidenced by intensive current activity in this field.[4]

Contributors of the second group involved in the calculation of intensities of radiation come from the ranks of the applied scientists and engineers who have contented themselves with a phenomenological description of the intensities of radiation emitted from gaseous bodies of various shapes, sizes, and compositions and who have based their predictions primarily upon empirically determined parameters such as effective over-all emissivities for pure gases and gaseous mixtures as functions of pressure, temperature, and path length. Although this approach has involved only

limited application of the fundamental relations determining the intensity of radiant energy emitted, it has nevertheless been developed to the point where reasonable predictions can be made for practical applications.[5]

It is apparent that use of the results of the theoretical physicists will suggest the most desirable lines of attack along which practical methods for the calculation of radiant heat transfer should be evolved. Accordingly, we shall devote our attention in this paper and in succeeding articles on radiant heat transfer to utilizing some of the established results relating to the calculation of radiant energy emitted from pure gases. For the present we shall content ourselves with developing and applying a simple and rather crude method for estimating gaseous emissivities by assigning an average absorption coefficient to an entire vibration-rotation band. Before proceeding with the presentation of details of this development, it appears desirable to review briefly the essential steps in estimating the intensity of radiation emitted from heated gases.

A gas emits radiation as the result of electronic, vibrational, and rotational transitions from excited energy levels to lower energy levels. The emitted radiant energy corresponding to these transitions is distributed over a wide wave-length region. Only the transitions corresponding to the infra-red vibration-rotation bands make an important contribution to the total radiant heat transfer at the temperatures of interest in connection with studies on combustion chambers. The total radiant intensity emitted from a given quantity of gas is obtained by summing the radiant intensities corresponding to each of the individual energy transitions. A calculation of this type requires knowledge of the following factors: 1. The number of molecules present in each of the various energy levels must be known. If thermal equilibrium obtains, this distribution can be calculated from quantum statistics. If thermal equilibrium does not exist, as may well be the case in a region of active combustion, then the equilibrium assumption and hence the numerical results derived from it are obviously invalid. 2. The transition probabilities for each of the possible energy transitions must be determined. Transition probabilities can be calculated with satisfactory precision for isolated quantum-mechanical systems such as vibrating-rotating diatomic molecules. At elevated temperatures and pressures, however, the various radiating systems may be perturbed as the result of interactions with neighboring molecules. These perturbations are neglected in the present calculations. 3. The frequencies corresponding to each of the energy transitions enter into the quantitative expressions for the radiant intensities. These frequencies can usually be determined with a high degree of precision from available spectroscopic data. 4. The spectral line shape must be known as a function of pressure and temperature. It can be calculated with relative ease if the familiar Lorentz collision formula is valid, and with some difficulty when it is not valid. In the present approximation, calculations of radiant heat transfer will be carried out without explicit allowance for line shape by introducing the restriction that the total pressure is sufficiently high to provide extensive overlapping of individual rotational lines.

II. BASIC RELATIONS BETWEEN INTEGRATED ABSORPTION, EINSTEIN COEFFICIENTS, AND RADIANT INTENSITIES

An energy transition from a lower energy level j to an upper energy level i (or conversely) is accompanied by the absorption (or emission) of radiation of frequencies close to the frequency ν_{ij} given by the familiar quantum relation $\nu_{ij}=\Delta E_{ij}/h$ where ΔE_{ij} is the energy difference between the two levels under consideration, and h is Planck's constant. Let $\rho(\nu_{ij})$ represent the volume density of radiant energy emitted by a blackbody in the frequency interval between ν_{ij} and $\nu_{ij}+d\nu_{ij}$. The integrated absorption $\int P_{\nu_{ij}}d\nu_{ij}$ is related to the Einstein coefficients of induced absorption and induced emission by the well-known relation[6]

$$\int P_{\nu_{ij}}d\nu_{ij}\simeq N_jB_{j\rightarrow i}h\nu_{ij}/c-N_iB_{i\rightarrow j}h\nu_{ij}/c = N_iA_{i\rightarrow j}h\nu_{ij}/c\rho(\nu_{ij}), \quad (1)$$

where N_j = number of molecules per unit volume in quantum state j, N_i = number of molecules per unit volume in quantum state i, $B_{j\rightarrow i}$ = Einstein coefficient of induced absorption, $B_{i\rightarrow j}$ = Einstein coefficient of induced emission, $A_{i\rightarrow j}$ = Einstein coefficient of spontaneous emission, and c = velocity of light. The symbol $P_{\nu_{ij}}$ indicates that the absorption coefficient with which we are concerned arises as the result of an energy transition between the levels i and j. The integration in Eq. (1) may be performed over all frequencies $-\infty<\nu_{ij}<+\infty$ if we adopt the convention of calling frequencies smaller than ν_{ij} negative and frequencies larger than ν_{ij} positive.

Treatments of intensities of emission and absorption involving the Einstein coefficients are derived under conditions of thermal equilibrium.[1,6,7] Nevertheless it is customary to assume[8] that energy transitions from the upper level i to the lower level j occur at the net rate,

$$N_i[A_{i\rightarrow j}+B_{i\rightarrow j}\rho'(\nu_{ij})]-N_jB_{j\rightarrow i}\rho'(\nu_{ij}), \quad (2)$$

even if thermal equilibrium does not exist. Here $\rho'(\nu_{ij})$

is the external energy density of radiation passing through the system under discussion.

An expression of the type given in Eq. (2) is not particularly useful for calculations of the net radiant intensity emitted. Instead we require a differential expression which can be obtained by considering the change of energy resulting from the passage of radiant energy through a radiating and absorbing system of emitters and receivers. If the incident radiant intensity (not necessarily the intensity of radiation emitted by a blackbody) is denoted as $I(\nu)$, the following differential equation results

$$dI(\nu)=P_\nu[c\rho(\nu)-I(\nu)]dX.$$

Here it is assumed that the fraction of radiant energy absorbed is proportional to the incident intensity of radiation (with the proportionality constant set equal to the spectral absorption coefficient P_ν) and that the net change in radiant energy is proportional to the change in optical density dX through the system of emitters and absorbers. Integration leads directly to the well-known relation

$$I(\nu)=c\rho(\nu)[1-\exp(-P_\nu X)] \qquad (3)$$

for the radiant energy emitted per unit area of surface by gaseous emitters distributed uniformly through a radiation path length of optical density X.

Equation (3) cannot be applied to practical calculations unless the dependence of P_ν on ν is known, a problem which requires detailed consideration of spectral line shape and its dependence on pressure, temperature, etc.[9,10] If Lorentz broadening obtains, P_ν is related to the integrated absorption by the dispersion formula

$$P_\nu=\frac{\delta}{\pi}\frac{\int P_{\nu,ij}d\nu_{ij}}{(\nu-\nu_{ij})^2+\delta^2}, \qquad (4)$$

where δ represents the spectral half-width. If individual rotational lines are sufficiently broadened to cause overlapping of lines, then the spectral absorption coefficient, for collision-broadened lines, is given by a sum of terms of the type shown in Eq. (4). Therefore, in this particular case, the intensity of radiation $I(\nu)$ can be calculated provided the half-widths δ and the integrated absorption $\int P_{\nu,ij}d\nu_{ij}$ are known for each transition. The half-width δ can be determined, for example, from the dependence of absorption on pressure[11] by utilizing the theoretical analysis of Elsasser.[12,13]

The dependence of δ on pressure and temperature can be calculated, approximately, for collision-broadened lines.[9,10] Individual values for integrated absorption for rotational transitions can be calculated if the integrated absorption for a vibration-rotation band has been determined experimentally. Calculations for diatomic molecules involve the use of theoretical results obtained by Oppenheimer[14] and applied by Dennison.[15] Similar calculations are also possible for the simpler polyatomic molecules.

III. A METHOD FOR THE APPROXIMATE CALCULATION OF THE INTENSITY OF RADIATION EMITTED FROM GASES WHICH ARE IN THERMAL EQUILIBRIUM

In this section we shall consider drastic simplifications of methods for making radiant heat-transfer calculations for gases.

A. A Method for Estimating an Upper Limit for the Emission of Radiant Energy from Pure Gases and Gaseous Mixtures

An upper limit is obtained for the total radiant energy $\int_{n\to n'} I_\nu d\nu$ emitted for frequencies corresponding to the vibrational transition from n to n' if we set

$$\int_{n\to n'} I_\nu d\nu = c\int_{\Delta\nu_{n\to n'}} \rho(\nu)d\nu, \quad . \quad . \quad (5)$$

where $\Delta\nu_{n\to n'}$ designates an appropriate band width for the vibration-rotation band under consideration. The total radiant energy emitted over all emission bands is evidently obtained by summing the contributions for all possible vibrational transitions, i.e., The maximum

$$I_T = \sum_{n,n'}\int_{n\to n'} I_\nu d\nu = c\sum_{n,n'}\int_{\Delta\nu_{n\to n'}} \rho(\nu)d\nu. \quad (6)$$

value of the effective emissivity ϵ'_{max} is defined by the relation

$$\epsilon'_{max} = \left\{\sum_{n,n'}\int_{\Delta\nu_{n\to n'}} \rho(\nu)d\nu\right\} \Big/ \int_0^\infty \rho(\nu)d\nu. \quad (7)$$

The calculation of an upper limit for the emissivity is seen to require an independent estimate of band widths $\Delta\nu_{n\to n'}$. It is to be expected that a suitable method for the calculation of $\Delta\nu_{n\to n'}$ will lead to theoretical upper limits for the emissivities which are in agreement with the experimentally observed limits approached by given emitters as the optical density is increased. The method suggested here for the calculation of effective band width approximately fulfills this requirement.[16] The principal factor determining the dependence of integrated absorption on rotational quantum number is of the form

$$j\exp(-E_{n,j}/kT) \quad \text{or} \quad j\exp(-E_{n,j-1}/kT),$$

where $E_{n,j}$ represents the energy of the nth vibrational and jth rotational level, k is the Boltzmann constant, and T represents the absolute temperature. These facts suggest that the band width $\Delta\nu_{n\to n'}$ be set equal to the frequency interval for which the factors $j\exp(-E_{n,j}/kT)$ or $j\exp(-E_{n,j-1}/kT)$ have values in excess of 10^{-3} of their maxima at a given temperature. This definition of $\Delta\nu_{n\to n'}$ is admittedly arbitrary. However, the exponential terms decrease so rapidly with increasing values of j that a different definition, such as setting $\Delta\nu_{n\to n'}$ equal to the frequency interval in which $j\exp(-E_{n,j}/kT)$ or $j\exp(-E_{n,j-1}/kT)$ have values in excess of 10^{-2} or 10^{-4} of their respective max-

[15] D. M. Dennison, Phys. Rev. 31, 503 (1928).

[16] The utility of an empirically determined effective band width seems to be supported by absorption measurements performed by the author and D. Weber. The "effective band width" of the CO fundamental at room temperature was found to increase only about 20 percent when the pressure of absorbing gas was increased from 5 mm to 200 p.s.i. at constant total pressure.

ima, would lead to substantially the same results as the definition of band width adopted for the present application. It should be noted that the definition of effective band width given here leads to similar results for all transitions of the form $n \rightarrow n+1$ provided the anharmonicities are not excessive. Estimates of overtone intensities indicate that the effective band widths of the overtones correspond, approximately, to the same limiting values for the rotational quantum numbers j as tor the fundamental

The foregoing considerations lead to a straightforward method for estimating effective band widths. The application of this method is described here for carbon monoxide.

In Fig. 1 a plot is shown of $j\exp(-E_{0,j}/kT)$ for carbon monoxide as a function of j for representative values of the temperature. Similar plots have been prepared for each of the following temperatures: 300, 500, 1000, 1500, 2000, 2500, and 3000°K. Reference to Fig. 1 shows that for all values of j up to about $j_{\max}=28$ the integrated absorption is larger than 10^{-3} of its maximum value at 300°K. Similar results are obtained at other temperatures. It follows from the preceding discussion that $\Delta\nu_{0\rightarrow1}\simeq\Delta\nu_{1\rightarrow2}\simeq\Delta\nu_{2\rightarrow3}\simeq\cdots=$ effective band width of the fundamental $=\nu_{\max}-\nu_{\min}$, where $\nu_{\max}$ and $\nu_{\min}$ are given, respectively, by the approximate relations

$$\nu_{\max}\simeq\frac{E(1,j_{\max})-E(0,j_{\max}-1)}{h} \tag{8}$$

$$\nu_{\min}\simeq\frac{E(1,j_{\max}-1)-E(0,j_{\max})}{h}. \tag{8a}$$

Band widths have been calculated for the fundamental vibration-rotation band of carbon monoxide from available spectroscopic data[17] by the use of this method. The results are summarized in Table I.[18]

For sufficiently large values of j a band head should be obtained beyond which the calculated maximum cutoff frequency should decrease with increasing values of $j_{\max}$. This phenomenon is observed for smaller j-values in the case of the first overtone of CO (see below). When a band head does occur, the cut-off frequency should evidently be chosen to coincide with the extreme frequency value corresponding to the band head rather than to a frequency calculated from either Eq. (8) or Eq. (8a).

In accord with the preceding discussion we set $\Delta\nu_{0\rightarrow2}\simeq\Delta\nu_{1\rightarrow3}\simeq\cdots=$ effective band width of the first overtone $=\nu'_{\max}-\nu'_{\min}$ where

$$\nu'_{\max}\simeq\frac{E(2,j_{\max})-E(0,j_{\max}-1)}{h} \tag{9}$$

$$\nu'_{\min}\simeq\frac{E(2,j_{\max}-1)-E(0,j_{\max})}{h}. \tag{9a}$$

As explained in the preceding paragraph, Eq. (9) or Eq. (9a) should not be used if a band head is observed for j values which are smaller than the appropriate values of $j_{\max}$. Relevant band width calculations for the first overtone of CO are summarized in Table II.

Since the integrated absorption of the second overtone of CO is very small compared with that of the fundamental and since, furthermore, the intensity of radiation emitted by a blackbody at temperatures below about 2000°K is relatively small in the frequency region in which the second overtone emission band is found, the contributions of the second overtone to radiant heat transfer will not become important until relatively high temperatures and large optical densities have been reached. These contributions may be included in radiant heat-transfer calculations by following the procedure outlined above for calculations on the fundamental and the first overtone.

If only the fundamental and the first overtone make significant contributions to the intensity of radiation emitted from a given gas, then Eq. (7) reduces to the relation

$$\epsilon'_{\max}=\frac{\sum_n\int_{\Delta\nu_{n\rightarrow n+1}}\rho(\nu)d\nu}{\int_0^\infty\rho(\nu)d\nu}+\frac{\sum_n\int_{\Delta\nu_{n\rightarrow n+2}}\rho(\nu)d\nu}{\int_0^\infty\rho(\nu)d\nu}=\epsilon_F'+\epsilon_0'. \tag{10}$$

The ratios ϵ_F' and ϵ_0' occurring on the right-hand side of Eq. (10) have been evaluated by using the effective band widths summarized in Tables I and II. These ratios have also been calculated for effective band widths determined by making a somewhat different choice for $j_{\max}$ at each temperature. The results of these calculations are plotted in Fig. 2. Reference to Fig. 2 indicates that the contribution to the radiant intensity emitted from the fundamental ϵ_F' shows a maximum value near 900°K. The fraction of the total radiant energy contributed by the first overtone ϵ_0' reaches a maximum value at temperatures in the neighborhood of 2000°K. At still higher temperatures contributions from upper harmonics will become important.

[17] H. Sponer, Molekülspektren (Verlag Julius Springer, Berlin, 1935); J. E. Mayer and M. G. Mayer, *Statistical Mechanics* (John Wiley and Sons, Inc., New York, 1940), pp. 468–469; for more recent spectroscopic data on CO, see G. Herzberg and K. N. Rao, J. Chem. Phys. 17, 1099 (1949).

[18] Band widths and corresponding emissivities have also been calculated for values of $j_{\max}$ somewhat different from those listed in Table I. The effect of the choice of $j_{\max}$, within reasonable limits, on the calculated emissivity was found to be small and is illustrated in Fig. 2.

According to the present procedure, the upper limit for the theoretical emissivity ϵ'_{max} is obtained by adding the contributions from the fundamental ϵ_F' and the first overtone ϵ_0' according to Eq. (10). It should be noted, however, that there is a certain inconsistency inherent in the use of a curve corresponding to the sum of the emissivity contributions from the fundamental and the first harmonic. Thus the integrated overtone absorption coefficient for a given rotational line is very small ($\sim 10^{-2}$ for CO) compared with the corresponding absorption coefficient of a rotational line of the fundamental. Therefore, the overtone will not act as a blackbody absorber or emitter until the optical density is exceedingly large. But for optical densities sufficiently large to make the overtone act as a blackbody, the intensity of radiation from the fundamental, which makes an appreciable contribution to the total radiant heat transfer, may be appreciable even for frequencies outside the range of the calculated band widths. Hence when the overtone acts as a blackbody, the fundamental must have an emissivity greater than the emissivity shown in Fig. 2.

Remarks similar to those made for radiant heat transfer from the first overtone apply to radiant heat transfer from upper harmonics.

The preceding considerations lead to the conclusion that for moderate values of the optical density it is to be expected that observed emissivity values will tend to approach and then slightly exceed the emissivity corresponding to the emission of radiant energy from the fundamental, with the fundamental acting as a blackbody emitter. This qualitative conclusion is borne out by experimental data of the emissivity of carbon monoxide measured by Hottel and Ullrich,[5,19] which are also shown in Fig. 2. The experimental data for an optical density corresponding to 5 ft.×atmos. are seen to follow the calculated blackbody emissivity curve of the fundamental with reasonable accuracy. In view of the approximations involved in the present calculations, the agreement between theory and experiment must be considered to be satisfactory.

In concluding this discussion it appears desirable to point out that the method for estimating upper limits for the emissivities described here lends itself readily to calculations on polyatomic molecules.

B. A Method for Estimating Emissivities of Pure Gases

A more realistic estimate of the emissivity of pure gases than is provided by Eq. (10) is obtained by using an appropriate average absorption coefficient for each of the vibration-rotation bands. In this case Eq. (10) should be replaced by the following relation for the emissivity ϵ':

$$\epsilon' = [1-\exp(-\bar{k}_F pl)]\frac{\sum_n \int_{\Delta\nu_{n\to n+1}} \rho(\nu)d\nu}{\int_0^\infty \rho(\nu)d\nu} + [1-\exp(-\bar{k}_{F.O.}pl)]\frac{\sum_n \int_{\Delta\nu_{n\to n+2}} \rho(\nu)d\nu}{\int_0^\infty \rho(\nu)d\nu} + [1-\exp(-\bar{k}_{S.O.}pl)]\frac{\sum_n \int_{\Delta\nu_{n\to n+3}} \rho(\nu)d\nu}{\int_0^\infty \rho(\nu)d\nu} + \cdots, \quad (11)$$

where $\bar{k}_F$ = average absorption coefficient for fundamental vibration-rotation band, $\bar{k}_{F.O.}$ = average absorption coefficient for first overtone, $\bar{k}_{S.O.}$ = average absorption coefficient for second overtone, p = partial pressure of absorber, and l = optical path length. If only the contributions to the total radiant heat transfer from the fundamental and from the first overtone are

[19] W. Ullrich, Thesis, Massachusetts Institute of Technology, Cambridge (1935).

of importance, it is evidently sufficient to use the first two terms on the right-hand side of Eq. (11). Numerical evaluation of ϵ' is facilitated by the use of the black-body intensity ratios over the effective band widths, i.e., ϵ_P' and ϵ_0', of the type presented in Fig. 2. The problem at hand therefore reduces to the evaluation of average absorption coefficients.

Before attempting to determine the numerical value of an average absorption coefficient it is appropriate to inquire about the existence of a coefficient of this type for an entire vibration-rotation band. A detailed consideration of this problem has indicated that for moderate values of the optical density pl an average absorption coefficient of the order of one-half the maximum absorption coefficient obtained with low spectral resolution should be observed provided P_ν can be represented as a linear function of ν.[20] The physical significance of a relation of the form, $\bar{k}=\frac{1}{2}P'_{\max}$ where $P'_{\max}$ is the maximum absorption coefficient observed under low resolution, is dubious. Of more obvious significance would be a relation between $\bar{k}$ and the integrated absorption of a given vibration-rotation band. A relation of this type can be derived by proceeding in the manner described next.

From Eq. (3) we obtain, for example, for the entire fundamental vibration-rotation band of a diatomic molecule with P and R branches but no Q branch, the relation

$$\sum_n \sum_j \int_{\substack{n\to n+1\\ \Delta j=\pm 1}} I_\nu d\nu = c\sum_n \sum_j \int_{\substack{\Delta\nu_{n\to n+1}\\ \Delta j=\pm 1}} \rho(\nu)[1-\exp(-P_\nu pl)]d\nu \quad (12)$$

where P_ν is given by Eq. (4) for collision-broadened lines. The subscript $n\to n+1$ indicates the type of vibrational transition, whereas the subscript $\Delta j=\pm 1$ identifies the rotational transitions. If the vibration-rotation band is sufficiently narrow, we may replace $\rho(\nu)$ by an average value over the effective band width $\Delta\nu_{n\to n+1}$. Denoting the product of (a) this constant value of $\rho(\nu)$, (b) the effective band width, and (c) the velocity of light by I_P^0, and denoting the intensity sum over the band branches on the left-hand side of Eq. (12) by I_P, we obtain the relation

$$\frac{I_P}{I_P^0}=\frac{1}{\Delta\nu_{n\to n+1}}\sum_n \sum_j \int_{\Delta\nu_{n\to n+1}} [1-\exp(-P_\nu pl)]d\nu. \quad (13)$$

For sufficiently small values of the optical density $P_\nu pl \ll 1$ for all values of ν. In this case we may expand the exponential in Eq. (13), retaining only the first two terms, and obtain the result

$$\frac{I_P}{I_P^0}=\frac{pl}{\Delta\nu_{n\to n+1}}\sum_n \sum_j \left(\int_{\substack{n\to n+1\\ j\to j-1}} P_\nu d\nu + \int_{\substack{n\to n+1\\ j-1\to j}} P_\nu d\nu\right) \quad (14)$$

The double sum in Eq. (14) evidently represents the integrated absorption over the fundamental vibration-rotation band. Relations similar to Eq. (14) can be derived for harmonic vibration-rotation bands.

By comparing Eq. (11) with Eq. (14) we obtain the following relations for the average absorption coefficients for sufficiently small values of the optical density:

$$\bar{k}_P=\frac{1}{\Delta\nu_{n\to n+1}}\sum_n \sum_j \left(\int_{\substack{n\to n+1\\ j\to j-1}} P_\nu d\nu + \int_{\substack{n\to n+1\\ j-1\to j}} P_\nu d\nu\right)=\frac{\alpha_{01}}{\Delta\nu_{n\to n+1}} \quad (15)$$

$$\bar{k}_{P.O.}=\frac{1}{\Delta\nu_{n\to n+2}}\sum_n \sum_j \left(\int_{\substack{n\to n+2\\ j\to j-1}} P_\nu d\nu + \int_{\substack{n\to n+2\\ j-1\to j}} P_\nu d\nu\right)=\frac{\alpha_{02}}{\Delta\nu_{n\to n+2}} \quad (16)$$

etc., where α_{01} and α_{02} represent the integrated absorp-

tion over the fundamental and the first overtone, respectively.

The validity of Eqs. (15) and (16) has been demonstrated only under the very restrictive condition that $P_\nu pl \ll 1$ for all ν. This result will not be of any particular practical significance. Fortunately, however, it can be shown that Eqs. (15) and (16) also represent reasonable approximations when the total pressure is sufficiently high. This result can be obtained by utilizing Elsasser's theoretical treatment for equally intense and equally spaced rotational lines.[12,13] Elsasser has shown that for this idealized rotational distribution the fraction of radiation absorbed as the result of a given transition is

$$\frac{I}{I_0}=1-\exp\left[\frac{1}{d}\int P_{\nu_{ij}}d\nu_{ij}\tanh\left(\frac{2\pi\delta}{d}\right)pl\right] \qquad (17)$$

where d represents the spacing between rotational lines. For equally intense and equally spaced rotational lines, to which Elsasser's treatment applies, the following identity must be valid

$$(1/d)\int P_{\nu_{ij}}d\nu_{ij}=\alpha_{01}/\Delta\nu_{n\to n+1}. \qquad (18)$$

From Eqs. (17) and (18) it may evidently be inferred that relations of the form of Eqs. (15) and (16) apply for the average absorption coefficients provided δ is sufficiently large compared to d, a result which will obtain for large total pressures. In fact, as was first pointed out by Elsasser,[13] an absorption coefficient equal to the ratio of integrated absorption to line spacing represents a good approximation provided the ratio of half-width to line spacing is greater than or equal to $1/\pi$. Equations (15) and (16) exemplify this result as applied to an entire vibration-rotation band. We therefore arrive at the important conclusion that average absorption coefficients, as given in Eqs. (15) and (16) represent a crude but approximately justifiable result for sufficiently large total pressures. The condition $\delta/d \geq 1/\pi$ will be fulfilled for many molecules at pressures in excess of a few hundred pounds per square inch. Thus the present results are seen to be immediately applicable to liquid-fuel and solid-fuel rocket motors operating at pressures of a few hundred to several thousand pounds per square inch provided line broadening is still accounted for by the dispersion formula. For the present purposes the assumption of collision broadening and, therefore, of the approximate validity of Eqs. (15) and (16) for approximate heat-transfer calculations at elevated pressures will be made.[21]

The principal practical value of relations of the form of Eqs. (15) and (16) is the result of the fact that the integrated absorption is approximately independent of temperature and pressure for a given number of emitters or absorbers. Therefore the temperature dependence of the average absorption coefficient can be calculated as soon as the effective band width is known. In this connection it may be of interest to note that the present method of calculation is, to some extent, self-compensating as far as errors introduced by a poor estimate of band width are concerned. Thus a small value of $\Delta\nu$ will be partly compensated by a large value of $\bar{k}$.

The total integrated absorption (neglecting anharmonicities) corresponding to a transition from the $(n-1)$th to the nth vibrational energy level is determined by the following approximate relation[15]

$$\alpha_{01}=\frac{\pi\epsilon_P^2 N_T n\exp(-E_{n-1}/kT)}{3\mu c\sum_n^\infty \exp(-E_{n-1}/kT)}[1-\exp(-h\nu_0/kT)]$$

where ϵ_P represents the effective charge, N_T is the total number of absorbing (or emitting) molecules per unit volume per unit pressure, μ is the reduced mass, and ν_0 is the frequency of the band center. Since, approximately

$$\frac{\exp(-E_{n-1}/kT)}{\sum_{n=1}^\infty \exp(-E_{n-1}/kT)}=\frac{\exp[-(n-1)h\nu_0/kT]}{\sum_{n=1}^\infty \exp[-(n-1)h\nu_0/kT]}$$

[21] Unpublished absorption measurements on the fundamental of CO at pressures up to 800 p.s.i. and at room temperature have led to experimental results which are described by Eq. (4). Details concerning this work will be published elsewhere.

it follows that

$$\alpha_{01}=\pi\epsilon_F^2 N_T/3\mu c. \tag{19}$$

Relations similar to Eq. (19) can be derived readily for diatomic molecules with Q branch and also for polyatomic molecules.[22] Equation (15) may be written, in terms of the effective charge, as follows:

$$\bar{k}_P=\frac{N_T\pi\epsilon_F^2}{3\mu c}\frac{1}{\Delta\nu_{n\to n+1}}. \tag{20}$$

Since N_T varies inversely as the temperature, i.e., for an ideal gas

$$N_T=\frac{7.34\times10^{21}}{T}\text{ molecules/cc}\times\text{atmos.} \tag{21}$$

it follows that

$$\frac{\bar{k}_P(T_1)}{\bar{k}_P(T_2)}=\frac{T_2\,\Delta\nu_{n\to n+1}(T_2)}{T_1\,\Delta\nu_{n\to n+1}(T_1)}, \tag{22}$$

$$\frac{\bar{k}_{P.O.}(T_1)}{\bar{k}_{P.O.}(T_2)}=\frac{T_2\,\Delta\nu_{n\to n+2}(T_2)}{T_1\,\Delta\nu_{n\to n+2}(T_1)}, \tag{23}$$

etc. Thus the average absorption coefficient at any desired temperature can be estimated from available room temperature measurements by the use of Eqs. (22) and (23).

C. Critique of the Approximate Method for Emissivity Calculations

The principal virtue of the suggested procedure for emissivity calculations is the result of the fact that semiquantitative information regarding gaseous emissivities at elevated total pressures can be obtained by very simple calculations without requiring more than highly approximate values for the integrated absorption. Thus the integrated absorption for the fundamental vibration-rotation bands is generally so high that for total pressures of several hundred p.s.i. or more the fundamental will act practically as a blackbody at relatively low partial pressures of absorber. At elevated temperatures somewhat larger partial pressures of absorber will be required because of an increase in the effective band width with temperature. As the result of rapid saturation for absorption and emission from the fundamental, calculated emissivities tend to be relatively insensitive to the numerical values of the average absorption coeficients, at least as far as emission from the fundamental is concerned. The contributions from the first overtone to radiant heat transfer do not become important until very high partial pressures of absorber and relatively high temperatures have been reached.

Although emissivity calculations are relatively insensitive to the numerical values of the average absorption coefficient, they depend strongly on the numerical value of the effective band width. It is indeed

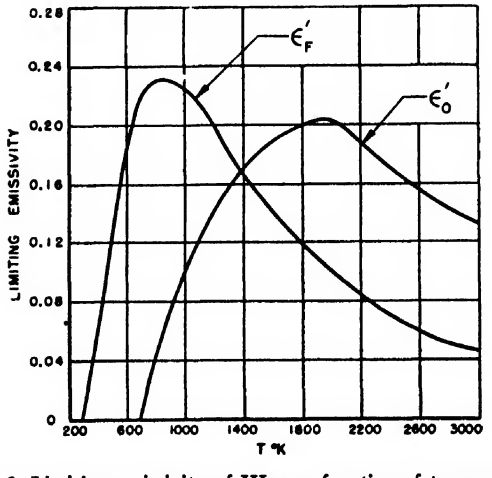

FIG. 3. Limiting emissivity of HI as a function of temperature.

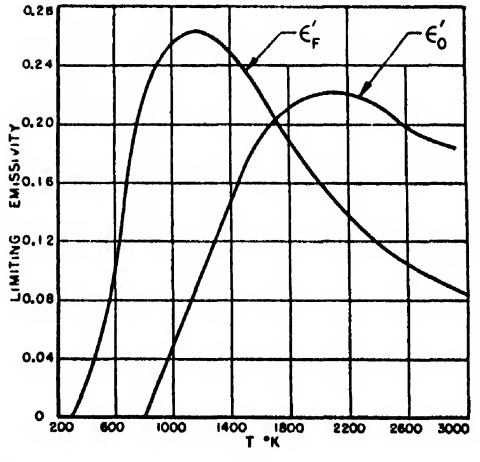

FIG. 4. Limiting emissivity of HBr as a function of temperature.

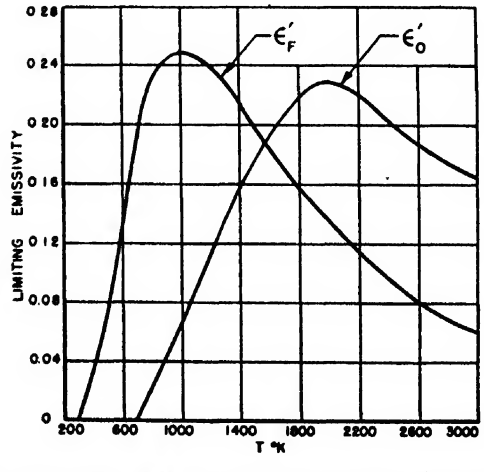

FIG. 5. Limiting emissivity of HCl as a function of temperature.

[22] M. W. Wolkenstein, J. Phys. USSR 5, 185 (1941); A. M. Thorndike, A. J. Wells, and E. B. Wilson, Jr., J. Chem. Phys. 15, 157 (1947); A. M. Thorndike, J. Chem. Phys. 15, 868 (1947).

fortunate that the effective band width does not vary rapidly with the pressure of absorbing gas.[16] This conclusion follows most obviously from an examination of the term $\exp(-P_e pl)$. The exponent is seen to be proportional to the optical density (pl) but changes with rotational quantum number as $j\exp(-E_{o,j}/kT)$. Since the effective band width is relatively insensitive to optical density, we are justified in concluding that curves of the limiting emissivity as a function of temperature for the fundamental vibration-rotation band, of the type shown in Fig. 2 for CO, represent a valuable indication of the semiquantitative variation of emissivity with temperature over a wide range of partial pressures of absorber at elevated total pressure and constant path length. As the partial pressure of the absorber is increased, the expected emissivity will exceed the limiting emissivity of the fundamental by roughly the amount contributed by the second term on the right-hand side of Eq. (11).

IV. APPLICATION TO DIATOMIC MOLECULES

The spectral emissivity for a number of diatomic gases can be determined, approximately, from available experimental data on integrated absorption by utilizing the method for calculating emissivities outlined in Section III-B. It should be noted that approximate heat-transfer calculations by the method proposed in this report will, in general, become less accurate as the rotational spacing increases. For example, emissivity calculations for HF (rotational spacing $\simeq 40$ cm^{-1}) will be considerably less reliable than for CO (rotational spacing $\simeq 4$ cm^{-1}) at a pressure of a few hundred pounds per square inch, because of inadequate overlapping of the rotational lines of HF. Since considerable uncertainty exists regarding the numerical value of the integrated absorption and of the corresponding effective charge, we shall present here only a tentative compilation of experimental data without extensive emissivity calculations. More reliable values for the integrated absorption should become available as the result of current measurements on diatomic molecules.[23]

A. Effective Band Widths for Diatomic Molecules at Different Temperatures

The results of effective band width calculations for CO have been presented in Tables I and II. Similar data for HI, HBr, HCl, and HF are given in Tables III to X.

It is a simple matter to calculate the ratios

$$\epsilon_F' = \left\{\sum_n \int_{\Delta\nu_{n\to n+1}} \rho(\nu)d\nu\right\} \Big/ \int_0^\infty \rho(\nu)d\nu$$

and

$$\epsilon_0' = \left\{\sum_n \int_{\Delta\nu_{n\to n+2}} \rho(\nu)d\nu\right\} \Big/ \int_0^\infty \rho(\nu)d\nu$$

by use of the effective band widths listed in Tables I to X. The results of these calculations for CO have been plotted in Fig. 2 and were discussed earlier in this paper. Limiting emissivities for the hydrogen halides obtained in this manner are shown in Figs. 3 to 6.

B. Effective Charges of Diatomic Molecules

The integrated absorption for the fundamental and the first overtone of CO was measured by a novel indirect method by Matheson in 1932.[24] He reported the values

$\alpha_{01} = 1.182\times 10^{13}$ (cm-atmos.)$^{-1}$ sec.$^{-1}$ at 300°K,
$\alpha_{02} = 1.54\times 10^{11}$ (cm-atmos.)$^{-1}$ sec.$^{-1}$ at 300°K.

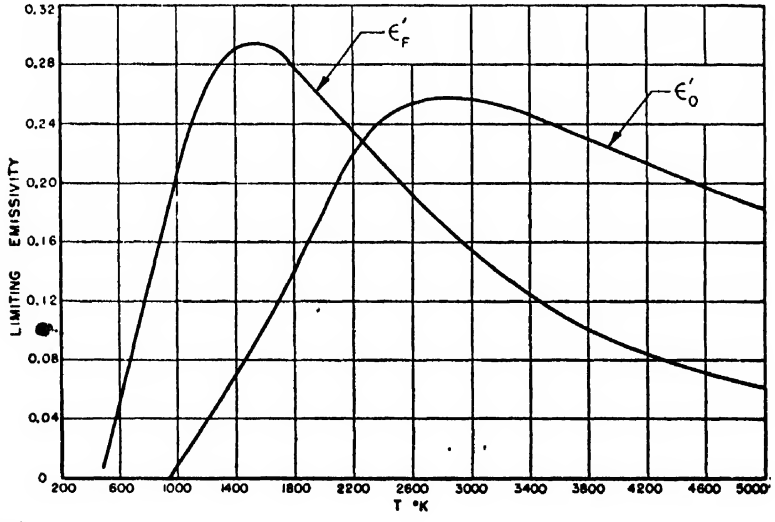

FIG. 6. Limiting emissivity of HF as a function of temperature.

[23] S. S. Penner and D. Weber (to be published).
[24] L. A. Matheson, Phys. Rev. 40, 813 (1932).

From the value of α_{01} it is seen that the effective charge of CO is $\epsilon_F = 3.9 \times 10^{-10}$ e.s.u.

The effective charges ϵ_F for three of the hydrogen halides have been determined by Bartholomé.[25] This work has been criticized by Kemble[26] because of lack of adequate spectral resolution used in making absorption measurements. In this connection it should also be noted that the value for the integrated absorption of HCl reported by Bartholomé is considerably smaller than the corresponding value observed by Bourgin some years earlier,[27] which was later shown to be in agreement with the value of the effective charge calculated from infrared dispersion measurements.[28]

For HI, HBr, and HCl Bartholomé[25] reported effective charges of $0.033e$, $0.075e$, and $0.086e$, respectively, where e is the charge of an electron. In order to estimate ϵ_F for HF, it was decided to extrapolate the values for the other hydrogen halides by plotting ϵ_F/e as a function of the electric moment μ' divided by the normal interatomic distance r_0 of the hydrogen halides.[29] The electric moment μ' for monomeric HF has been reported as 1.91×10^{-18} e.s.u.[30] A plot of ϵ_F/e as a function of μ'/r_0 was found to lead to the result $\epsilon_F \simeq 0.11e$ for HF. According to the measurements of Bourgin[27] and Rollefson and Rollefson[28] it appears likely that these values for the effective charges are too small. As an approximate correction, multiplication by the factor (1/0.42) of all the effective charge values of the hydrogen halides is suggested. The correction factor (1/0.42) represents the ratio of the effective charge of HCl reported by Rollefson and Rollefson[28] to the effective charge of HCl observed by Bartholomé.[25]

Reliable experimental values of the integrated absorption for the first overtone for the hydrogen halides are not available. For this reason it is suggested to calculate $\bar{k}_0$ directly by use of a theoretical relation derived by Rosenthal[31] which can be shown to lead to the relation

$$\frac{k_0}{\bar{k}_F} = \frac{x_e(1-5x_e)}{(1-3x_e)^2}, \tag{24}$$

where x_e is the anharmonicity constant for the molecule under discussion. Equation (24) gives a lower limit for the average absorption coefficient $\bar{k}_0$ since the derivation of this relation includes only contributions to the intensity of the first overtone resulting from the first term in the expansion of the electric moment in terms of internuclear distance. The calculated lower limit for the intensity of the overtones represents a reasonably good approximation to the true intensity in some cases. This assertion has been verified for HCl by comparison with measured intensity ratios.[31] The ratio $x_e(1-5x_e)/(1-3x_e)^2$ is seen to be somewhat smaller than the integrated intensity ratio of overtone to fundamental for CO, using Matheson's data.[24]

C. Application to Emissivity Calculations

The results listed in Tables I to X, together with the quantitative absorption measurements summarized in Section IV-B, provide the data necessary for approximate emissivity calculations at elevated total pressures. Because of the uncertainty in the quantitative absorption measurements, we shall not present extensive emissivity tables at this time but rather illustrate the method of calculation by a representative example.

It is desired to determine the emissivity of HF at 3000°K when the gas is uniformly distributed through a radiation path length l of 10 cm and the partial pressure of undissociation HF is 15 atm.[32] The total pressure is 25 atm.

From the data given in Section IV-B the average absorption coefficients are found to be $\bar{k}_F = 2.41 \times 10^{-3} \times (1/0.42)^2 = 13.7 \times 10^{-3}$ (cm×atmos.)$^{-1}$ and $\bar{k}_0 = 4.64 \times 10^{-5} \times (1/0.42)^2 = 26.3 \times 10^{-5}$ (cm×atmos.)$^{-1}$, respectively. Using the limiting emissivity plots of Fig. 6 we find for the upper limits of the emissivities of the fundamental and the first overtone the values 0.155 and 0.256, respectively. Hence the emissivity ϵ' is

$$\epsilon' = [1-\exp(-13.7\times10^{-3}\times15\times10)]0.155 + [1-\exp(-26.3\times10^{-5}\times15\times10)]\times0.256 = 0.144.$$

The author takes pleasure in expressing his appreciation for many stimulating discussions to Dr. Martin Summerfield, who initiated the program of the calculation of gaseous emissivities from spectroscopic data. The numerical calculations were performed by the computing group of the Jet Propulsion Laboratory under the supervision of Mrs. Macie Roberts.

[29] This extrapolation of observed values of ϵ_F for HCl, HBr, and HI to yield the effective charge ϵ_F for HF is based on the relation $\epsilon_F = (d\mu'/dr)_{r=r_0} \simeq 3\mu'/r_0$ which, although apparently not valid for the hydrogen halides, may give a reasonable relation for the change of ϵ_F with μ'/r_0. The effective charge of HF will be measured in the near future. The effect of association of HF on emissivity has been neglected since association would not be expected to be of importance at elevated temperatures.

[32] It should be noted that p always refers to the partial pressure of the undissociated emitter since the atomic species H, C, O, I, Br, Cl, and F do not radiate in the infra-red and therefore do not make an appreciable contribution to radiant heat transfer at temperatures below about 5000°K.

X-Ray Measurement of Long Range Order in β-Brass*

D. CHIPMAN AND B. E. WARREN
Massachusetts Institute of Technology, Cambridge, Massachusetts
(Received February 6, 1950)

The long range order in β-Brass has been determined by measuring the integrated intensity of the (100) superstructure reflection from a single crystal held at various temperatures. With a single crystal, and CuKα-radiation obtained by a balanced Ni-Co filter, there is ample intensity for measurement with a Geiger counter spectrometer. The measured long range order parameter S is in satisfactory agreement with the theoretical predictions.

I. INTRODUCTION

THE β-Brass phase exists at about the composition CuZn. There is a critical temperature of approximately 465°C, above which the structure is disordered body-centered cubic, and below which it is an ordered CsCl structure. In a perfectly ordered AB structure, the A atoms are at α-sites and the B atoms at β-sites. In a structure with partial long range order, if r_α represents the fraction of α sites rightly occupied by an A atom, the Bragg and Williams[1] long range order parameter is given by $S=2r_\alpha-1$. For perfect order $S=1.0$ and for complete disorder $S=0.0$. For an AB structure with partial long range order, the structure factor is given by

$$F=[f_B r_\beta+f_A(1-r_\beta)]+[f_A r_\alpha+f_B(1-r_\alpha)]\times\exp[\pi i(h+k+l)].$$

For the superstructure reflections $h+k+l=$ odd

$$F=(f_B-f_A)(2r_\alpha-1)=(f_B-f_A)S. \qquad (1)$$

The integrated intensity is proportional to F^2, and hence a measurement of the integrated intensity of a superstructure reflection gives directly the square of the long range order parameter.

Since $(f_{Zn}-f_{Cu})$ is small, superstructure lines on a powder pattern of β-Brass are extremely weak. The difference in scattering factors has been increased by the use of ZnKα-radiation[2] and it can be further enhanced by the use of crystal monochromated CuKβ-radiation. However, by using a single crystal of β-Brass, the (100) reflection is strong enough to be readily measured. In general, with crystal monochromated radiation there will be a half-λ from the continuous spectrum reflected from (200) of the sample and superimposed on the (100) peak. This can be eliminated by using (111) of fluorite as the monochromator. We have used CuKα-radiation with a balanced Ni-Co filter and the tube run at 15 kv constant potential. This eliminated half-λ-difficulties and gave ample intensity for the measurements.

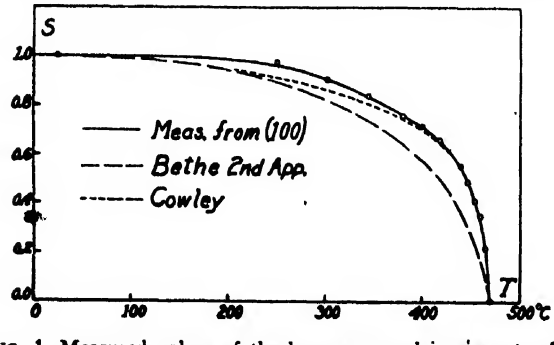

FIG. 1. Measured values of the long range order parameter for β-Brass compared with theoretical values.

II. MEASUREMENT OF LONG RANGE ORDER IN β-BRASS

The single crystal of β-Brass was cut parallel to a (100) face and polished and etched. It was mounted in a small furnace provided with a Ni foil window for the primary and diffracted beams. A slow stream of nitrogen was used to prevent oxidation. The temperature was measured by a thermocouple fastened to the back of the crystal. The crystal was mounted at the center of a Geiger counter spectrometer. With a wide counter slit and fixed position of the counter, rocking curves were made plotting intensity as a function of crystal angle.

The long range order at room temperature was measured by comparing the integrated intensities of (100) β-Brass and (600) NaCl.

$$A_{CuZn}\left[\frac{F^2(L\cdot P)e^{-2M}}{\mu v_a^2}\right]_{NaCl}=A_{NaCl}\left[\frac{F^2(L\cdot P)e^{-2M}}{\mu v_a^2}\right]_{CuZn}, \qquad (2)$$

where A is the measured rocking curve area, F is the structure factor, $(L.P.)$ is the Lorentz-polarization factor, e^{-2M} is the temperature factor, μ is the linear absorption factor, and v_a is the unit cell volume. The Hönl correction[3] was applied to the scattering factors. From (2) we obtain F for β-Brass in absolute units, and using (1) we get directly the long-range order parameter S. The value obtained was $S=1.08$. This value has been interpreted as meaning that within the

[3] R. W. James, *The Optical Principles of the Diffraction of X-Rays* (G. Bell and Sons, London, 1948), p. 608.

experimental error the long range order in β-Brass at room temperature is essentially perfect.

To measure long range order as a function of temperature, the crystal of β-Brass was held at a series of temperatures up to and above $T_c=465°C$. A rocking curve was made at each temperature. The rocking curve areas, corrected for a temperature factor e^{-2M}, are proportional to S^2. Normalizing the areas to make $S=1.00$ at room temperature, the values of S shown in Fig. 1 were obtained. The measured values of S are compared with the theoretical curves of Bethe[4] and Cowley.[5] The Cowley curve is a plot of the equation

$$\ln(1+S^2/1-S^2)=2S^2(T_c/T), \qquad (3)$$

using $T_c=738°K$. There is qualitative agreement with either curve. The quantitative agreement with the Cowley curve is probably within the experimental error.

III. ANTIPHASE DOMAINS IN β-BRASS

If antiphase domains in an ordered structure are small enough, they show up by a broadening of the superstructure lines. Although antiphase domains are to be expected in ordered Cu_3Au, the structure of ordered CuZn is such that they are not to be expected. However, it was thought worth while making a set of line breadth measurements to test the point. The counter slit was made very narrow and the counter set at a series of positions to plot out the diffraction peak. At each position of the counter, the crystal was turned at constant velocity through the reflecting range, and the total count recorded. The peak breadth obtained in this way is independent of any mosaic structure in the crystal.

Two samples were prepared; one cooled from above T_c to room temperature in five hours, and the other quenched from 500°C into brine. Both samples were then polished and etched, and peaks plotted out for the (100) reflection. Within experimental error the two breadths were the same--about 11 min. in 2θ. Although a measurement of the breadth of the (100) peak is not a sensitive test for antiphase domains, the results indicate that there is no prominent antiphase structure in β-Brass.

IV. EFFECT OF ANTIPHASE DOMAINS ON THE INTEGRATED INTENSITY OF A SUPERSTRUCTURE LINE

It is important in the determination of the long range order parameter that the integrated intensity of a superstructure reflection is independent of the existence of antiphase domains.

Imagine the ordered crystal to be divided into blocks N_1a_1, N_2a_2, N_3a_3, where N_1, N_2, N_3 are numbers of the order 10–20. Cells within a block are numbered $m_1m_2m_3$ and the blocks are numbered $n_1n_2n_3$. To allow for any system of antiphase domains or displacements within the crystal we assign an arbitrary phase $\varphi_{n_1n_2n_3}$ to the amplitude from each block. The amplitude of diffracted radiation from the crystal is then

$$\begin{aligned}\text{Amp}=F\textstyle\sum_m \exp[(2\pi i/\lambda)(s-s_0)\cdot(m_1a_1+m_2a_2+m_3a_3)]\\ \times\sum_n \exp[i\varphi_n]\exp[(2\pi i/\lambda)(s-s_0)\\ \cdot(n_1N_1a_1+n_2N_2a_2+n_3N_3a_3)],\end{aligned}$$

where F is the structure factor per cell and s, s_0 are unit vectors giving the directions of the diffracted and primary beams. Let

$$s-s_0=\lambda(h_1b_1+h_2b_2+h_3b_3),$$

where $b_1b_2b_3$ are the reciprocal vectors and $h_1h_2h_3$ are continuous variables. The intensity from the crystal is then

$$\begin{aligned}I(h_1h_2h_3)=F^2\textstyle\sum_m\sum_{m'}\exp[2\pi i\{h_1(m_1-m_1')\\ +h_2(m_2-m_2')+h_3(m_3-m_3')\}]\\ \times\{N_B+\sum_{\substack{n\ n'\\ n\neq n'}}{}'\exp[i(\varphi_n-\varphi_{n'})]\\ \times\exp[2\pi i\{h_1N_1(n_1-n_1')+h_2N_2(n_2-n_2')\\ +h_3N_3(n_3-n_3')\}]\} \qquad (4)\end{aligned}$$

where N_B is the number of blocks in the crystal.

The measured integrated intensity of a reflection is proportional to an integral of the interference function throughout a sufficient region in reciprocal space about the point hkl to include everything contributing to the hkl reflection.

$$P=K\int\int\int I(h_1h_2h_3)dh_1dh_2dh_3. \qquad (5)$$

Substituting (4) in (5) and considering a term $n\neq n'$

$$\begin{aligned}\int_{h-\frac{1}{2}}^{h+\frac{1}{2}}\exp[2\pi ih_1\{(m_1-m_1')+N_1(n_1-n_1')\}]dh_1\\ =\exp[2\pi ih\{(m_1-m_1')+N_1(n_1-n_1')\}]\\ \times\frac{\sin\pi\{(m_1-m_1')+N_1(n_1-n_1')\}}{\pi\{(m_1-m_1')+N_1(n_1-n_1')\}}.\end{aligned}$$

The integrals are zero for all terms where $n\neq n'$ and

$$\begin{aligned}P=KF^2N_B\int\int\int\textstyle\sum_m\sum_{m'}\exp[2\pi i\{h_1(m_1-m_1')\\ +h_2(m_2-m_2')+h_3(m_3-m_3')\}]dh_1dh_2dh_3.\end{aligned}$$

The measured integrated intensity is the number of blocks N_B times the integrated intensity from each block and independent of the arbitrary phases φ_n. Hence a measurement of the long range order parameter S from the integrated intensity of a superstructure reflection is independent of whether or not antiphase domains exist in the ordered structure.

The Resolving Power of an X-Ray Microscope

EDWARD PRINCE*
General Electric Research Laboratory
(Received February 10, 1950)

A formula for determining the resolving power of an x-ray microscope built according to the design suggested by Kirkpatrick and Baez is derived, and an estimate of that resolving power given. The optimum resolving power is such as to resolve points separated by a distance of the order of 2000A.

INTRODUCTION

PAUL Kirkpatrick and A. V. Baez[1] have described a method of forming optical images with x-rays, making use of the total reflection at grazing incidence. The x-rays are reflected from two cylindrical mirrors in such a way that one mirror brings all horizontal lines to a focus, and the other brings all vertical lines to a focus. On the basis of diffraction theory, Kirkpatrick and Baez set the limit of resolution of such a system at about 70A, assuming perfect geometrical focusing and unit magnification. Since perfect focusing with mirrors is a condition which may be achieved only for infinitesimally small objects, these assumptions are not directly applicable to the analysis of an actual x-ray microscope built according to this design, and it is, therefore, desirable to make an estimate of the optimum conditions in a practical instrument, taking into consideration both the geometrical and the diffraction effects at the same time.

MATHEMATICAL ANALYSIS

In order to evaluate the combined effects of geometrical aberration and diffraction, let us first derive an applicable formula for each in turn. The effect of diffraction can be determined easily from the usual

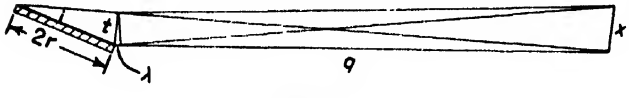

FIG. 1.

formula (see Fig. 1):

$$x=(\lambda q)/t \tag{1}$$

where x is the separation of two resolved spots in the image; t is the width of the aperture; q is the distance from the aperture to the image; and λ is the wavelength. Let y be the resolution, p the distance from the object to the aperture, and $2r$ the width of the mirror. The resolution is then:

$$y=(xp)/q \quad \text{or} \quad y=(\lambda p)/t. \tag{2}$$

If i is the critical glancing angle, and is small, so that $\sin i=i$, then the resolution due to diffraction is given by:

$$t=2ri, \quad y=(\lambda p/2ri). \tag{3}$$

It is now necessary to find an expression for the resolution in terms of the geometrical aberrations. This is difficult, because it is dependent on the distribution of intensity around the focus, but the distance by which the extreme ray misses the focus gives a sufficient condition which probably does not differ from the necessary condition by more than a factor of 2 or 3. Kirkpatrick and Baez evaluate this quantity for a circular section:

$$y=\tfrac{3}{2}(r^2/R) \tag{4}$$

where R is the radius of curvature and $R\gg r$. A minimum value of y may be obtained by equating expressions 3 and 4, giving:

$$\frac{\lambda p}{2ri}=\frac{3r^2}{2R}, \quad r=\left(\frac{\lambda pR}{3i}\right)^{\frac{1}{3}} \tag{5}$$

or

$$y=\left(\frac{3\lambda^2 p^2}{8Ri^2}\right)^{\frac{1}{3}}. \tag{6}$$

CONCLUSION

If $p=10$ cm $R=20$ m and i is the value used by Kirkpatrick and Baez, $i=7\times10^{6}\lambda$, then y is equal to about 3400A. By the use of different curves and with skillful operation, it is probable that this figure can be reduced by a factor of 2, and possibly by as much as a factor of 4, but it is highly doubtful that the limit can be reduced much more than that in a practical instrument with reasonable magnification. This makes the x-ray microscope potentially an instrument with resolution between that of the ordinary optical microscope and that of the electron microscope, with an advantage of high penetrating power.

The author wishes to express his thanks to Dr. David Harker and Miss C. M. Lucht, of the General Electric Research Laboratory, who suggested this investigation.

Metallic Evaporation and the Diameter of Tobacco Mosaic Virus with the Electron Microscope*

H. KAHLER AND B. J. LLOYD, JR.
National Cancer Institute, Bethesda, Maryland
(Received March 13, 1950)

Tobacco mosaic virus has been used as a known test object for the intercomparison of several methods of small particle measurements, all involving metallic evaporation. Various characteristics of these methods, which determine their accuracy, were investigated. Measurement of groups and the derivation of a mean size therefrom is primarily limited in accuracy only by the exactness of juxtaposition of the successive particles in the group. The measurement of the images of single particles is subject to the relatively large error associated with the uncertainty in the relationship between the true particle edge and the image of the edge which has received a coating of metal. The measurement of shadow lengths reduces this error by the factor $2\tan\alpha/2$. A symmetrical shadow method is described which reduces the error of substrate tilt, and is insensitive to amount of metal deposited. An average over the four best methods gave a value 150.0±3.6A agreeing closely with the x-ray determination.

INTRODUCTION

ONE of the most important problems in electron microscopy is the measurement of the size of small particles. The percentage errors which arise in such measurements obviously should increase as the size of the particle diminishes down to the resolving power of the instrument. The object of the present investigation was to intercompare several methods of measurement in regards to general accuracy and reliability. Tobacco mosaic virus, TMV, is one of the few small objects which have been extensively studied for size (diameter) and its use as a test object would appear to be satisfactory for the present study. The methods studied all involved the evaporation of metallic films upon the specimen; it was, therefore, necessary to make some supplemental studies upon the relation of metal film to TMV particle.

While this study was under way an inter-laboratory comparison of a much larger particle (polystyrene latex Dow No. 580) was initiated by Gerould[1] following the work of Williams and Backus. Agreement to ±2 percent was obtained by 12 out of 16 laboratories for the mean of the particle size, the value reported by us being 2600±65A, which was within 0.4 percent of the inter-laboratory mean. In certain phases of our work this material was therefore used for determination of magnification power.

METHOD

The preparation of TMV was put on Formvar films (the Formvar having been cleared of large aggregates by a one hour centrifugation at 20,000×g). The different arrangements of components in the vacuum evaporator is illustrated in Fig. 1. Single filament evaporation takes place with the filament at Y_1, and double evaporation with filaments at Y_1 and Y_2. The angle α, of evaporation, is 90 degrees with the filament at the position Y (vertical evaporation). When the long axis of the TMV is in the direction OX, it is parallel to the evaporation beams from Y_1 and Y_2, and when in the direction OZ it is perpendicular to the evaporation beam.

The electron microscope was used without an objective aperture. The microscope calibration was done with a 20,000 line/inch diffraction grating replica, coated with chromium, and in some cases with polystyrene latex (Dow No. 580). Low magnification photos (×8000) were made with the unbiased gun and large angle of illumination while high resolving power photos at ×23,000 were taken with the biased gun, compensated objective and an additional fine focusing potentiometer.

Method I. Group Measurement

It is possible to obtain the metal coated specimen in the form of a horizontal linear array of particles or monomolecular film,[2] which is in some respects a one-dimensional crystal. Measurement across a number of the particles, excluding the extremes of the array, gives

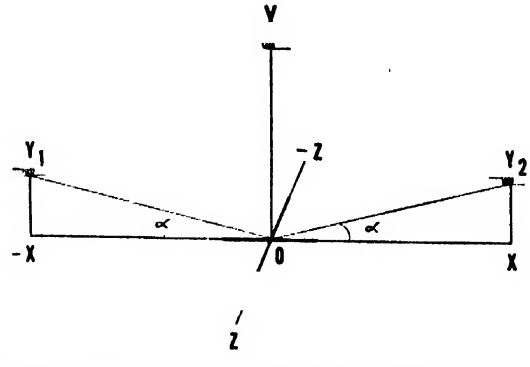

FIG. 1. Sketch of set-up in vacuum evaporator. Filaments at Y_1 for single evaporation, at Y_1 and Y_2 for double evaporation and at Y for vertical evaporation. Long axis of TMV in direction OX, evaporation parallel to axis; TMV in direction OZ, evaporation perpendicular to TMV axis.

an average particle spacing which is independent of the metal coating and boundary diffraction effects. The chief uncertainty in this procedure is in the unknown juxtaposition of consecutive particles. It was shown by Bernal and Fankuchen[3] that the minimum particle spacing in a TMV gel was 175A, with a hexagonal close packed two-dimensional lattice. When this gel was air dried to a hexagonal crystal the spacing shrank to 152A decreasing to 150A upon vacuum drying over P_2O_5 with a high degree of uniformity in size. These authors postulated a water shell on the particles about 10A thick, preventing a closer approach than 175A as long as any free water was present. From this it may be concluded that TMV particles deposited from the aqueous film onto the Formvar screen have a minimum spacing of 175A while still in the wet state. For such a system as the dried monomolecular TMV on the Formvar substrate, the x-ray data gives no direct evidence as to the final packing dimension, though it could be argued that the spacing should be somewhere between 150 and 175A.

Experimentally,[4] a value of 152 without an estimate of deviation has been reported, and a value 130±6A was assigned to a related cucumber virus where the 6A refers to deviation between group means σ_M rather than individual variation. We have found that the mean for different groups of 8 to 20 TMV particles range in size from 152 to 160A with a standard deviation σ_M between groups of 3A and a mean of 155A. The variation in packing and measurement of individual particles

[3] J. C. Bernal and I. Fankuchen, J. Gen. Physiol. 25, III (1941).

[4] C. A. Knight and G. Oster, Arch. Biochem. 15, 289 (1947).

σ deduced from groups of 10 would obviously be larger as $\sigma = (n-1)^{\frac{1}{2}}\sigma_M = 9$A where n is the number of particles per group. From this it would appear that those groups of particles which have the smallest spacing or are packed the closest give nearest to the x-ray measurement for a completely desiccated particle. It also indicates that desiccation on the screen is accompanied by a shrinkage of the group spacing from 175A to a value close to 150A.

A variation of this procedure namely a replication of crystal surfaces should give an even closer correspondence with Bernal and Fankuchen's results.

It appears that the group method gives a mean value whose error is only slightly larger than the usual calibration errors of the electron microscope.

Method II. Direct Measurement on Doubly Coated Particles

This method consists in evaporating a thin coating of metal, from two oppositely placed filaments, upon opposite edges of the particles, and measuring the distance across the highly magnified image of particles having their long axis perpendicular (*OZ*) Fig. 1 to the metal beam direction.

For the direct measurement of particle diameter, the electron microscope was fitted with a compensated objective to reduce astigmatism[5] and to increase resolving power (estimated to be 20A).

Using the double coating method it was found possible to decrease the amount of evaporated chromium to the point where shadows were scarcely visible but contrast of the particle edges was sufficient for measurements, (Fig. 2). In this photo the apparent widening of the particles is evident as the particles approach a perpendicular direction to the evaporation beam. This widening is more rapid than would be expected on the basis of the amount of metal deposited on the particle. Actually, the particles parallel to the evaporation beams are narrower than the calculated value. In Fig. 3 there is shown a focal series for two particles, one a long aggregated virus rod nearly perpendicular to the direction of the evaporation beams (arrows) and a shorter rod nearly parallel to the beam direction. Figure 3 is reproduced as a print of a negative since previous authors have used such prints in discussing diffraction patterns. As an aid to the estimation of the in-focus position, the diffraction fringes on a polystyrene latex sphere placed on the screen after shadowing were noted (Fig. 2). The magnitude of the out-of-focus position was estimated from the data obtained for displacement of the specimen *versus* objective lens currents after the method of Hillier and Ramberg.[5]

This series is characterized by two minima (black) near each edge of the rods for the overfocused positions and a single minimum near the edge for the underfocused images. The measurement across the diameter

[5] J. Hillier and E. G. Ramberg, J. App. Phys. 18, 48 (1947).

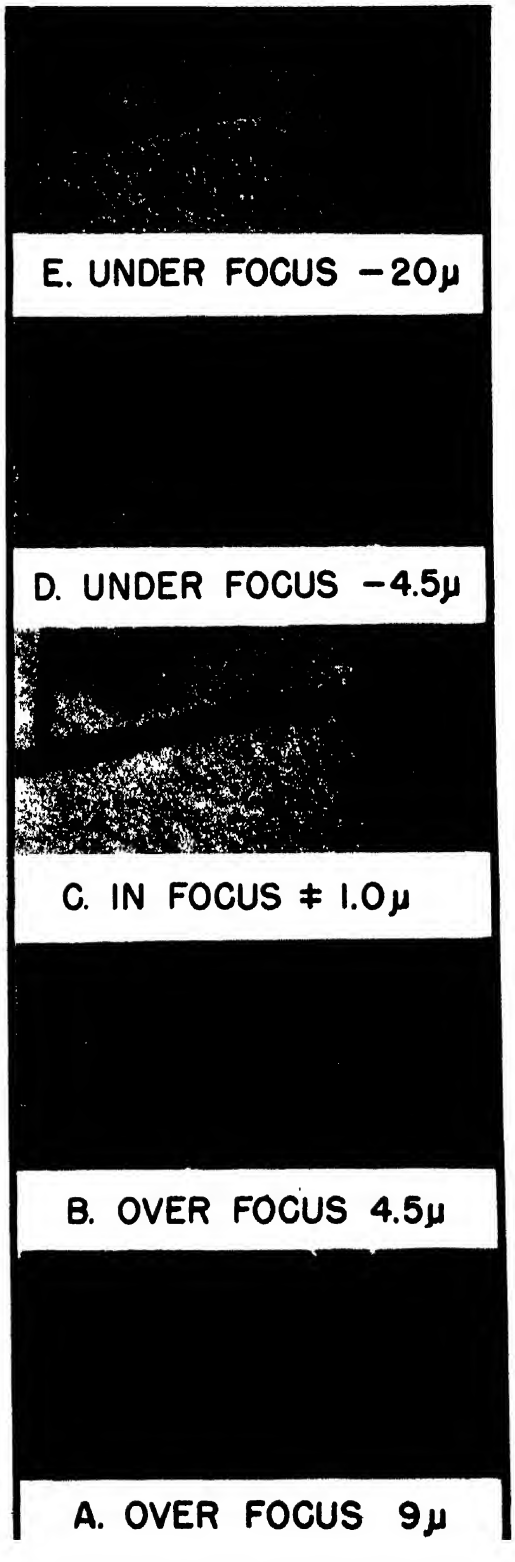

FIG. 3. Focal series of TMV double coated with 2×5.5 mg Cr $\tan\alpha = 2/12$ biased gun, compensated objective. In-focus position estimated with aid of diffraction pattern of polystyrene latex spheres added to the specimen screen after shadowing (not shown). Direction of evaporation beam shown by arrows. Print of negative.

of the particles between fringe centers in the three upper pictures (*c*, *d*, *e*) is approximately the same (to within ±10A); in the lower pictures (*a*, *b*) a similar value is obtained when the measurement is made between the mid-point, (maximum), of each pair of fringes. Thus, over a focal range of 29μ, an invariant measurement (to within ±10A) is obtained between selected points of the edge fringes.

The diffraction minima of the metallic coating cannot be exactly defined in position with respect to the original uncoated particle edge. Part of this uncertainty lies in the variable difference between effective thickness of the metal and its calculated thickness. When a light coating of chromium is deposited on the particle edges in a perpendicular direction, the intensity minima of the slightly underfocused images lie between the middle of the coating and the outer coating edge.

A series of measurements showed that the distance between fringe minima was 10±20A larger than the calculated distance between the centers of the metallic coatings.

For other positions of the TMV such as long axis parallel to the evaporation beam the disposition of metal is no longer principally upon the extreme edges so that frequently the images are too narrow. The same holds for vertical evaporation (filament at *Y* Fig. 1).

Method III. A Combination of I and II

A light symmetrical coating is deposited as in method II, producing intensity minima near the edge of the particles. Then two particles lying side by side are compared with a single particle close by and parallel in order to eliminate the edge error. For the single particle the measured distance between fringe centers reduced by the magnification factor is,

$$X_1 = D + 2e$$

where *e* is the amount by which the fringe deviates from the true edge, *D* is the true diameter.

For the double particle,

$$X_2 = 2D + 2e$$

from which

$$X_2 - X_1 = D.$$

The value obtained by this procedure was 152±11A.

The chief precautions to be observed are equality of shadowing and, as in method II, the use of high magnifications.

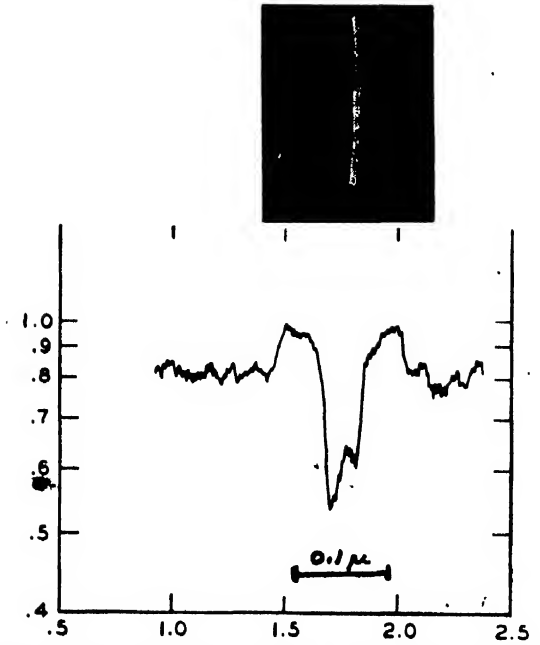

FIG. 4. Microphotometer tracing across a photo of a double shadowed virus particle. Two shadow beams of chromium were unequal, resulting in unequal metallic coatings. Print of a positive. Non-biased gun, low power original.

Method IV. Direct Measurement Following Single Metallic Coating

Coatings of gold of a series of thicknesses were deposited on the TMV by evaporation from a single filament at an angle of 10 degrees. The measurement was made across the particle. This method has all the faults of the double coating method (II) and in addition, the more serious error which asymmetry introduced into the measurement giving values too erratic to quote.

Method V. Double Shadows

The set-up for the production of double shadows is identical with that of the double coating procedure (II), with evaporation sources at Y_1, Y_2. The only difference is in the employment of a larger amount of metal to be evaporated.

A microphotometer tracing (courtesy of W. C. White of these laboratories) of a photograph of a heavily shadowed particle is shown in Fig. 4. In this experiment, more metal was incident on the particle in one direction than in the opposite direction resulting in unequal shadows and a displacement of the central line. Figure 5 illustrates the case where the two metal beams are nearly equal.

One of the sources of error in the single shadow method (VI) described in a following section, is variation in shadow length due to unknown local tilting of the substratum.[6,7] In the double shadow method, this error is considerably diminished, since a tilt in the substrate results in a shortening of one shadow and a lengthening of the other shadow, the two errors partially compensating.

Thus, if the shadowing beam in the evaporator makes an angle α with the horizontal and the substrate is tipped at an angle β with the horizontal, $2X$ being the length of the total shadow on the horizontal plane, the length of the shadow on the tilted plane is

$$B_1 + B_2 = X\left[\frac{\sin\alpha}{\sin(\alpha+\beta)} + \frac{\sin\alpha}{\sin(\alpha-\beta)}\right],$$

[6] F. W. Boswell, British J. Exp. Path. **28**, 253 (1947).
[7] R. C. Williams and R. C. Backus, J. App. Phys. **20**, 98 (1949).

where B_1 is the short shadow, B_2 the long shadow. For $\alpha=10°$ and $\beta=3°$, B_1 is 77 percent of X, B_2 is 142 percent of X while the sum or double shadow length is 110 percent of $2X$.

It is obvious that a simple inspection of a double shadowed photograph will given an estimate of the flatness and angle of the substratum. Such photographs yield fairly consistent values for the particle height

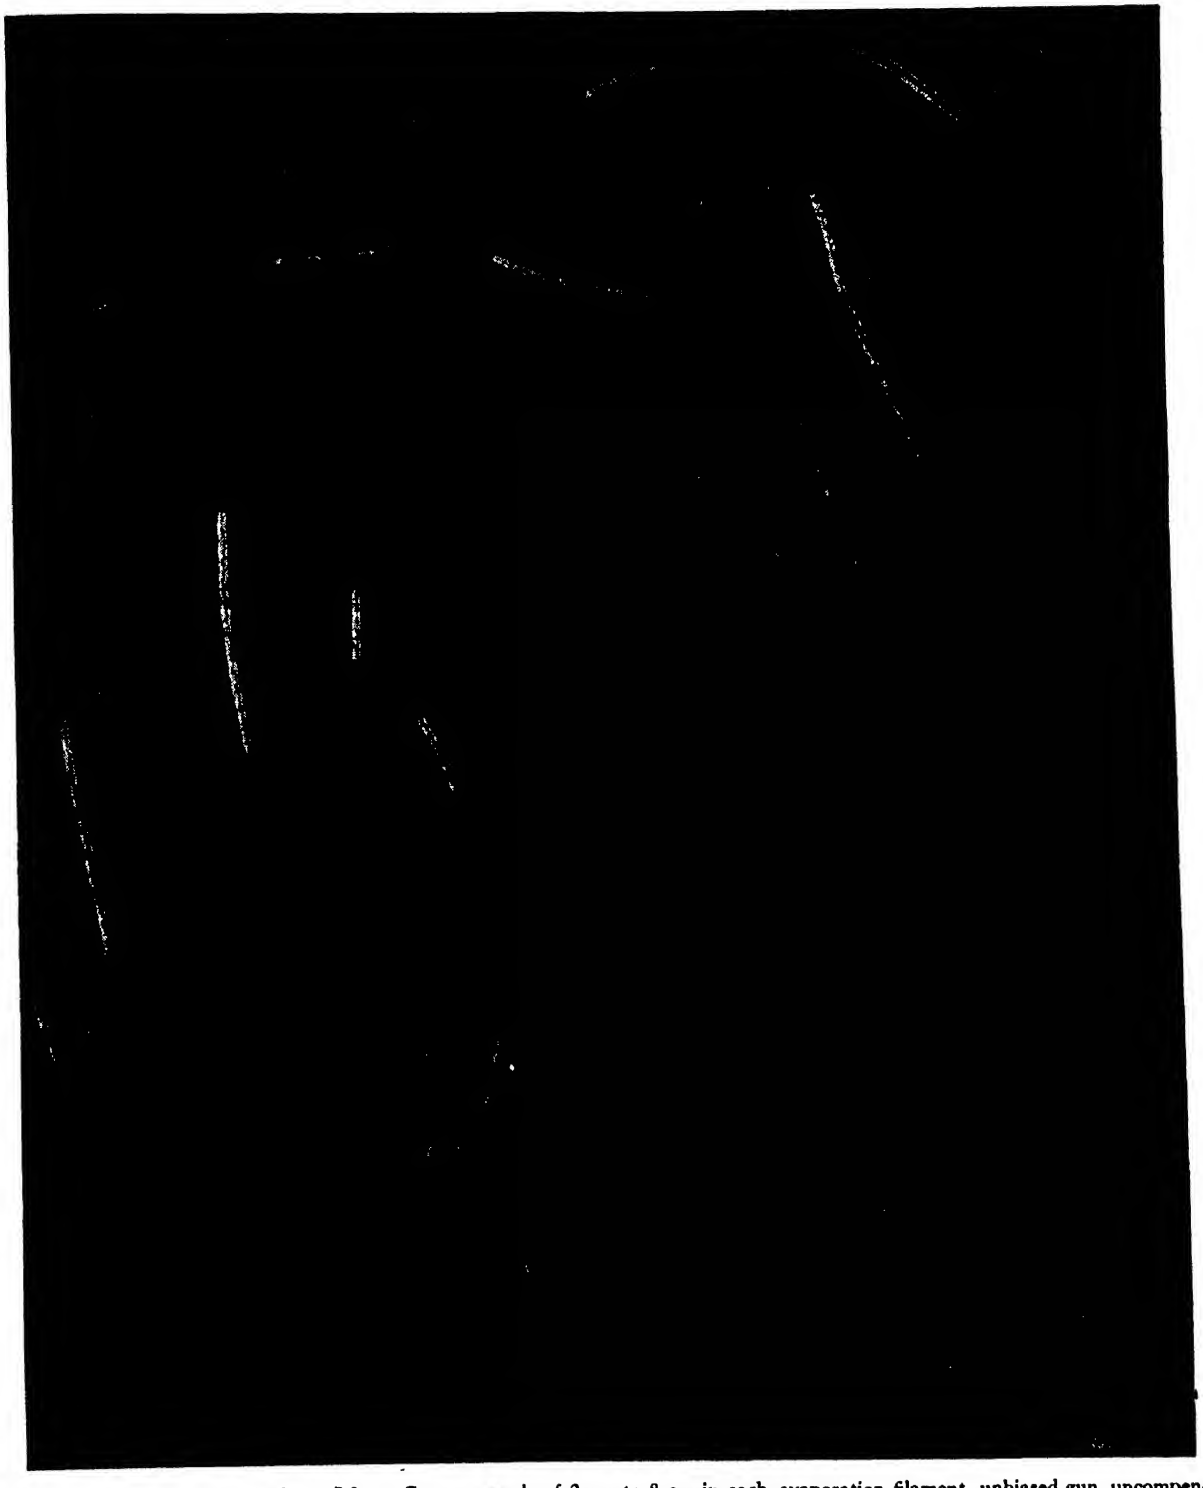

FIG. 5. Heavy Cr double shadows, 7.2 mg Cr at an angle of 2 cm to 8 cm in each evaporation filament, unbiased gun, uncompensated objective. Arrows indicate direction of chromium evaporation beams. Print of a positive.

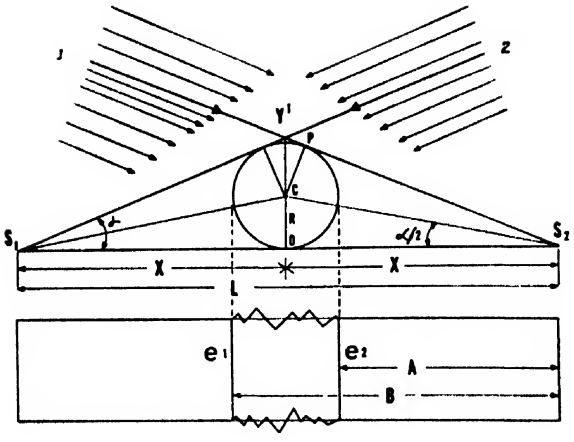

FIG. 6. Diagram of shadowing detail. Single evaporation from filament at 1, shadow measured A or B. Double evaporation from 1 and 2, double shadow length is L.

from $2R=L/M\tan\alpha/2$ where R is the radius of the particle, L is the double shadow length, M the magnification, α is the angle of evaporation. In all shadow methods the use of $2\tan\alpha/2$ instead of $\tan\alpha$ as is ordinarily done is preferable since from Fig. 6 $X\tan\alpha$ gives OY' whereas $2X\tan\alpha/2$ gives $2R$. The error in using $\tan\alpha$ instead of $2\tan\alpha/2$ for 10° is 1 percent, for 20° is 3 percent, for 30° is 8 percent and for 40° is 15 percent. The increase in the length of shadow due to accumulated metal on the top of the particle will be partially compensated by a shortening of the shadow due to an accumulation of metal on the backbround.

The double shadow method has the disadvantage of a low shadow contrast the metal thickness outside the shadow being twice that inside. In order to obtain the maximum shadow contrast, lower magnifications (8000–10,000) have been more satisfactory than photographs taken at 20–25,000 times.

The Formvar screens for these measurements were precoated with a thin layer of evaporated aluminum in order to prevent any sinking of the particles into the Formvar. Then TMV was put on the aluminum surface. In the evaporator the filaments were straight tungsten wires arranged horizontally with Au and Al[8] in the weight ratio 3.5/1 wrapped around the wires. This was done to obtain an accurate measurement of the evaporation angle. Latex No. 580 was then added to the screens for calibration of magnification. Measurements of the photographs of these specimens gave a value of 145.8±8.2A. This is within the expected errors in magnification and determination of exact shadow boundary.

[8] *International Critical Tables*, Vol. II, p. 402.

This method is therefore comparable in accuracy to group method I and method II.

Method VI. Single Shadows

Evaporation of metal from filament I, Fig. 6, gives a cast shadow[9] from which the diameter, $2R$, of the particle may be estimated either by measurement of distances A or B. Since $R=X\tan\alpha/2$, $X=A+R$ and $X=B-R$ by substitution

$$2R=\frac{2A}{M}\frac{\tan\alpha/2}{(I-\tan\alpha/2)}$$

and

$$2R=\frac{2B}{M}\frac{\tan\alpha/2}{(I+\tan\alpha/2)},$$

where M is the magnification. The errors made in estimating A and B are reduced to about 0.2 because of the trigonometric factor with a shadowing angle of 10°. The length B requires a correction for metal thickness at e_1; because of the comparatively heavy coatings required by shadowing methods a large fraction of the image appears opaque. The only recourse is to measure to the outer limit of the image and to subtract the full metal thickness to obtain B. It may be noted that the circle of confusion errors at the extremities of the B measurement tend to cancel out while for the A measurement they are additive.

The procedure which gave the most consistent results was the use of a system of 3 slits interposed between a line filament and the specimen screens 20 cm away in the evaporator in order to define the angle of evaporation, utilizing gold and the low intensity microscope gun. Measurements on 24 views gave for the A measurement 147.6±13A and for the B measurement 152.2 corrected to 146.2±14A. Despite the insignificant difference between these 2 values, the B measurement seems from other series of tests to be the more reliable of the two.

It may be remarked that the single shadow method gives a hybrid measurement, the shadow region corresponding to height and the remainder of the measurement across the particle being width.

SUMMARY OF MEASUREMENTS

An average taken over the better methods should reduce the methodical error. The mean of method (I) 155A, (III) 152A, (V) 146A, (VI) 147A, is 150.0±3.6A. This agrees with the mean value obtained by the x-ray method.

The Apparent Size of Objects as Observed in the Electron Microscope*

STANLEY F. KERN AND RAYMOND A. KERN
Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana
(Received March 24, 1950)

The image formed in the electron microscope of shadowed polystyrene latex spheres is larger than the image of unshadowed spheres. This increase in image size and probable causes are discussed. Implications of this phenomena on the study of viruses and other biological specimens are mentioned.

INTRODUCTION

IN our studies with the electron microscope it has been felt that there is a real difference in the image size of small objects depending upon whether they are shadowed or unshadowed. This difference has been thought by some workers to be accounted for by the increased contrast resulting from the deposition of the metal, together with the actual amount of metal deposited. This has not been a satisfying explanation.

After Williams and Backus[1] announced the remarkable uniformity of particle size of the small spheres in Dow Latex No. 580 *G*, Lot No. 3584, some of this material was obtained to use as a rapid internal check of magnification of the electron microscope. A few preliminary experiments indicated that the size of the image of the latex particle is different for shadowed and unshadowed specimens. Since these particles are remarkably uniform for a given method of sample preparation, it was felt that a study of size changes resulting from shadowing could be undertaken using the styrene particles as a standard specimen.

EXPERIMENTAL

Effect of Electron Bombardment

Since the proposed experiments were to involve exposing a specimen to the electron beam for a time longer than usual, and since it is well known that a specimen grows when bombarded,[2-4] it was necessary to ascertain the extent of growth of the Dow Latex particles under conditions of bombardment. In these experiments an early model *B*, RCA electron microscope with an unbiased gun, operating at 60 kv accelerating potential was used. For observation of the specimen a beam current of 250 microamperes was employed with a spot 7 to 10 microns in width, and 15 to 20 microns in length. The findings are summarized as follows:

1. Near the wire of the supporting screen bombardment of the specimen resulted in a rapid growth of the particle. Bombardment for eighteen minutes caused the diameter of the unshadowed balls to increase 570A u. while the shadowed balls had increased 320A u. This may or may not be a significant difference.

2. When observations are confined to the center of the opening the beam does not hit the wire of the supporting screen. Under these conditions bombardment for eighteen minutes resulted in a growth of the particles of about 80 A.° u. In eight minutes no size change could be measured. To more closely approximate the conditions to be expected in later experiments where repeated exposures were to be made, thirty exposures of one unshadowed field were made. No measurable change in size was found until the twenty-fifth exposure. It was concluded, therefore, that ten to fifteen exposures of a field could be made without danger of a measurable particle growth due to electron bombardment, if the field chosen was in the center of an opening.

Effect of Shadowing

In these studies a mixture of platinum and palladium was used as the shadowing metal. Fifteen milligrams of platinum and five milligrams of palladium were evaporated from a 20-mil tungsten filament placed 8.5 cm from the specimen. In all cases except where indicated

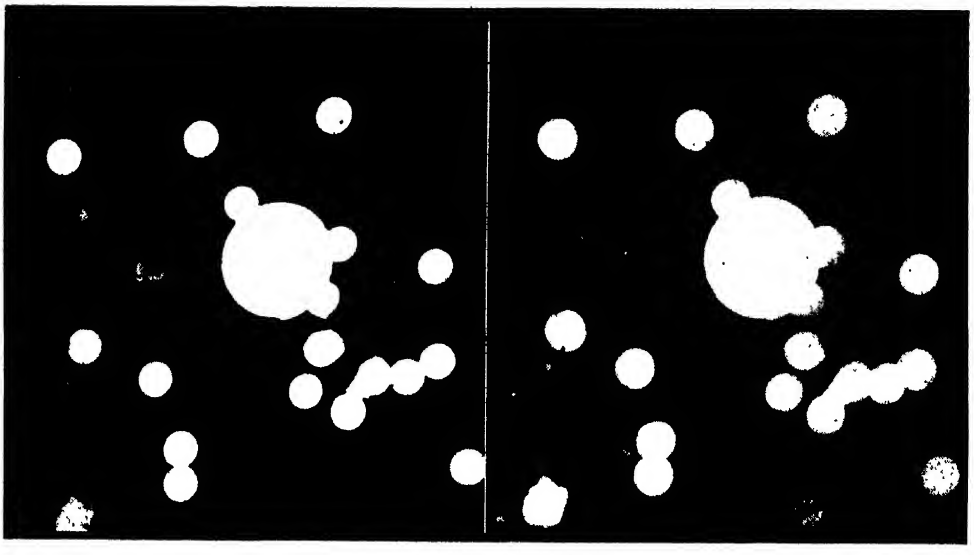

FIG. 2. (a) Latex particles before shadowing. (b) Same field after shadowing. 21,700×.

the angle of shadowing was 10°. A new filament was used for each experiment. The filament with shadowing metal in place was weighed before and after shadowing. The weight loss of the filament and metal was less than the combined weight of the platinum and palladium. It can be safely estimated, therefore, that a layer of metal 10A u. or less was deposited on a flat portion of the field.

Figure 1 is an electron micrograph showing shadowed and unshadowed polystyrene spheres in the same field. A small drop of the latex was allowed to dry on a replica of a diffraction grating and the sample shadowed. Then a second drop of latex was applied to the screen and allowed to dry. The shadowed balls are easily differentiated from the unshadowed balls and their size difference measured. The unshadowed balls measure 2590A u. ±50A u., whereas the shadowed balls measured 2840A u. ±50A u.

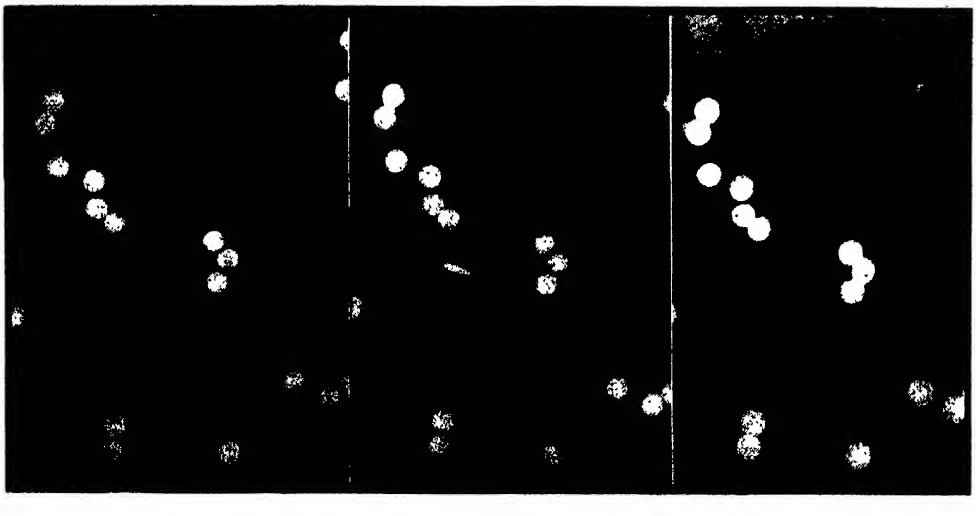
To determine the change of diameter on an individual sphere, micrographs were made of the same field before and after shadowing, Fig. 2. Again the size of the average sphere before shadowing was 2590A u. and after shadowing was 2840A u.

Measurements were made on only those particles which were not in contact with another particle. All measurements on shadowed spheres were made perpendicular to the direction of the shadow.

DISCUSSION

These results show that the image size changes when the specimen is shadowed and that the amount of change is relatively constant. At this time no definite explanation for the observed facts is offered. However, the following have suggested themselves.

One possible explanation is the deposition of extraneous materials during shadowing and electron bombardment. This possibility appears to be ruled out by our



(a) (b) (c)

FIG. 3. (a) Unshadowed latex particles; (b) Same field vertically shadowed; (c) Same field after oblique shadowing. 14,250×.

studies on the effect of electron bombardment on the size of the polystyrene spheres, and, secondly, by the fact that shadowing at a vertical angle does not cause a comparable change in particle size. This experiment will be discussed later. The sharp image obtained also indicates that this is not an over-all deposition of a scattering material.

A second possibility which was considered was the effect of contrast differences resulting from the shadowing. It was felt that possibly the addition of the highly absorbing metal film would materially affect the position of greatest contrast at the edge of the image and would, as a consequence, change its apparent size. Consideration of such a phenomenon shows that this effect could not account for any such large change in particle size.

A third possibility which presents itself is the possibility that a charge differential exists between the polystyrene sphere and its surroundings. If the spherical particle is charged negatively with respect to its surroundings, the potential gradient around the particle would constitute a negative electron lens acting on those electrons passing through and near the particle. Such a lens action would result in the size of the image of the sphere being smaller than would be expected if the sphere were not charged.

Shadowing the specimen at a low angle with a conducting film of platinum-palladium provides an electrical contact which substantially eliminates any charge differential between the particle and its surroundings. This reduces or eliminates the lens effect. The resulting image would be larger.

If this is correct, vertical shadowing of the spheres in such a way that no electrical contact is made between the metal cap on the sphere and the metal deposited on the film should result in no decrease of the charge on the particles, and the image size should be that of unshadowed particles. Figure 3 shows three electron micrographs of the same field—Fig. 3a before shadowing, Fig. 3b after vertical shadowing, and Fig. 3c after oblique shadowing. A just measurable increase in the size of the spheres was found for the vertical shadowed balls. This could be accounted for in that the amount of metal deposited on the ball and film in vertical shadowing was much greater than for oblique shadowing. The obliquely shadowed spheres in Fig. 3c are larger than the unshadowed and vertically shadowed spheres.

It appears that this experiment substantiates the charge theory; and it has been observed, also, that there is a difference in the position of the Fresnel diffraction lines on the shadowed and unshadowed side of a polystyrene sphere for any given setting of the objective lens current. This can be interpreted to mean that the shadowed side and the unshadowed side of the sphere are not brought simultaneously into the best focus.

Close observation of fields having spheres lying partially within the shadows of other spheres (see Fig. 3c) reveals that the portion of the sphere within the shadow of another sphere, and hence not shadowed, has a smaller radius of curvature than the adjoining portion which is shadowed. The sharpness of this effect leads one to believe that whatever the ultimate basic cause of these observations it must be well defined and intimately related to the presence or absence of a continuous film of metal.

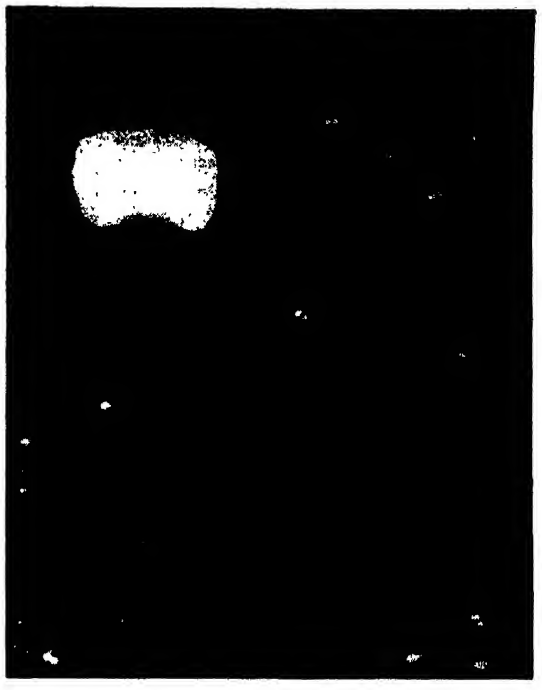


FIG. 4. *Streptomyces Griseus* Phage. The size differences between the shadowed and unshadowed phage are more than can be accounted for by the added platinum-palladium. 33,750×.

In spite of these findings it is still possible to use the spheres as a rapid check on calibration as well as for an internal standard of magnification calibration, if one first ascertains the image size to be expected for the condition under which the spheres are used.

The question arises whether objects other than polystyrene latex particles are also subject to this phenomenon. In Fig. 4 is shown one of the phages of *Streptomyces Griseus*. A few are within the shadow of the conidium; and therefore they are not shadowed. Others are outside the shadows and are themselves shadowed. The shadowed bodies are obviously much larger than the unshadowed. This is an indication that the same electron optical condition demonstrated for the polystyrene latex particles also affects the image size of these phage particles. If the present qualitative interpretation of these observations is correct, it is anticipated that this inherent error in apparent size of unshadowed objects in the electron microscope may be very generally encountered.

The Current-Hysteresis of the Electrolytic Aluminum-Oxide Rectifier

A. J. Dekker and Helen M. A. Urquhart
*Physics Department, University of British Columbia, Vancouver, British Columbia, Canada**
(Received January 3, 1950)

A hysteresis in the rectification of the contact aluminum-aluminum oxide-electrolytic solution was found by Dekker and van Geel. In the present paper, measurements of the current-voltage characteristics between 1 and 2000 cycles are described. A tentative explanation of the hysteresis is given in terms of a pre-breakdown phenomenon.

I. INTRODUCTION

WHEN, in a solution of ammonium-borate, an aluminum plate is used as anode and an inert counterelectrode as cathode, the current, for constant applied voltage, decreases with time until only a small current remains flowing.[1] During the decrease of the current an oxide layer is formed on the aluminum. The final thickness of the layer is approximately proportional to the applied voltage (formation voltage) and amounts to about 0.1 micron per 100 volts.[2] During the formation process the current is carried almost completely by ions migrating under the influence of the high electric field in the layer[3] (10^6-10^7 volts per cm). The small "leak-current" observed after the formation process has ceased is probably caused by electrons flowing from the solution through the oxide into the aluminum.[2] Because of the high capacity per unit area of these layers, they find application in electrolytic condensers. The so-called "porous-layers" will not be discussed in this paper.[4]

It is well known that the system aluminum-aluminum oxide-electrolyte exhibits rectifying properties: the currents are very small for the aluminum positive (below the formation voltage, of course) with respect to the solution, while for opposite polarity they may be very large. It may be noted in passing that zirconium and tantalium show similar properties. The relation between current and voltage of the system is treated in this paper. In particular the behavior of the rectifier when a.c. voltages are applied will be discussed.

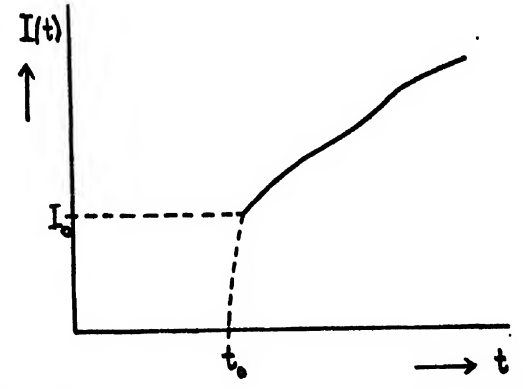

Fig. 1. The current I of an electrolytic rectifier as a function of time, for a d.c. voltage applied in the forward direction at a time $t=t_0$.

The d.c. current-voltage characteristics have been the subject of many previous investigations.[5] However, the origin of the observed time-effects discussed in Section II below, is not completely understood. Investigations of the a.c. characteristics, mainly at 50 cycles, were started by Dekker and van Geel.[6] These authors found a large hysteresis loop in the forward current (aluminum negative). In the present paper the a.c. characteristics for frequencies ranging from 1–2000 cycles per second will be discussed.

II. D.C. CURRENT-VOLTAGE CHARACTERISTICS

Since the d.c. current-voltage characteristics have a bearing on the behavior of the electrolytic rectifier for a.c. voltages, they will be briefly reviewed. It will be assumed that only voltages below the formation voltage are applied to the rectifier, so that no further oxidation takes place.

Suppose that at time $t=t_0$ a constant voltage V is applied in the forward direction (Al negative). The forward current generated by V is not constant but varies with time (Fig. 1). The current reaches a certain "instantaneous" value I_0 by the time a meter responds (approx. one sec.) and then increases slowly but erratically with time. Because no saturation value of the current is reached over a period of several hours, it is possible that during this time chemical changes occur in the layers that lower their resistance. This change of resistance will be referred to as the after effect. What happens between $t=t_0$ and the time when the meter responds will be discussed below (Section VI). The "instantaneous" value I_0 introduced above is determined not only by V but also by the "history" of the

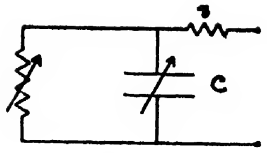

FIG. 2. Equivalent circuit of a rectifier.

rectifier. In general, voltages applied in the forward direction before $t=t_0$ tend to increase the "instantaneous" value, while voltages in the reverse direction tend to decrease it. This effect will be referred to as the hysteresis. For each forward voltage V a set of $I(t)$ curves may be obtained, each curve corresponding to a different "history" of the plate, that is, corresponding to events in the time between $t=-\infty$ and $t=t_0$.

Similar phenomena occur when d.c. voltages are applied in the reverse direction. When for $t<t_0$ a voltage in the forward direction was applied to the rectifier and at $t=t_0$ a voltage V is applied in the reverse direction, the current will reach an "instantaneous" value and then decrease, usually within a few seconds, to a constant value.

It will be clear from the preceding discussion that the d.c. characteristics can be given unambiguously only by specifying the conditions under which they were measured. The most reproducible results are obtained when before each measurement of the "instantaneous" current the rectifier is kept at the formation voltage (in the reverse direction) for a few minutes. The current in either direction is then approximately proportional to the square of the voltage. The rectification ratio, that is, the ratio of the forward and reverse current for the same absolute value of the applied voltage, may be as high as 10^4 for a plate oxidized at about 300 volts. For the measurements described in this paper, the formation voltage was applied for a few minutes before the photographs of the a.c. characteristics were taken in order to make the initial conditions for each photograph nearly the same.

III. THE CAPACITY OF THE RECTIFIER

In connection with the method for measuring the a.c. current-voltage characteristics (see Section IV) it is necessary first to point out some features of the equivalent circuit of the electrolytic rectifier.

It is well known that the simplest equivalent circuit for a *dry* rectifier that describes the electric properties of such a metal-insulator-semiconductor contact, consists of a non-linear resistance R shunted by a non-linear capacitance C, the two in series with a linear resistance r (Fig. 2). The capacitance C arises from the insulating layer (chemical barrier layer) and a physical barrier layer (Schottky layer) existing in the semiconductor next to the insulator. The effective thickness of the latter depends on the applied voltage and hence leads to a non-linear capacitance. The voltage dependence of C is most pronounced for zero bias voltage. Also, the voltage dependence of C decreases with increasing thickness of the chemical barrier layer.

To investigate to what extent the circuit of Fig. 2 can be applied to the *electrolytic* rectifier, the following experiments were carried out: An aluminum plate which was 50 cm² in area, was oxidized to a formation voltage of 285 volts in a solution of ammonium-borate (sp. res. 490Ω cm). Tinfoil was used as counter electrode. The impedance of the system thus obtained was measured at zero bias voltage for frequencies between 60 and 15,000 c.p.s. The measurements were carried out by using a General Radio 716-*B* capacitance bridge and a General Radio 608-*A* oscillator. The output of the oscillator was so adjusted that the effective voltage across the rectifier was 0.5 volt. The results obtained could be accounted for over the whole frequency range by the circuit of Fig. 2 with the following numerical values: $C=1.65$ μf, $R=10^5\Omega$ and $r=23\Omega$.

The impedance of the rectifier was also measured with different bias voltages in the reverse direction. No changes in the capacitance could be detected. Similar measurements with bias voltages in the forward direction are practically impossible as a consequence of the after effect mentioned in the previous section. There is no reason to believe, however, that the capacitance

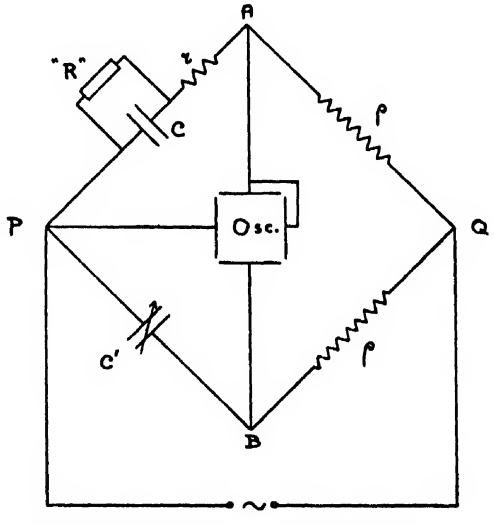

FIG. 3. Circuit for measuring the a.c. current-voltage characteristics.

would be different for voltages in the forward direction and therefore the capacitance will be treated as a constant in the following sections.

IV. METHOD FOR MEASURING THE A.C. CHARACTERISTICS

The a.c. current-voltage characteristics of *dry* rectifiers are usually obtained by putting a known resistance ρ in series. The voltage across ρ gives the current through the system and may be applied to the vertical deflection plates of an oscillograph. Using the voltage across the rectifier as the time base in the horizontal direction, the current-voltage characteristic may be readily observed.

FIG 4. Current-voltage characteristics at 2 (below) and 3 (top) cycles Current vertical, voltage horizontal

FIG. 5. From the bottom · characteristics at 3, 15 and 30 cycles

As a consequence of the presence of the capacitance C in the equivalent circuit (Fig. 2), however, $C\omega$ may become comparable with $1/R$ at high frequencies and the characteristic will then be distorted, especially in the reverse direction. The frequencies where this occurs are sometimes very high, for instance for germanium point-rectifiers (microwave region), whereas in other cases this region may lie in considerably lower ranges. It may be noted that Lehovec[7] has pointed out that this distortion in the reverse direction may be used to determine the capacitance of a rectifier.

For the *electrolytic* rectifier considered here, distortion due to the capacitance becomes noticeable at frequencies as low as 10 c p.s , as may easily be verified from the numerical values of C and R given in the preceding section. In this section a method to compensate for this effect, suggested by Dekker and van Geel, will be discussed.

In branch PAQ of the bridge in Fig. 3, the rectifier is represented by a constant capacitance C, shunted by a rectifying element "R" the nature of which is the subject of the present investigation, the two in series with the resistance r of the electrolyte. It should be noted that, because of the observed hysteresis (Section VI), the element "R" cannot be represented by a non-linear resistance only Suppose then that an a.c. voltage $V_0e^{j\omega t}$ is applied between P and Q. The current $I(t)$ flowing through "R" is some periodic function of time, depending on the input voltage, and may be developed in a Fourier series

$$I(t)=\sum_n I_n e^{jn\omega t}.$$

The voltage across the known resistance ρ may be calculated from the following differential equation

$$\rho C(d/dt)\{V_0e^{j\omega t}-(1+r/\rho)V_{QA}\}+\rho I(t)=V_{QA}.$$

Assuming V_{QA} can be expressed in a Fourier series, the solution is

$$V_{QA}=\rho\sum_n I_n e^{jn\omega t}\cdot\frac{1}{1+jCn\omega(r+\rho)}+j\frac{\rho C\omega V_0e^{j\omega t}}{1+jC\omega(r+\rho)}. \quad (1)$$

[7] K. Lehovec. J. App. Phys. 20, 123 (1949).

It is evident that for $\omega\to 0$ the voltage across ρ is directly proportional to $I(t)$ and hence in that case gives the current through "R" directly. It is also clear from (1) that for $\omega\neq 0$ the capacitance C gives rise to an "extra" capacitive current through ρ, leading to the second term in (1). This effect was compensated by Dekker and van Geel by using the branch PBQ, consisting of a variable capacitance C' and a series resistance ρ (equal to the one in the upper branch) in parallel with PAQ. Assuming that no current flows between A and B, the following equation holds for V_{QB}

$$\rho C'(d/dt)(V_0e^{j\omega t}-V_{QB})=V_{QB}.$$

This leads to

$$V_{QB}=j\frac{\rho C'\omega V_0e^{j\omega t}}{1+jC'\omega\rho} \quad (2)$$

It is evident that for $C'=C$ and $\rho\gg r$, the second term of (1) becomes equal to V_{QB}. Hence, by using a capacitance C' equal to the capacitance of the rectifier, the voltage across AB becomes

$$V_{AB}=\rho\sum_n I_n e^{jn\omega t}\frac{1}{1+jCn\omega\rho} \text{ for } r\ll\rho. \quad (3)$$

This expression shows that V_{AB} gives a picture of $I(t)$ which is distorted in two ways: the phase of each component of the Fourier expansion is shifted and, besides, the higher terms are more suppressed than the first term. However, the hysteresis loop does not show any discontinuities or peaks and, hence, only a few terms of the expansion are of importance. Therefore, V_{AB} will be approximately proportional to $I(t)$ if the condition $C\omega\rho\ll 1$ is fulfilled. For a given rectifier this condition puts a limit on the frequency range for which the method can be used.

The adjustment of C' can be made simply by measuring the capacitance C as indicated in Section III. A more convenient method of adjustment is the following: in the reverse direction $I(t)$ is practically zero for sufficiently low voltages. This means that C' has to be so

adjusted, that $V_{AB}=0$ in the reverse direction. Both methods gave the same value for the compensating capacity within the experimental error.

It should be remarked that complete compensation of the second term in (1) may be obtained by using between P and B in addition to C', a resistance equal to r in series. This becomes mainly important at very high frequencies where $C\omega\rho$ becomes equal or larger than unity. There, however, the method breaks down for another reason given above. The effect of not using a compensation resistance for r at high frequencies may be seen from (1): In the reverse direction, for $I(t)=0$, expression (1) yields

$$V_{QA}\simeq(1-r/\rho)V_0e^{i\omega t}, \quad \text{also} \quad V_{QB}\simeq V_0e^{i\omega t}.$$

Therefore, the voltage V_{AB} in the reverse direction, instead of being zero and leading to a horizontal line for the characteristic, will now give rise to a line with slope r/ρ. This was confirmed by the experiments (Fig. 6) described in the next section.

V. RESULTS

For investigations at frequencies below 60 cycles an oscillator of the Wien-bridge type, driving a push-pull amplifier with cathode-follower output, was built. Frequencies down to about one cycle/sec. with output of about 50 volts could be obtained with this apparatus.

Typical examples of characteristics at 2 and 3 cycles obtained with the circuit of Fig. 3 are given in Fig. 4. The rectifier consisted of an aluminum plate 50 cm² in area, oxidized in an ammonium-borate solution. The capacity of the rectifier was 0.80 μf. The resistances ρ were both 50 ohms. The solution in which the characteristics were measured had a specific resistance of 76 ohm-cm, leading to a series resistance r of about 0.5 ohm. Graphite counter-electrodes were used. For 3 cycles $C\omega\rho=8.10^{-4}$; hence (Section IV) the capacity has practically no influence on the shape of the loop obtained. The spot on the screen of the oscillograph follows the lower part of the loop for increasing forward voltage and returns along the upper part for decreasing forward voltage. This is in agreement with the results obtained by Dekker and van Geel at 50 cycles. In the reverse direction there is practically no current flowing and the characteristic becomes a straight horizontal line. The essential difference between Fig. 4 and the characteristic of a dry rectifier is of course the presence of the loop in the forward direction. These experiments show clearly that the loop is not due to a hysteresis in the capacity but arises from a time lag in the conduction mechanism. The characteristics are well reproducible if the formation voltage is applied for a short time before each photograph is taken.

At higher frequencies of, say 30 cycles, the following is observed: if no compensation capacity is used ($C'=0$ in Fig. 3), the characteristic in the reverse direction, instead of being a horizontal line, now "opens" up in a similar fashion as for a dry rectifier at high frequencies. This indicates that the effect is a consequence of the capacity C, and is confirmed by the fact that by using the circuit of Fig. 3 with $C'=C$, a straight line is again obtained in the reverse direction.

In Fig. 5 some results are shown for the plate at 3, 15 and 30 cycles. The effective voltage in each case was 34 volts. It will be noticed that the currents decrease with increasing frequency. This was observed also for other frequency ranges. The peak value of the current in the picture for 30 cycles in Fig. 5 corresponds to about 20 mA.

With increasing voltage, the general shape of the loop does not change. As a consequence of the non-linearity of the system, however, the peak value of the current increases more than linearly and the loop as a whole changes accordingly. The results of Dekker and van Geel gave a peak current approximately proportional to $V^{\frac{1}{2}}$. At higher voltages a loop in the reverse direction also becomes noticeable.

At high frequencies there is an advantage in using small plate area, since the capacity C and hence the distortion of the characteristic will be reduced in this way. There is also the advantage that the currents flowing remain small and hence the internal resistance of the oscillator used does not lower appreciably the voltage in the forward direction. That this happens may be seen from Figs. 4 and 5. There is, however, the disadvantage of increasing r and less sensitivity. As a consequence, compensation for r as well as amplification of the signal V_{AB} become necessary, unless the value of ρ is increased.

Some examples of a series of characteristics obtained for a small strip of oxidized aluminum are given in

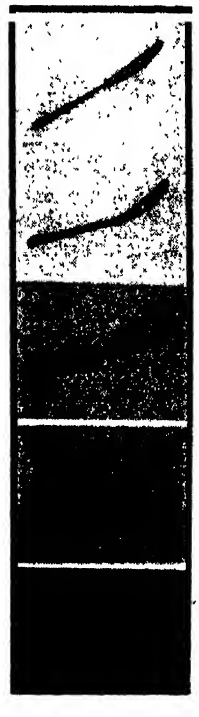

FIG. 6. Examples from a series of characteristics obtained with a small strip of oxydized aluminum. From the bottom: 20, 30, 150, 200, and 2000 cycles. No compensation for the series resistance was used in this case.

FIG. 7. Characteristics obtained for a strip of oxidized aluminum. From the bottom: 200, 300, and 400 cycles. In this case the series resistance of the electrolyte was compensated.

Fig. 6. The strip was oxidized to a formation voltage of 260 volts. Its capacity was 0.031 μf and the specific resistance of the solution was 76Ω cm. An effective voltage of 50 volts was used for all the photographs. Here again it is clear that the currents decrease with increasing frequency. Because only a capacity was used between P and B in Fig. 3, the effect of the series resistance r shows clearly: the characteristic in the reverse direction is no longer horizontal, but has a slope increasing with frequency. That this is indeed due to r may be seen from Fig. 7, where three pictures are shown obtained with a similar strip, but with a resistance to compensate for r shunting the capacity C'.

VI. DISCUSSION

The results obtained show definitely that the hysteresis loop is due to the conduction mechanism of the rectifying element "R" (Fig. 3). Therefore, any theory of the electrolytic rectifier should contain a mechanism that establishes a time lag between the current and the applied voltage. Logically, this time lag may either be caused by chemical changes in the layer which affect its conductivity, or, by processes of a physical nature that involve time, as, for instance, the building up of space charges in certain regions of the oxide.

In connection with the first possibility, experiments carried out by Störmer[8] are of interest. After preparing an oxide layer on an aluminum plate by anodic oxidation in an electrolytic solution, he applied a voltage in the forward direction for a certain length of time and used the plate thus prepared as a dry rectifier with aquadag as counter electrode. Störmer found that this treatment could improve the conductivity in the forward direction by factors up to a few hundred. He interprets his results by assuming that during the time that the forward voltage is applied to the plate in the solution, oxygen ions of the oxide are bound by hydrogen ions from the electrolyte. This leads to a semiconducting material with excess aluminum. This idea is compatible with experiments of Hartmann,[9] who found that aluminum oxide after certain heat treatments can become an excess semiconductor.

The chemical reduction, suggested by Störmer, seems the most reasonable explanation for the after effect referred to in Section II. For frequencies of the order of one cycle sec. or higher, however, it does not seem likely that changes of this type will occur and therefore the following "physical" interpretation of the hysteresis is tentatively put forward:

Suppose an aluminum plate is oxidized with a formation voltage of 300 volts. The thickness of the layer is then about 0.3 micron. For a voltage in the forward direction of, say, 30 volts, the field strength is about 10^6 volts per cm and is of the same order as the breakdown voltages for many ionic compounds. Electrons entering the oxide from the metal side (forward voltage) are accelerated by the field and may reach sufficient energy to eject electrons from energy levels below the conduction band. In view of the fact that the thickness of the layer is large compared with the mean free path (about 10^{-7} cm), the same reasoning may be applied to the secondary electrons and thus a multiplication process takes place. As a consequence of this process, positive holes are created, the number of which will increase with the distance from the metal.

In connection with the nature of these holes, it is important to note that the color of the luminescence, observed under certain circumstances during the anodic oxidation, depends on the kind of impurities contained in the aluminum. It seems reasonable, therefore, to assume that in the oxide layer localized electron levels between the highest filled band and the conduction band are present.[10] Electrons ejected from these localized levels will leave immobile holes behind and give rise to a space charge. As a consequence of the multiplication process, the positive space charge density increases with increasing distance from the metal. Also, the field at the metal-oxide interface will be larger than without space charge. Therefore, when a constant forward voltage is applied to the rectifier, the current increases with time until a stationary state is established in which the number of holes produced equals the number of electrons trapped by the holes.

Suppose then that an a.c. voltage is applied across the layer and that no space charge is present initially. For small voltages in the forward direction, the electrons will not gain sufficient energy from the field to produce secondaries and the field will be constant throughout the layer. When, however, the voltage reaches a certain critical value, a space charge will be built up. This explains why the forward current remains small for low voltages and then increases rapidly in the neighborhood of the peak value. During the subsequent decrease of the forward voltage, a certain time is involved in neutralizing the space charge so that a time lag between current and voltage is established.

[9] W. Hartmann, Zeits. f. Physik **102**, 709 (1936).
[10] See S. Anderson, reference 4.

On the basis of the pre-breakdown mechanism suggested here, it is also clear that the currents should decrease with increasing frequency. This is in agreement with the experimental results.

At very low frequencies, the after effect becomes important. According to the results obtained, there seems to be a continuous transition from the hysteresis to the after effect.

ACKNOWLEDGMENT

The authors wish to express their thanks to Dr. A. van der Ziel,* Physics Department of the University of British Columbia, Vancouver, British Columbia, Canada, for designing the oscillator for low frequencies and for many valuable and stimulating discussions.

Scheme for Analyzing Capillary Measurements on Non-Newtonian Liquids

ORRIN H. CLARK AND M. L. DEUTSCH

Socony-Vacuum Laboratories, Research and Development Department, Paulsboro, New Jersey

(Received January 12, 1950)

A powerful new scheme is presented for analyzing capillary flow measurements on non-Newtonian liquids. The basic disability of the capillary method, namely its inability to assign to a flow measurement any particular shear rate, or even a known range of shear rates, is overcome. This is accomplished by developing simple relations connecting the directly measured quantities, pressure and flow rate, with viscosity and shear rate. Application to Bingham bodies is easy and an illustration is given. Application to measurement at high rates of shear is immediate in principle, but there are certain allied measuring difficulties. These are discussed briefly. Finally, a simple approximate formula applicable to cases of moderate deviation from Newtonian behavior is given.

I. INTRODUCTION

A POWERFUL new scheme is presented for analyzing the results of capillary flow measurements on non-Newtonian liquids. The classic capillary tube viscometer suffers from one intrinsic disability when applied to liquids whose viscosity varies with rate of shear. It can only measure flow corresponding to a complete range of shear rate, from zero to a maximum. Hitherto, there have been no satisfactory means of translating measurements over such a range into viscosity values at individual shear rates.[1] The present paper develops a simple method of obtaining the desired individual viscosity values from measurements of flow over a range of applied pressure.

II. DEVELOPMENT OF ANALYSIS OF CAPILLARY FLOW MEASUREMENTS

The data obtainable from capillary flow measurements consist of values of volume flow rate corresponding to applied pressures, together with the geometric constants of the capillary tube. In the case of non-Newtonian liquids such data do not immediately reveal any information about viscosity, nor even about the range of shear rate which was applied. To obtain such information explicitly, it is necessary to develop a relation between the two measured variables, flow rate and pressure, on the one hand, and the desired variables, viscosity and shear rate, on the other.

The following symbols will be used: Q=flow rate, volume per unit time; P=applied pressure difference; l=capillary length; a=capillary radius; r=radius of any annulus within the capillary ($0\leq r\leq a$); v=velocity of flow at any annular distance r; S=rate of shear ($S=-dv/dr$); η=viscosity.

The connection between viscosity and shear rate is immediately obtained from the differential equation appropriate to capillary flow, in which viscosity may vary with radius:

$$-Pr/l=d/dr[\eta r(dv/dr)]. \tag{1}$$

Integrating, noting that considerations of finiteness require the integration constant to be zero, and replacing dv/dr by $-S$:

$$\eta=(Pr/2lS). \tag{2}$$

Specifically, at $r=a$ and for pressure P:

$$\eta(Pa)=[Pa]/[2lS(Pa)]. \tag{3}$$

Equation (3) gives the desired connection. However, the function, $S(Pa)$, is unknown in the case of non-Newtonian liquids. $S(Pa)$ is now obtained in terms of the (experimental) flow-pressure curve. The flow rate may be written:

$$Q=\int_0^a 2\pi rv\,dr. \tag{4}$$

An expression for v is obtained by noting that

$$v=\int_a^r \frac{dv}{dr}dr=-\int_a^r S\,dr. \tag{5}$$

This involves the assumption $v=0$ for $r=a$, i.e., there is no slippage at the wall.

[1] For example, see H. Green, *Industrial Rheology and Rheological Structures* (John Wiley and Sons, Inc., New York), Chapters 1–3.

It will be helpful to introduce two new variables, $\rho = Pr$, and $\rho_1 = Pa$. In a single experiment ρ_1 is constant but is variable when a range of pressure is considered. Now (4) becomes

$$Q = \frac{2\pi}{P^2}\int_0^{\rho_1} \rho v d\rho, \tag{6}$$

and (5) becomes

$$v = \frac{1}{P}\int_{\rho}^{\rho_1} S d\rho. \tag{7}$$

The last integral separates into two parts, one of which has constant limits.

$$v = \frac{1}{P}\int_0^{\rho_1} S d\rho - \frac{1}{P}\int_0^{\rho} S d\rho, \tag{8}$$

$$= (say) \frac{1}{P}[A(\rho_1) - A(\rho)]. \tag{8a}$$

Introducing (8a) in (6):

$$Q = \frac{2\pi}{P^3}\left[\frac{\rho_1^2}{2} A(\rho_1) - \int_0^{\rho_1} \rho A(\rho) d\rho\right], \tag{9}$$

since $A(\rho_1)$ does not depend upon ρ. Differentiating (9) with respect to ρ_1, after placing $P = \rho_1/a$, we find

$$\frac{dQ}{d\rho_1} = -\frac{3}{\rho_1} Q + \frac{\pi a^3}{\rho_1} \frac{dA(\rho_1)}{d\rho_1}. \tag{10}$$

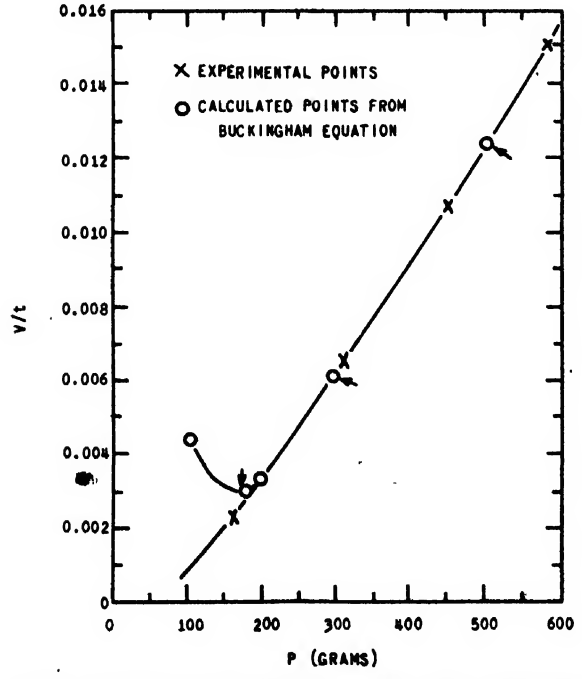

FIG. 1. Capillary flow data on a Bingham body. Reproduced by permission from *Industrial Rheology and Rheological Structures* by H. Green (John Wiley and Sons, Inc., New York, 1949).

Now noting the definition of $A(\rho_1)$,

$$dA(\rho_1)/d\rho_1 = S(\rho_1), \tag{11}$$

solving (10) for $dA(\rho_1)/d\rho_1$, and restoring the original variables we obtain

$$S(Pa) = 1/\pi a^3[3Q + P(dQ/dP)]. \tag{12}$$

Equation (12) specifies for any pressure P the shear rate (at $r = a$) in terms of directly measured quantities. An expression for the viscosity corresponding to this shear rate was given in Eq. (3). A complete graph of viscosity against shear rate may be obtained merely by plotting flow against pressure, obtaining the slopes dQ/dP at a number of pressures, and using Eqs. (3) and (12).

It will be noted that the shear rate given by (12) at each pressure is the maximum existing within the capillary tube, so that the range obtainable from the equations is the greatest possible, viscosity being obtained at the greatest shear rate in the liquid.

These results have great generality. It has been assumed there is no slippage at the wall. The only other limitation is implicit in Eq. (1), in which it is assumed that the applied pressure is opposed only by viscous forces, i.e., that there is no appreciable yield point or shear elasticity. This last restriction is easily removed. The yield stress bears a simple relation to the threshold pressure at which flow starts and is taken into account by a minor modification in the capillary flow equation. In the case of Bingham bodies the threshold pressure is not even required. This will be shown in the next section, which will serve to illustrate the method generally as well as the means of handling yield stress.

III. APPLICATION TO BINGHAM BODIES

Bingham bodies are characterized by a definite yield point (denoted by f), viscosity being constant after flow starts. In this case (1) must be modified to include the yield stress.

$$-Pr/l + f = d/dr[\eta r(dv/dr)]. \tag{13}$$

Integrating, and taking $r = a$:

$$f = Pa/2l - \eta S, \tag{14}$$

with S given by (12) as before. At the threshold pressure $S = 0$ and f is obtained at once. In the case of Bingham bodies any two points on the flow-pressure curve suffice to determine f and η; the constancy of η may be verified by additional points.

An example is given using data on pigment-vehicle mixtures published by Green.[2] These are reproduced in Fig. 1. Pressure values of 200, 300 and 500 are selected. Sufficient accuracy will result from using direct differences in the table to obtain slopes, and the 300 to 500 difference will be used for pressures of 300 and 500

[2] See reference 1. Reproduced by permission.

both. Then:

$$P=200,\quad dQ/dP=0.0000289,\quad S=159,$$
$$P=300,\quad dQ/dP=0.0000315,\quad S=287,$$
$$P=500,\quad dQ/dP=0.0000315,\quad S=547.$$

Using the values for $P=200$ and $P=300$ in (14), and changing grams to dynes gives:

$$f=422 \text{ dynes/cm}^2,\quad \eta=3.92 \text{ poises}.$$

The check using points $P=300$ and $P=500$ yields the values:

$$f=428 \text{ dynes/cm}^2,\quad \eta=3.86 \text{ poises}.$$

IV. HIGH RATES OF SHEAR

The extension of capillary flow measurements to high rates of shear encounters formidable measuring difficulties quite apart from the problem of variable shear rate which has been treated above. These difficulties arise from the necessity for high pressures and large amounts of internally developed heat, resulting in serious gradients in temperature and pressure within the capillary. Analysis of flow results including allowance for viscosity variation due to temperature and pressure effects is very difficult.

Since the starting point for the scheme just developed assumes the possession of true values of flow for given pressures, it apparently has no immediate application to these measuring difficulties. However, the development of an experimental technique for measurement at high shear rates has been pushed to an advanced stage at the Petroleum Refining Laboratory, Pennsylvania State College,[3] with the result that data are obtained which merit discussion from the viewpoint of analyzing the effect of variable shear rate.

Details of this experimental technique are not relevant to the discussion. It is sufficient to state that the method achieves the assignment of an "apparent viscosity" to each measured flow rate which is the viscosity of a Newtonian liquid producing the same flow rate at the same applied pressure. Approximate corrections for temperature and pressure effects have thus been incorporated in the apparent viscosity. For the purpose of comparative work the apparent viscosity is used directly to characterize the liquid.

If, however, a description of the fluid's non-Newtonian characteristic, i.e., its viscosity dependence upon shear rate, is desired, it is necessary to find means of assigning corresponding shear rates to the apparent viscosities resulting from capillary flow measurements. This is the very purpose for which the equations of Section II are designed. It is only necessary to translate the apparent viscosities into corresponding apparent flow rates by using Poiseuille's law. This will give the flow-pressure data needed and permit the construction of an explicit viscosity to shear rate relation.

[3] The authors are acquainted with this work through the courtesy of seeing the report to the American Petroleum Institute, P.R.L.-9-49, by Fenske, Klaus, and Dannenbrink.

TABLE I. Data for Fig. 1, experimental points.

P (g)	V/t (cc/sec.)	P	V/t
160.1	0.00230	100 calculated	0.00443
307.9	0.00652	174 calculated	0.00279
450.1	0.01084	200[a]	0.00320
588.2	0.01513	300[a]	0.00609
729.6	0.01963	500[a]	0.01239

Radius of capillary, 0.031365 cm
Length of capillary, 3.162 cm

[a] Points taken on experimental curve for calculating f and η.

It will be noted that no additional assumption is involved in applying Poiseuille's law to the apparent viscosities, for these are defined in terms of equivalence of flow rate.

A simplified procedure for assigning shear rates to the apparent viscosities is possible by introducing another Newtonian approximation. To the capillary flow in question there is assigned an effective shear rate defined as the shear rate effective in producing flow for Newtonian liquids. Thus:

$$\bar{S}=\frac{\int SdQ}{\int dQ}$$
$$=\frac{1}{Q}\int_0^a S2\pi rvdr$$
$$=\frac{1}{Q}\int_0^a \frac{Pr2\pi rP}{2l\eta 4l\eta}(a^2-r^2)dr$$
$$=(4/15)(Pa/l\eta). \qquad (15)$$

The validity of the approximation (15) will in general depend upon the magnitude of the deviation from Newtonian behavior. It should be noted, however, that in the case of the Petroleum Refining Laboratory work cited Eq. (15) constitutes an entirely satisfactory assignment of shear rate. It gives results agreeing within experimental error with those obtained by applying the method of Section II. However, one advantage does accrue from using the method of Section II; it makes possible the extension of the viscosity relation to substantially higher shear rates.

Interpretation of Fracture Markings

J. A. Kies, A. M. Sullivan, G. R. Irwin
Naval Research Laboratory, Washington, D. C.
(Received March 23, 1950)

This paper presents a study of the sequence of events by which cracks "grow." A careful investigation was made of the origin, development, and characteristic pattern of level-difference markings left by rapidly moving fractures in a wide variety of materials. Characteristic markings indicating discontinuous propagation are found in fractures of plastics, polycrystalline and single-crystal materials, coal, mica, photographic film from which the emulsion was stripped, etc. Thus, the continued occurrence of essentially discontinuous initiations which comprise fracturing becomes clear. These considerations are sufficient to explain a number of well known fracture markings and to clarify what is mean by brittleness and fracture velocity.

INTRODUCTION

THE detailed markings on fracture surfaces of metals, plastics, and ceramics show many common characteristics. A number of these are illustrated and reviewed in this paper for the purpose of showing what one may infer from these markings concerning the growth and propagation of fracturing.

LEVEL DIFFERENCES

De Freminville,[1] Preston,[2] and others have called attention to the importance of fracture level differences and crack directions as indicators of the stress pattern in glass. The mechanism by which level differences arise has been given relatively little attention. A comparative study of metals, transparent crystals, plastics, and glass, etc., sheds new light on this mechanism.

A disconnected initiation beyond the crack head is well illustrated by Fig. 1. This shows an aluminum foil under dead weight loading. The fracture is propagated by joining a sequence of holes originating at widely separated points. T. W. George and others at NRL have shown this to be the rule in the fracture of ductile foils.

For the purpose of studying fracture markings in thick specimens, lucite serves as a convenient model. Figure 2 shows the fracture surface of a Lucite plate, $\frac{1}{16}$-in. thick, broken in tension. One finds that the areas separated by the parabola-like lines are at different levels. Thus, these lines owe their visibility to the existence of sharp changes in level and may be termed "level-difference lines." More details of this are shown in Fig. 3 at higher magnification. Usually there is a barely resolvable pit or hole at the focus surrounded by a circular zone of high specular reflectivity. The streamers radiating from the focus and trailing off in the direction of the crack propagation are the boundaries of various sublevels within the parabola. It can be shown that the point of origin of the fracture of fractures making up the parabola was at or very near the the focus. Similar details can be found on finer and finer scale to the limit of resolution of the ordinary microscope. This leads to the inference that all level-difference lines or edges, especially those leading in the direction of fracture can be associated with separate initiations of fracture.

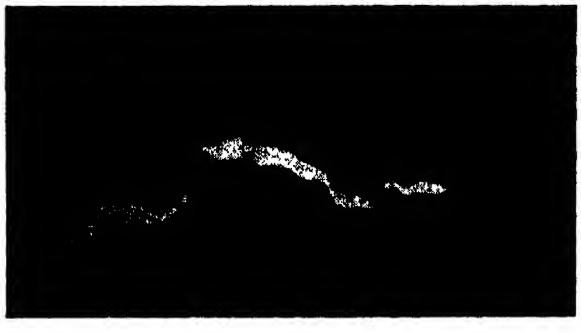

FIG. 1. (×15) Creeping fracture backlighted in 0.002-in. thick 2S aluminum foil (after T. W. George). The specimen had been under dead load for 30 days. The propagation consisted of the opening up of advance pinholes in severely strained regions followed by a joining process in which each subsidiary fracture spread backwards as well as forwards. Some such microfractures were not included in the joining process.

FIG. 2. Parabolic figures on the fracture surface of a Lucite plate (×75). Direction of crack propagation: Left to right. Each parabola outlines the area included in an individually initiated subsidiary fracture. The lines are visible becaues of differences in level.

FIG. 3. Enlarged view of the foci of a group of parabolas from the preceding figure (×250). Satisfactory proof exists that fracture elements were initiated at the foci.

FIG. 4. (×7.5) Parabola head complete with focal pit and streamers on the fracture surface of a fine grained steel tensile bar. The vertex of the parabola points toward the spot where the main fracture first initiated. (Courtesy, Dr. W. Harris.)

FIG. 5. (×20) Enlarged view of the parabola shown in the preceding figure. At the focus is a small crater with sheared conical walls. The weakening influence presumably within the pit is not revealed.

The structural components of the parabola in lucite have individual analogs within the comparable portions of the cup-cone fractures in ductile steel. Figure 4 shows a fracture in a tensile bar, kindly supplied to us by Dr. W. J. Harris of the NRL Metallurgy Division. The main fracture originated at the lower right and at a later time another prominent weakness at another level gave rise to a similar process starting from the focus of the parabola occurring at the upper left of center. Note that the parabola in the steel, Fig. 5, at higher magnification has a volcano-like focal crater indicating shearing at the focus. This is better illustrated in Fig. 6. Surrounding the shear is a bright granular area with streamers analogous to the pattern of Fig. 3 in Lucite. This area in the steel surrounding the focus also resembles the "mirror" in a glass fracture. Inasmuch as a granular appearance on a fracture in steel has been associated with high speeds of fracturing and low energy absorption, one may conclude that the toughest part of this fracture element was at the focus and that, once some shearing was completed, the subsequent development occurred far more rapidly. The sharp transition back to a more ductile appearance may be explained by reasoning that, at least locally, the fast fracture entailed a sudden expenditure of stored elastic energy and sudden stress relieval. This resulted in a slowing down or momentary hesitation of the crack front.

SCALLOPED LEADING EDGE

In order to establish the time sequence of events in the generation of parabola-like figures and conchoidal markings, microscopic observations were made during the progress of fracture in cellulose acetates and in a large crystal of KBr. In the case of cellulose acetate two photographs, Figs. 7 and 8, serve to show the positions of the main crack at the instants of halt or very slow propagation in response to a controlled relieval of the force exerted on the knife blade used to propagate the crack. The arrow points to the focal spot of a parabola-like figure and at the second position new parabola heads have been created within the outline of the original one.

The leading edge was deeply scalloped with a succession of finer and finer scallops superimposed on the principal ones. Each main scallop was the leading edge of a parabola-like fracture element within which could be found an individual point of initiation.

In the case of the fracture in KBr a razor blade was forced into the material by a steady motion of a screw. In this case the scalloped leading edge of the crack more or less following a cleavage plane was essentially the same in appearance as in cellulose acetate. The main scallops were observed to progress with a rapid succession of pulses and halts self-controlled by the specimen.

Conchoidal fractures are all produced in this way except that the fracture surface is not constrained to follow a natural cleavage. It is important to recognize that such discontinuous propagation generally involves many, not just one, transitions in mode from fast to slow. During slow stages more time is allowed for plastic flow, hence a conchoidal fracture or more generally any brittle but pulsating fracture may involve local ductile

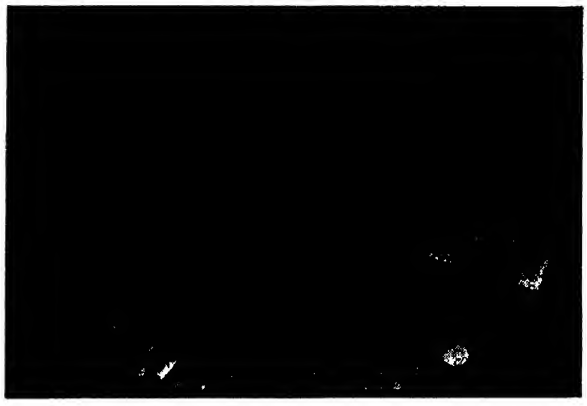

FIG. 6. (×7.5) The sector at the left was formed by radial crack propagation and corresponds to the parabolas of the preceding figures. A micro flaw is presumed to have been located at the focal pit lying within the volcano-like sheared structure. A small granular area surrounding the volcano suggests fast fracture at the expense of a local quick release of elastic energy. This was followed by slower more fibrous fracture at a somewhat lower mean stress. (Specimen supplied by Dr. W. Harris.)

FIG. 7. (×50) A fracture, traveling to the right, viewed within cellulose acetate. Note the well formed parabola head with focal point. A chisel is being forced into the material but the crack is momentarily halted. Note the lagging crack front at points where the level changes.

behavior. Klier has recently shown examples of this in ferrite.[3]

CHEVRON MARKINGS

The chevrons or herringbone in ship plate are easily modeled. Figure 9 shows an example of a tearing fracture in cellulose acetate. The concentration of gross fracture centers is greatest near the centerline. The fracture front obviously led at the center and lagged at the surface. However, chevrons need not point toward the origin of the running crack, provided the edges of the fracture can be made to lead. Figure 10 shows a plate of cellulose acetate in which side scratches promoted reverse herringbone.

[3] E. P. Klier, "A study of cleavage surfaces in ferrite," Pennsylvania State College, Mineral Industries Expt. Station, Final Report to ONR, October 15, 1948–1949.

Although the chevron pattern was widely considered to be indicative of brittle and therefore unsatisfactory behavior of the ship plates in failed merchant vessels, it should be understood that a considerable amount of plastic deformation was present. Tipper has pointed out that shearing was in evidence along the lines sometimes called herringbone.[4] More generally these are level-difference lines where the fracture lagged and hesitated. The final joining up of the levels by spreading towards one another involved the initiation of a new fracture front with an initially slow and therefore relatively ductile stage.

Our association here of high energy absorption with slowness of crack propagation rested partly upon the microscopic observations previously mentioned in connection with the fracture initiation foci within parabola heads in various materials. Such an association was thoroughly demonstrated on a grander scale by numerous dead loading and other more common experiments on various metal foils and plates of plastics in which central slots or scratches served to locate the beginning of fracture. In these experiments the work absorbed per unit length of crack was plotted against propagation speed and crack length. Invariably the initial or creeping stages of the crack growth required a rate of energy input several orders of magnitude higher than later, faster stages. This has been discussed by Irwin[5] and forms the main basis for his statement of the necessary and sufficient conditions for the onset of instability or the transition from ductile to brittle fracture.

GEOMETRICAL FIGURES

It is easy to show that simple geometrical figures on fracture surfaces are to be expected as a result of the interference between neighboring fracture elements.

FIG. 8. (×50) An advanced stage of the fracture, traveling to the right, shown in Fig. 7. The sides of the main parabola are greatly developed and newer, smaller parabolas have been created within the main one.

[5] G. R. Irwin, "Fracture dynamics," "Fracturing of metals," Am. Soc. Metals, 147 (1948).

FIG. 9. (×50) Herringbone or chevron fracture produced in a cellulose acetate plate. The fracture propagation was left to right. The heads of parabolas are clearly shown as concentrated at the center of the plate thus showing centrally located but discontinuous initation and propagation to be the reasons for such markings. The scalloped crack front was generally normal to the sides of the parabolas. Note that some figures become rapidly divergent and have hyperbolic outlines. This is due to local speed effects.

FIG. 10. (×7.5) Reversed chevrons or herringbone fracture in a cellulose acetate plate. Side scratches promoted initiation near the plate surface rather than in the center. As the fracture proceeded from left to right the fracture led at the surface and lagged in the middle contrary to normal chevrons in ship plate. Parabola heads are present but too small to be seen at this magnification.

For example, a rectilinearly propagating crack with a straight line front and a radially propagating crack with a circular front both in the same plane will meet on a conic section. If the velocities are equal, the figure is a parabola. If the circular- or disk-shaped crack is the slower, an ellipse will result. An example of this is shown in Fig. 11. A slight level difference for the two fractures makes the figure easily visible. In any case a relatively slow element will be surrounded and stopped by its faster neighbors. The ensiform tips in Fig. 11 thus represent extinctions of fracture elements. These are also junction points in river systems to be mentioned later. A hyperbola-like figure is to be expected as the boundary of a fast fracture element if it spreads more rapidly than its neighboring fracture elements. Such an outline is suggested at several places in Fig. 9.

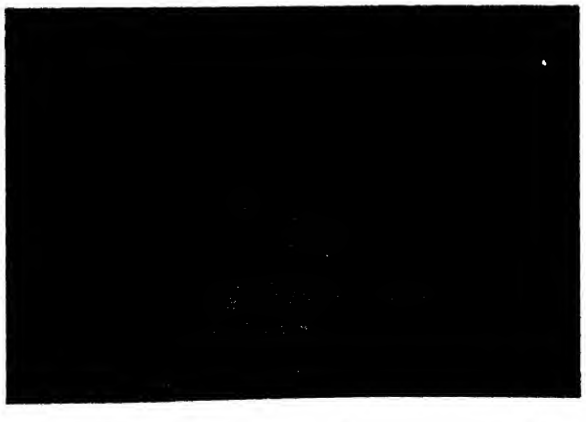

FIG. 11. (×50) Fracture surface in cellulose acetate created by a crack traveling right to left at 0.01 in./sec. Note the elliptical figure swept out by a fracture element which was engulfed and cut off by surrounding elements which ran ahead. Each ensiform tip is the trailing end of a fracture element which was crowded out by faster adjoining elements. Parabola heads are too small to show at this magnification.

River systems result from the consolidation of level differences as the faster elements shoot ahead and stop the slower ones. Many such examples have been shown without this explanation in publications by Zapffe and others.[6] A large scale example of river systems is shown in Fig. 12. This is a face spall in steel armor. The rod-shaped pieces lying within the overlap of neighboring fracture elements are often thrown off as fragments designated (in French) by De Freminville as "stries". A complete understanding of the origin of these shards and the separate fracture elements creating them cannot be gained by the observation of fractures in glass and hardened steel alone since in these materials the scale of events is too fine or is obscured by crystallinity. In plastics, however, each tributary of a river system can be seen to be a level difference between fracture elements originating from separate initiation points or operative flaws. In general, only one limb of the parabola-like figure associated with each initiation persists with enough level difference to be noted as a tributary in the system. The flaw-like nature of these initiations is demonstrated by Fig. 13 in which the boundaries of poorly molded particles of Lucite provide many such points for fracture initiation. Such examples lead to the inference that operative flaws play a promi-

FIG. 12. (×.5) Face spall in 4-in. thick Class *A* armor. The fracture initiated at the top of the picture. Note the banded structure with repeating river systems. Each tributary marks a difference in level between adjoining components of the fracture. Tributaries converge because some fracture elements were too slow to compete. Each band edge is a position of the crack front at an instant of hesitation in the propagation.

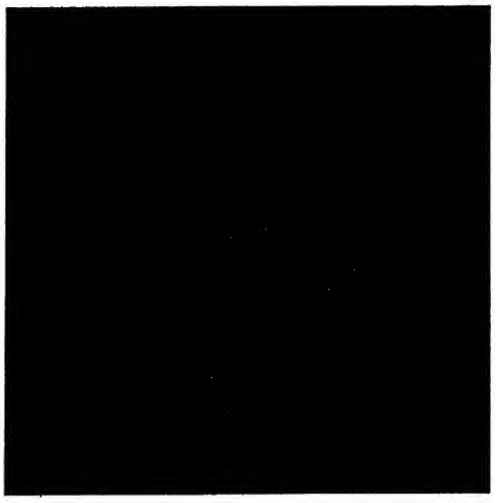

FIG. 13. (×250) "Grain boundary" weakness in imperfectly molded Lucite.

FIG. 14. (×50) Multiplicity of fracture initations contributing to a high speed shattering fracture in Lucite. The star-like components have spread more or less concurrently so that a system of honeycomb boundaries separates the components lying at slightly different levels. There is no evidence of a main crack front here. The presence of such a system is enough to insure low ductility and low dw/dx.

nent role in the propagation of fractures in all materials showing gross fracture patterns of the kinds described here.

EXPLOSIVE FRACTURE

The conditions of propagation as modified by high overstress can be indicated by the system of star-like fracture components shown in Fig. 14. Each one resembles the star in a tensile fracture of steel. Their independence of the main fracture results in their circular form. The regions between the initiations were evidently encroached on by many spreading fractures and thus little opportunity for plastic action was permitted. It is conceivable that operative flaws, e.g., lattice imperfections or dislocations, may be created anywhere in any solid material provided that there is sufficient time and an appropriate set of stresses. It follows that any material, however tough in static tests, can be made to fracture in a brittle manner provided that many flaws become operative simultaneously. This condition is readily achieved in suitable explosion tests of steel plate and hollow vessels. In such cases the over-all or apparent fracturing consists of many widely separated fractures joining together in more or less orderly sequence.

CONCLUSIONS

In conclusion, it may be stated that:

(1) The propagation of fracture is, in carefully observed cases, essentially and generally discontinuous and consists of the joining up of multitudes of separately initiated components of fracture.

(2) The more brittle the substance, the more striking are the effects of speed variations in creating markings usually called clam shell or conchoidal. Speed differences between components are responsible for the flowing together of markings resembling river systems and for the creation of geometrical patterns visible as parabolas, ellipses, and hyperbolas.

(3) Chevron or herringbone markings on ship plate may be explained on the basis of centrally concentrated gross initiation coupled with a centrally leading but scalloped crack front. Some initiations may be far in advance of the main crack and backwards propagation must occur locally.

(4) The transition from slow to moderately fast but not explosive fracture in hardened steel is accompanied by finer and finer scaled elements initiating closer and closer to the leading edge of the main crack as the local velocity of propagation increases. Fewer and fewer main elements persist with individually smoother faces.

(5) The over-all velocity of propagation of a crack is governed by the rate and distance at which advance initiations can occur and the rapidity with which subsidiary multiple fractures can be joined up. Many component joinings may occur simultaneously. This may be described as explosive fracture.

(6) In cases of high speed fractures traveling in high stress fields, the great number of fracture elements operating simultaneously tends to produce a condition in which the material in the path of the oncoming crack is permeated by multitudes of local stress raisers and flow restricters. Material surrounded by initiating fractures is subjected to a condition similar to that in a sharply notched tensile impact bar. Low ductility is a consequence.

The authors gratefully acknowledge the help and cooperation received from the following: Dr. W. Harris of the NRL Metallurgy Division, who supplied us with the tensile fractures in steel. Mr. C. Hauver, Head of the Photographic Section, Mechanics Division, NRL, who prepared some of the photographs. Messrs. H. L. Smith and W. J. Ferguson of the Mechanics Division, NRL, who performed many necessary fracture experiments contributing to this report. Dr. W. H. Sanders, Consultant, Mechanics Division, NRL, who assisted by editorial criticism and advice.

Letters to the Editor

An Absolute Measurement of Copper-Copper Interfacial Free Energy

G. W. Sears
General Electric Research Laboratory, Schenectady, New York
March 31, 1950

IT has been proposed by Smith[1] that the dihedral angles formed by three intersecting grain and phase boundaries are determined by a simple mechanical balancing of the interfacial tensions. He presented a mass of evidence to substantiate his assumption. On this basis he measured the ratio of copper(solid)-copper(solid) to copper(solid)-lead(liquid) interfacial free energies to be 0.59 from measurements of the dihedral angles formed at the junction of a pair of copper grains with liquid lead.

Following a suggestion of Fisher[2] the equilibrium angles at the edges of liquid lead drops equilibrated on a copper single crystal at high temperature were studied in an attempt to obtain an absolute value for the copper(solid)-lead(liquid) interfacial free energy and in conjunction with Smith's data an absolute value of the copper grain boundary free energy.

Outgassed cylinders of OFHC copper were polished on one end. The samples were placed polished side up in a hydrogen atmosphere and dusted lightly with lead powder. The specimens were heated for 8 hr. at 800°C.

After cooling, the samples were plated with 0.012 in. of copper. The specimens were cross-sectioned and polished normal to the lead-covered surface. The polished face was given a light dichromate etch and examined at 500× with a Bausch and Lomb metallograph.

After measuring approximately 500 dihedral angles at the edge of lead drops, it was established that they had distorted upon solidification while cooling to room temperature.

At the suggestion of W. Schockley it was assumed that shape of the drops remained undistorted upon solidification. On this basis the angles were calculated from measured lengths and thicknesses of the lenticular lead drops. The preliminary results on these measurements yield angles consistent with the random cross sectioning of lenticular drops normal to their median planes and having constant dihedral angles at their edges. Recent high temperature microscopic studies have independently confirmed Shockley's suggestion.

A preliminary value of 510 ergs/cm² has been obtained for the copper(solid)-lead(liquid) interfacial free energy. In addition a value of 720 ergs/cm² for the copper(solid)-lead(vapor) surface free energy was found. This differs from the value of 1370 ergs/cm for the copper(solid)-copper(vapor) surface free energy measured by Udin, Shaler, and Wulff.[3]

In conjunction with Smith's data a copper(solid)-copper(solid) interfacial free energy of 860 ergs/cm² has been determined. This represents the first absolute measurement of a solid-solid interfacial free energy to be reported in the literature.

Limiting Negative Pressure of Water

Lyman J. Briggs
National Bureau of Standards, Washington, D. C.
February 20, 1950

AT the 1949 meeting of the National Academy of Sciences in Washington I presented the results of some measurements, by a new method, of the limiting negative pressure of water. Improvements in technique have since led to values higher than those provisionally reported.[1] In particular, the investigation of the effect of temperature has disclosed a remarkable 10-fold change in the limiting negative pressure of water between 0° and 6°C.

The liquid under examination by this method is held in a capillary tube *open at both ends*. About 1 cm from each end the tube is bent back upon itself through an angle of 140° to form a Z. After thorough cleaning the tube is cemented (with thinned Duco) symmetrically to the web of a spinner of I-beam cross section. The spinner is mounted at its center on the upper end of the vertical shaft of a high speed three-phase induction motor, driven by a variable-speed motor-generator, equipped with an electric tachometer.

The motor and spinner are enclosed in a cylinder 25 cm in diameter, fitted with soft rubber gaskets at both ends and resting on the base supporting the motor. A tempered glass plate closes the top. When operating, the internal air pressure is reduced to 3 or 4 cm Hg.

The capillary tube spins in its Z plane, which is horizontal and is so mounted that its *center intersects the projected spin axis*. Consequently, the liquid column at this point is visible even at high angular speeds. The breaking of the column is signalized by a marked change in the refraction of the tube.

When the liquid under examination is an electrolyte, the rupture of the column can also be conveniently detected in the following way. A strip of filter paper 3 cm wide is cemented by its edges to the inside of the cylinder at the height of the spinner. Over this a continuous strip of open-mesh metal gauze 2.5 cm wide is cemented by its edges to the filter paper. The gauze and cylinder are connected in series with a 135-v B battery and a 25-v voltmeter. Normally the voltmeter shows no deflection. But the instant the column breaks and the electrolyte is thrown against the filter paper, a strong kick on the voltmeter is observed. In working with pure water, the filter paper is first activated by moistening with a solution of NaCl and then dried.

In the centrifugal field, one-half of the liquid column is pulling against the other. If one meniscus is nearer the spin axis than the other when the motor starts, it immediately retreats and the other advances until equilibrium is restored. The maximum stress is at the center. If L is the measured distance between the menisci in the bent legs of the tube, the effective length of the column is $r = L/2$.

The force exerted on any element of liquid in the column of length dx is $a\rho\omega^2 x\,dx$, where a is the cross section in cm², ρ is the density of the liquid, and ω is the angular velocity in radians per second. Integrating, from 0 to r, $F = \frac{1}{2}\rho\omega^2 r^2$ dynes/cm². The nega-

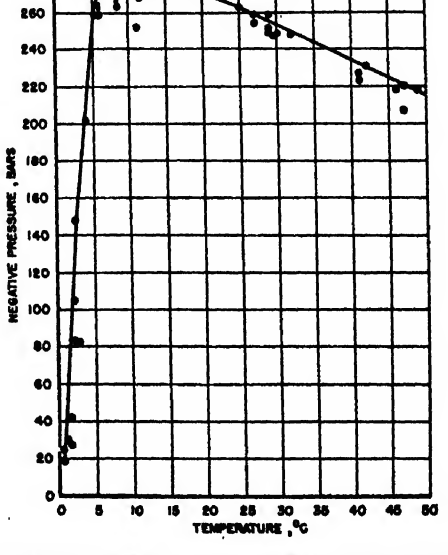

FIG. 1. The limiting negative pressure of water between 0° and 50°C.

tive pressure is given in bars (1 bar = 10^6 dynes/cm^2 = 0.987 standard atmosphere).

Scrupulous cleanliness is necessary in the measurement of negative pressure. The open-ended tube possesses a great advantage in being easy to clean and fill. To aid in these operations, the open ends of the tube project about 3 mm beyond the side of the supporting spinner.

The results of the measurements are presented in graphical form in Fig. 1. Points with arrows mean that the water column was subjected to the indicated negative pressure without rupture. It will be noted that the negative pressure is greatest (277 bars) around 10°C and decreases as the temperature is increased to 50°C. This decrease was expected, for at the critical temperature the negative pressure must be zero. The temperature coefficient from 25° to 50°C is about −2 bar/°C.

Between 5° and 0°C, the limiting negative pressure of water undergoes an enormous change, dropping to less than 10 percent of the maximum value. It presents another anomaly in the behavior of water in this interesting region. It cannot be accounted for by the change in density alone, for the density of water at 0° is only 0.00013 less than at 4°C; whereas a decrease in density of 0.009 occurs in raising the temperature of water from 25° to 50°C, which is accompanied by a change of only 20 percent in the limiting negative pressure.

The negative pressure measurements given in Fig. 1 are believed to be correct within three percent (one percent for ω and 0.5 percent for L). The temperatures corresponding to high values of the negative pressure are somewhat uncertain. The work done by the spinner on the residual gas in the chamber progressively raised its temperature and it is not known how closely the glass-enclosed liquid at the center of the column follows the temperature of the gas. Further measurements by a modified method are in progress.

The distilled water used in these measurements cannot be said to be air-free. The container from which the capillary tube was to be filled was completely immersed in distilled water and boiled vigorously. Inasmuch as the solubility of air in water decreases as the temperature is increased, it is assumed that the residual air in the boiled water was in a state of true solution at the lower temperatures at which the experiments were carried out.

Finally it must be emphasized that with this method we cannot tell whether the rupture of the column originates on the wall of the capillary (loss of adhesion) or in the body of the liquid (loss of cohesion). Strictly speaking, the measurements reported should be considered as applying to boiled water in a Pyrex glass capillary 0.6–0.8 mm internal diameter.

A fuller account of this work with additional data will appear in the *Journal of Research of the National Bureau of Standards*.

The Effective Permeability of Iron Dust Particles

LEONARD LEWIN
Standard Telecommunication Laboratories, Ltd., Enfield, Middlesex, England
March 30, 1950

IN a recent paper on attenuators,[1] Theodore Miller quoted a formula on loaded materials from my paper "The electrical constants of a material loaded with spherical particles."[2]

As he says that the radii of the particles do not enter into the formula, I think there must have been some misunderstanding of the symbols I have employed, since the formula certainly contains the particle radius, although it is not shown explicitly.

The formula for the permeability, μ_m of the mixture is

$$\mu_m = \mu_b\left(1+\frac{3f}{(\mu_p+2\mu_b)/(\mu_p-\mu_b)-f}\right),$$

where μ_b is the permeability of the binder, usually unity, μ_p is the effective permeability of the particles at the frequency under consideration, and f is the volume ratio of particles to total volume.

The trouble arises over μ_p, which is *not* the permeability of the material from which the particles are made. If we call this latter permeability μ_2, then $\mu_p = \mu_2$ only when the radius of the particle is so small that the field completely penetrates the article. The general relation is

$$\mu_p = \mu_2 F(\theta)$$

where

$$F(\theta) = \frac{2(\sin\theta - \theta\cos\theta)}{(\theta^2-1)\sin\theta + \theta\cos\theta} \cong 1 + \frac{\theta^2}{10} + \frac{9\theta^4}{700} \text{ for } \theta \text{ small},$$

and $\theta = ka(\mu_2 K_2)^{\frac{1}{2}}$, $k = 2\pi/\lambda$ (λ is the free-space wave-length in cm), a = particle radius in cm, K_2 = complex permittivity of the particle material. For a metal $K_2 = -j60\lambda\sigma$, where σ is the conductivity in mho/cm. If the particle radius is much greater than the skin depth this gives $\mu_p = -j(\lambda/\pi a)(\mu_2/K_2)^{\frac{1}{2}}$, which is much smaller than μ_2. The general agreement which Miller obtains between theory and experiment probably points to the particle size being small enough for the approximation $F(\theta) \simeq 1$ to be used in most cases. The discrepancies actually recorded correspond to a value of F less than 1, which is in agreement with the formula for F, since θ^2 is negative for the values of the constants used.

Magnetically Controlled Wave-Guide Attenuators

THEODORE MILLER
Electronics and Nuclear Physics Department, Westinghouse Research Laboratories, Pittsburgh, Pennsylvania
April 7, 1950

I WISH to thank Mr. Lewin for bringing to my attention an erroneous impression which I unwittingly created in a reference to his article which appeared in my paper "Magnetically controlled wave-guide attenuators."[1] I did not mean to imply that Mr. Lewin did not include the radii of particles in his general derivation for the effective permeability of a dielectric loaded with spherical particle, but rather that my application of his formula did not involve the radii.

Mr. Lewin's formula for the permeability of a loaded dielectric μ_m is[1]

$$\mu_m = \mu_b\left[1+\frac{3f}{(\mu_p-2\mu_b)/(\mu_p-\mu_b)-f}\right],$$

where f is the volume ratio of particles to total volume, μ_d is the permeability of dielectric, and μ_p is the high frequency permeability of the particles.

In his paper, Mr. Lewin relates the permeability of iron particles with the wave-length through an equation involving the particle radii, the conductivity, and the low frequency permeability of the iron material. However, since there was considerable uncertainty as to what values to assign to the conductivity and low frequency permeability of the iron material, it was decided to use Kittel's[2] value for the high frequency permeability of a thin film (2.5μ thick) instead of applying Mr. Lewin's equation which in part reads

$$\mu_p = \mu_2 F(\theta),$$
$$\theta = ka(\mu_2 K_2)^{\frac{1}{2}},$$
$$K_2 = -j60\lambda\sigma$$

where μ_2 is the permeability of iron material, σ is the conductivity, a is the radii of iron particles, and $k = 2\pi/\lambda$.

A Note on the Error Coefficients of a Servo Mechanism

JOHN L. BOWER
Department of Electrical Engineering, Yale University, New Haven, Connecticut
March 24, 1950

IN a linear servo system, it is convenient to be able to relate the error to the various disturbances on the system, the primary one of which is the input, θ_i. For a system initially at rest, one can write the following expression for that part of the error due to θ_i:

$$\epsilon(t)=\int_0^\infty d\lambda w(\lambda)\theta_i(t-\lambda). \tag{1}$$

The weighting function, $w(\lambda)$, is the inverse transform of the familiar transfer function relating the error to the disturbance, θ_i. For all physical systems, it includes a delta-function of order zero and of unit amplitude at the origin. If we assume θ_i to be a function which is differentiable through order n for all λ up to some λ_d, then we can write Maclaurin's formula for $\theta_i(t-\lambda)$ as a function of λ:

$$\theta_i(t-\lambda)=\theta_i(t)-\lambda\theta_i'(t)+\tfrac{1}{2}\lambda^2\theta_i''(t)+\cdots\frac{(-\lambda)^{n-1}}{(n-1)!}\theta_i^{(n-1)}(t)+R_n,\quad 0<\lambda<\lambda_d. \tag{2}$$

Here, R_n will be given the form,

$$R_n=\frac{(-\lambda)^n}{n!}\theta_i^{(n)}(t-\Delta\lambda)\text{ where }0<\Delta<1\text{ and }0<\lambda<\lambda_d. \tag{3}$$

We use the form $\theta_i^{(r)}(t-\lambda)$ to designate the rth derivative of θ_i with respect to the bracketed quantity. By inserting the identity (2) into (1), we have immediately an expression for error in terms of the derivatives of the input, θ_i, evaluated at t:

$$\epsilon(t)=C_0\theta_i(t)+C_1\theta_i'(t)+\frac{C_2}{2}\theta''(t)+\cdots\frac{C_{n-1}}{(n-1)!}\theta_i^{(n-1)}(t)+\frac{K_R}{n!}+K_d \tag{4}$$

where

$$C_r=\int_0^{\lambda_d}d\lambda(-\lambda)^r w(\lambda); \tag{5}$$

$$K_R=\int_0^{\lambda_d}d\lambda(-\lambda)^n\theta_i^{(n)}(t-\Delta\lambda)\cdot w(\lambda);$$

$$K_d=\int_{\lambda_d}^\infty d\lambda w(\lambda)\theta_i(t-\lambda). \tag{6}$$

It is obvious that the above series is most useful only when the last two terms are small enough to be neglected in the computation of $\epsilon(t)$. If the first m derivatives of the input are known to exist over all time, if the mth derivative is bounded by $\pm M$, and if m is sufficiently large that the corresponding remainder is negligible, we can represent the error by use of the coefficients up through C_{m-1}. The conditions here make for a simple calculation of the remainder, since $\lambda_d=\infty$, $K_d=0$, and

$$|K_R|\leq M\int_0^\infty d\lambda\lambda^m|w(\lambda)|. \tag{7}$$

Such a case as this might arise, for example, where the mth derivative is a stationary time series. The matter of evaluating the coefficients from (5) can be handled simply if the transfer function $H(s)$ relating the error to the input is known, for by definition of $w(\lambda)$,

$$H(s)=\int_0^\infty d\lambda e^{-s\lambda}w(\lambda). \tag{8}$$

By differentiating r times with respect to s, and taking s to zero in the result, we have

$$\left.\frac{d^rH(s)}{ds^r}\right|_{s=0}=\int_0^\infty d\lambda(-\lambda)^r w(\lambda)=C_r,\text{ for }\lambda_d=\infty. \tag{9}$$

These steps are clearly valid for any stable system, since its transfer function, $H(s)$, must be analytic in the neighborhood of the origin. The expression (9) places the coefficients of the power series in the familiar form shown in textbooks.[1] The inverses of C_0, C_1, and $C_2/2$, respectively, are referred to as the position-, velocity-, and acceleration-error coefficients of the servo.

For the ordinary rational fractional forms of $H(s)$ with simple poles, an upper limit for (7) can be obtained easily. We note that

$$\int_0^\infty d\lambda\lambda^m|w(\lambda)|=\left|\frac{d^m}{ds^m}\int_0^\infty d\lambda e^{-s\lambda}|w(\lambda)|\right|_{s=0}. \tag{10}$$

An upper bound for this quantity can be obtained by making a partial-fraction expansion of $H(s)$, substituting magnitudes of residues for the residue coefficients and replacing the poles by their real parts, after which the differentiation in s is performed and s is taken to zero. The result, placed in (7), is

$$K_R\leq M\int_0^\infty d\lambda\lambda^m|w(\lambda)|\leq M m!\sum_{k=1}^N\frac{|a_k|}{(R\alpha_k)^{m+1}}, \tag{11}$$

where the α_k are the locations of the N poles of $H(s)$, whose real parts are indicated by $R\alpha_k$, and whose residues are a_k. The form of (11) shows the tendency to weight most heavily the poles nearest the origin when m is large. For the usual servo these poles will be close to the real axis, which circumstance will make this bound on K_R approximate the value $M|C_R|$.

The series (4) may be useful even though the derivatives of sufficient order for application of the above method do not exist over all time. If the nth derivative fails at some λ_d which is sufficiently large that K_d from (6) is known to be small, and if (7) and (9) are good approximations for K_R and C_r, respectively, we can proceed as in the earlier case.

It might be mentioned that the above relations are valid for servo systems whose weighting functions, $w(\lambda)$ vary with time, t, as a parameter, in such a way that the law of superposition applies for each value of t.

The Use of Critical Point Phenomena in Preparing Specimens for the Electron Microscope*

THOMAS F. ANDERSON
Johnson Research Foundation, University of Pennsylvania, Philadelphia, Pennsylvania
April 21, 1950

A SERIOUS handicap in the use of the electron microscope has been the fact that specimens must be dried before they can be examined in the high vacuum of the instrument. Delicate biological specimens are particularly susceptible to damage by the force of surface tension which flattens and sometimes disrupts them in the last stages of evaporation of the suspending medium. We report here a technique which eliminates the passage of a phase boundary through the specimen while it is being dried. After the specimen has been fixed, its water is replaced by alcohol, and the alcohol replaced in turn by each of a series of miscible liquids, the last in the series being one which has a conveniently low critical temperature. The temperature of the specimen in a bomb completely filled with the latter liquid is then raised above the critical point where the liquid changes imperceptibly into a gas. Then the gas is allowed to escape at the higher temperature leaving behind a dried specimen through which no phase boundary has passed. As a result, specimens like the hemolysed human red cells shown in the stereoscopic pair of electron micrographs of Fig. 1 retain their round shapes when dried in this way rather than being pressed flatly against the supporting Formvar membrane by the tension in the surface of an evaporating water droplet as they would have been in the conventional method of mounting specimens.

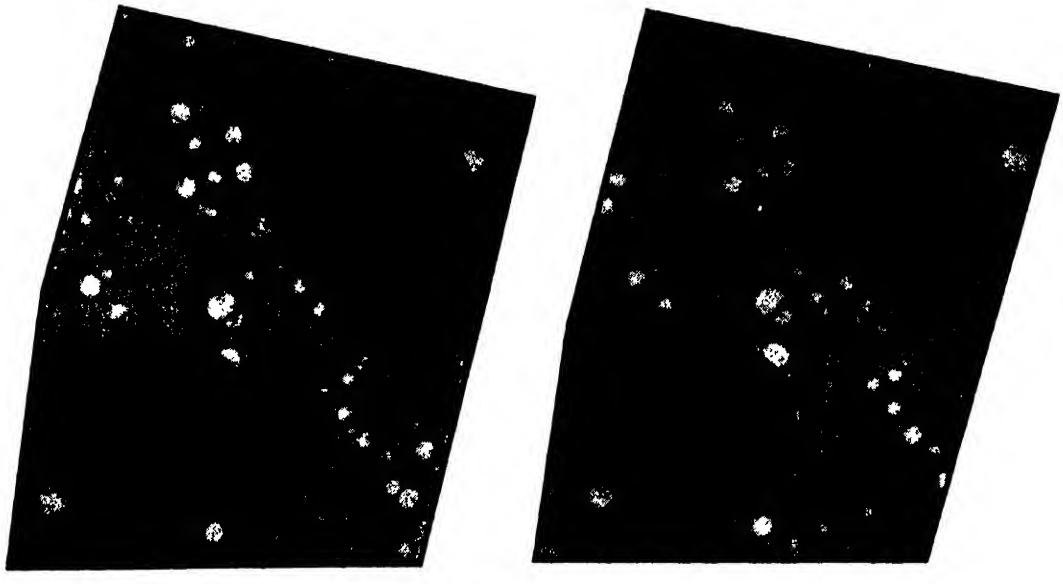

FIG. 1. Stereoscopic pair of micrographs of hemolysed red cells. Whole blood was diluted 1:10 in physiological saline, and the hemoglobin removed from the cells by the addition of an equal volume of water. A droplet of the hemolysed cells was then placed on a Formvar-coated specimen screen, fixed in osmic acid vapor, taken through alcohol to amyl acetate and then to liquid nitrous oxide in a pressure bomb at 25°. The temperature was then raised to 45° and the now gaseous nitrous oxide allowed to escape. The hollow "ghosts" of the cells may be seen adhering to the Formvar membrane.

International Congress on Electron Microscopy at Paris, September 14–22, 1950

A preliminary announcement has been received in this country concerning the above meeting. The following information has been abstracted from this announcement:

1. The Congress will include Sections on Electron Optics and Microscopes, Electron Diffraction, Metallurgical Applications, Chemical Applications, and Biological Applications as well as an Exhibition devoted to "The Microscope" and an Exhibition of the work of those attending.
2. The official language will be French but papers may be presented in English.
3. Titles and abstracts of papers should be submitted by June 1st to the General Secretary of the Congress, M. Locquin, Lab. de Cryptogamie, 12 rue de Buffon, Paris 5°, France.
4. The manuscripts of papers should be submitted by August 1st. The Congress reserves to itself the right to publish such manuscripts unless it has given a written release to the contrary.

Further details may be obtained from C. J. Burton, American Optical Company, Southbridge, Massachusetts.

Conductivity of Liquid Selenium—200°–500°C*

HERBERT W. HENKELS
Moore School of Electrical Engineering, University of Pennsylvania, Philadelphia, Pennsylvania
(Received October 20, 1949)

The conductivity of liquid selenium has been measured in the temperature range 200°–500°C. The resistivity was expressed by $\log_{10}\rho = A + (B/T)$. Average values for different selenium lots and melts of A and B were -3.81 and 5850. The maximum deviations from the averages were 10 percent and 3.4 percent respectively. The resistivity was a function of temperature alone.

Various non-metal impurities Cl_2, I_2, P lowered the resistivities and produced different values of B in different temperature ranges. Mercury addition caused no change in either A or B although that metal greatly influences the resistance of solid hexagonal selenium. Melts doped with Cl_2 or Br_2, along with Hg exhibited behaviors different from those with single additions.

It was concluded that selenium is an ideal semiconductor in the range of measurement.

INTRODUCTION

STUDIES of the electrical properties of selenium are in progress at the University of Pennsylvania. Investigations on the subject have been summarized in Technical Report No. 9 entitled "Summary of Recent Work on the Conductivity of Selenium." It develops from a consideration of the data presented that a satisfactory explanation of conduction and the absence of measurable Hall effect[1] in solid selenium may require data on the conductivity of pure and doped, liquid and amorphous selenium. Existing data is scarce and unsatisfactory for reasons to be discussed later.

The study was considered profitable for several additional reasons. Satisfactory solid samples must at present be made according to an entirely empirical procedure. Studies of solid samples are greatly influenced by the crystalline condition of the sample. Therefore a detailed examination of the conditions of the selenium in all stages of sample preparation seemed highly desirable. Selenium is the simplest of the materials forming a stable amorphous phase. The data presented may prove useful in the further development of the theory of the liquid state. Commercial rectifiers are prepared from selenium doped with different halides. A continuous indication of the percentage impurity present in the molten selenium batch would be useful. The present report shows the possibilities of such an indication.

EXISTING DATA

Pelabon[2] reported a single measuring series with temperature variation from 390 to 690°C. The data was represented by:

$$\log\rho = 8.506 - 0.0095t(°C).$$

At 300° the resistance was noticed to decrease suddenly with a velocity that made measurements impossible. The origin of the selenium used in the experiments was not mentioned.

Borelius *et al.*[3] presented data on the resistance of solid and liquid selenium. Various selenium samples were sealed in glass tubes equipped with suitable platinum electrodes and the resistance was measured both as functions of periods of heating and of temperature. In the range measured, the specific resistance ρ followed the law, $\log\rho = A + (B/T)$, where T is the absolute temperature, A and B are constants. The results are given in Fig. 12.

* The following work has been done under contract NObs 34144 of the Bureau of Ships, United States Navy Department and previously reported as Technical Report No. 13 for that contract.

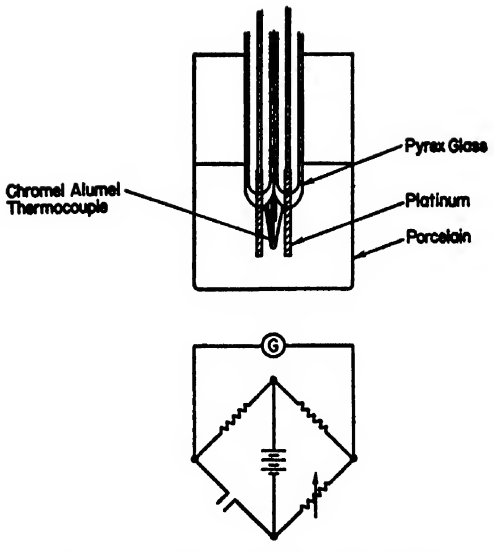

FIG. 1. Conductivity cell (liquid 200–500°C).

The values of A and B were observed to vary with the sample, period of heating and with depth of the electrodes in the melt. The heating periods were quite long (about 1800 hours). On the basis of the variation of resistance with depth of electrodes and differences observed in the conductivity of the cooling products of different strata of the melt, two liquid phases were postulated, a heavier one with low value of B and a lighter one with higher value of B. The properties of liquid selenium were adjudged similar to those of liquid sulfur.

NEW DATA

Source of Selenium

Selenium for the experiment was obtained from the Canadian Copper Refiners, Ltd. The analysis of the C.P. shot, performed by the laboratory of the company, was as follows:

Cu	Fe	Te	N.V.R.
0.1	0.8	0.2	5

parts per million. The selenium was purified in the following steps:†

1. Distillation at atmospheric pressure;
2. Oxidation in vapor state to SeO_2;
3. Resublimation of the SeO_2, followed by reduction in vapor state with NH_3 to elemental selenium;
4. Distillation of selenium in quartz apparatus, followed by condensation and shotting in distilled water.

Experimental Arrangements

Resistance was measured with a conductivity cell in an ordinary d.c. bridge circuit.

The conductivity cell is sketched in Fig. 1. Forty mil platinum wires were sealed in Pyrex tubing with 15 mm exposed. The glass tubes were then fastened together so that the electrodes were spaced 9 mm apart. A third glass tube with the end drawn to a small diameter and sealed, was fastened to the other tubes and served as the well for a thermocouple. This arrangement was placed in the center of a small porcelain beaker containing the sample which in turn was situated in the center of an electrically heated oven.

Decade resistance boxes were used as the arms of the bridge. These were calibrated and were found to have an error less than 1 percent. A Weston galvanometer with sensitivity of 0.25×10^{-6} amp./mm was used as null indicator.

For temperature measurements a chromel alumel thermocouple was introduced into the thermometer well. One wire was threaded into a piece of fine tubing to prevent shorting after the insulation had melted. The thermocouple hot junction was in contact with the thin drawn walls of the well. The e.m.f. was measured with a type K potentiometer whose smallest scale division was 5 microvolts. A Rubicon galvanometer with sensitivity

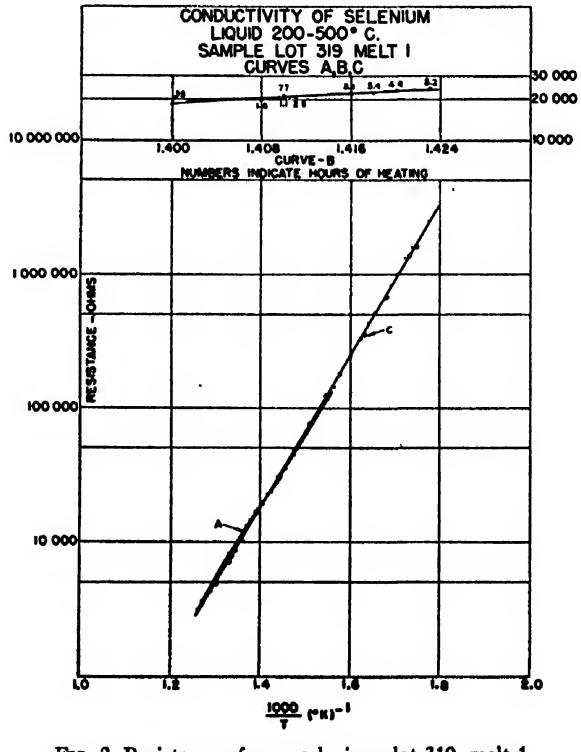

FIG. 2. Resistance of pure selenium, lot 319, melt 1.

of 6×10^{-10} amp./mm was used for null indicator. The standard e.m.f. was furnished by a new Eppley cell recently calibrated. Cold junction temperature was measured with a small mercury thermometer.

The conductivity cell constants were determined by calibration against an 0.01N KCl solution. The depth of the electrodes in the solution did not affect the value. The cell constants were the order of 1 ohm cm/ohm.

Consideration of Contact Resistance

Measurements on a cell with variable distance between the electrodes showed that contact resistance is of no importance.[3] This result agrees with the observations of Schweickert and Ioffe on the connection between

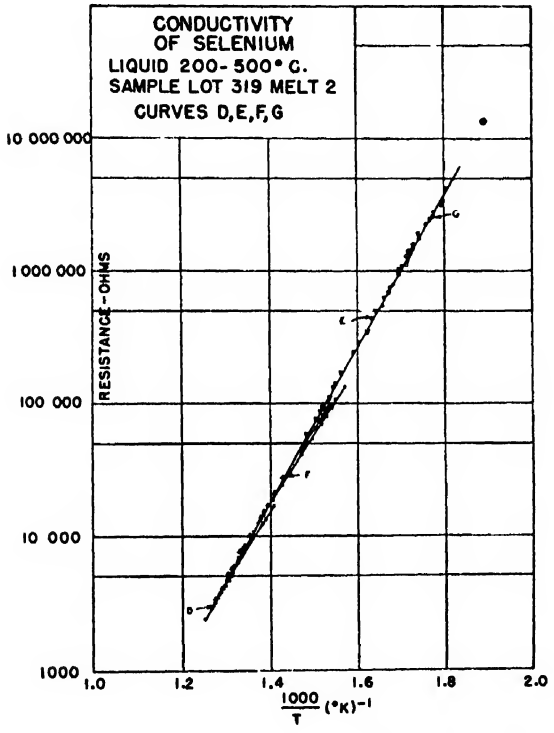

FIG. 3. Resistance of pure selenium, lot 319, melt 2.

contact resistance of metals against selenium and the work function of the metals.[4,5]

Procedure

The cell was carefully washed, rinsed in absolute methyl alcohol and dried in an oven. Selenium shot was introduced and melted. The heating procedure was varied from run to run in order to establish the dependence, if any, of the resistance on previous treatment. The thermocouple e.m.f. was measured simultaneously with the resistance. Care was taken to avoid contaminating the selenium with dust. Any contamination

[4] Schottky, Zeits. f. Physik 118, 539 (1941).

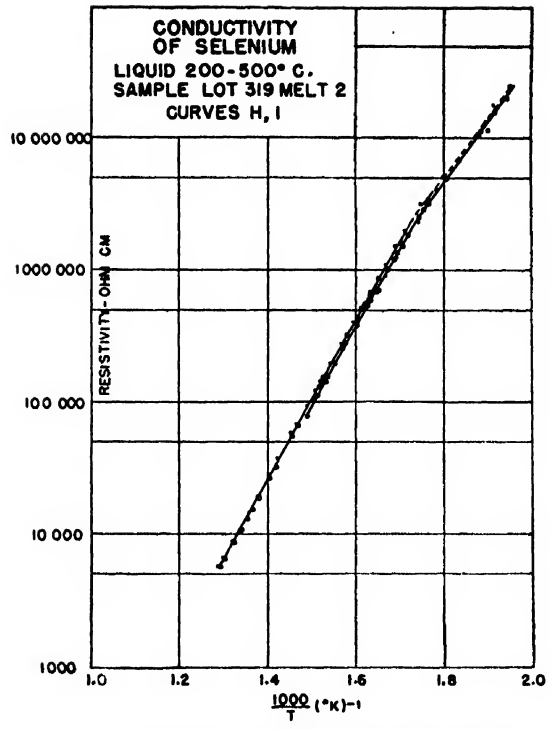

FIG. 4. Resistivity of pure selenium, lot 319, melt 2.

was evidenced by the presence of small crystallized spots in the amorphous selenium surface after cooling slowly to room temperature.

Accuracy of Measurements

The precision of measurement of resistance was limited by the spread of the null indication. At low resistances the error was less than 1 percent, at high values (10 megohms) perhaps as high as 5 percent. The error in reading temperatures was about ±1.00°C arising from difficulty in balancing the bridge and the potentiometers simultaneously. The cell calibration was accurate to ±5 percent.

Data

The data collected is plotted in curves in Figs. 2–12. The results are reviewed in the discussion.

DISCUSSION

Pure Selenium

Care was taken in assembling the data to attain equilibrium conditions. Time rates of change of temperature varied from run to run but averaged about two or three degrees per minute. This rate gave satisfactory curves throughout most of the range. Below 300° a slower rate was desirable. Curves were retraced on reversing the sign of the temperature change. At low temperatures hysteresis loops occurred in a few cases (see curves *N*, *O*, *Q*, *V*, *AE*).

TABLE II.

Sample	Curve	Temp.	A	B
lot 319 melt 2	H, I	215–500	−3.99	5900–6010
lot 319 melt 2 1% I_2	J	215–500	−1.79	3980

I_2 K	L	215–500	−1.96	4240
I_2 L	M	215–500	−2.12	4420

TABLE III.

Sample	Curve	Temp.	A	B
lot 319 melt 3	N	250–500	−3.87	5930
lot 319 melt 3 with 0.1% mercury	O	250–500	−3.87	5930
lot 319 melt 3 with 0.1% mercury	Q	250–500	−4.00	6040

Curves $A, B, C, D, E, F, G, I, N, V, W, X, Y, AG, AH$ give data on pure selenium. Temperature dependence of resistance followed the law

$$\log_{10}\rho = A + B/T$$

with values of A and B given in Table I. An average of the values of B gives 5850 with maximum deviation 3.4 percent, of A gives −3.81 with 10 percent deviation.

Curves $H, I, O, Q, V, W, X, Y, AD, AE$, perhaps N, AG and AH show a slight change in temperature coefficient about 300°C. The kink is most easily noticeable in experiments with selenium that has been exposed to air a considerable length of time. This change has been attributed to the presence of SeO_2.

Curve B shows the effect of a short period of heating at about 400°C on the resistance of pure selenium. No change in resistance is apparent. A study of temperature coefficients, B, in Table I, does reveal a slight change in slope with prolonged heating but this is almost within the experimental error of the procedure. The curves AD, AE, AF of Fig. 10 of results on pure melts 5 and 6 give rather low temperature coefficients ($B=5200$ in curve AD). Incidentally, the kink at about 300° is well shown in AE. It was evident from the appearance of crystallized portions in the melt on cooling in the oven that these samples were contaminated. Sample AF completely crystallized on cooling. After the experiment was completed the entire apparatus (oven, hood, etc.) was cleaned thoroughly. Lot 504–2 melt 1 then repeated the values of slope obtained in former samples.

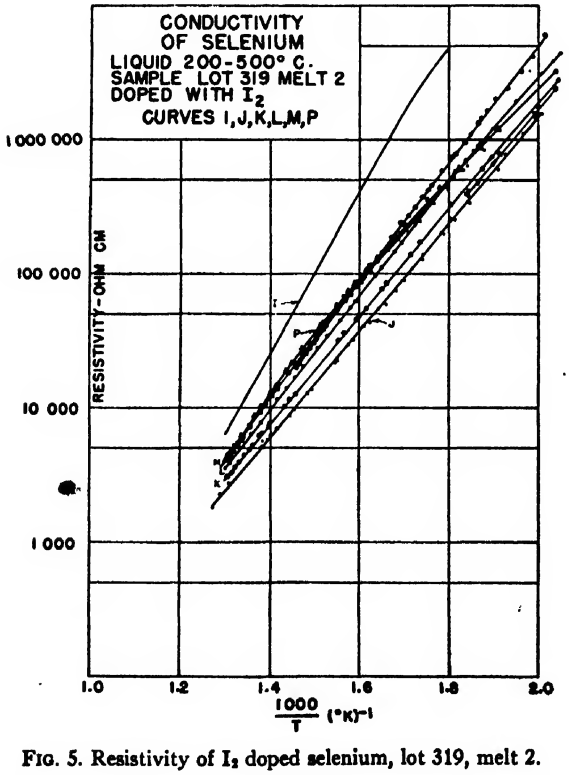

FIG. 5. Resistivity of I_2 doped selenium, lot 319, melt 2.

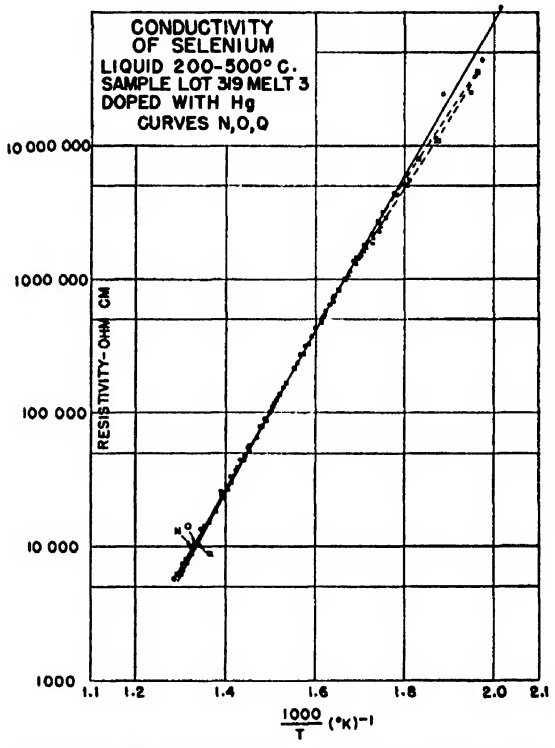

FIG. 6. Resistivity of Hg doped selenium, lot 319, melt 2.

The results of H Pélabon are plotted in Fig. 12. At 300° the resistance decreased suddenly with a velocity such that measurements were not possible. This observation was not checked by our data. At temperatures below 220° all samples crystallized (except those containing phosphorous) with a velocity depending on the amount and type of impurity present.

The data of Borelius is plotted in the same figure. Temperature coefficients varied considerably among samples of different purity (as would be expected) but also changed with different measurements on the same

sample and with depth of the conductivity electrodes in the melt. An equilibrium of two liquid phases of different densities and conductivities was postulated. In our data all pure samples gave the same results. No variation of resistance with depth was noticed. A. N. Campbell and S. Epstein[6] found no indication of shifting internal equilibrium in density measurements over the range 20–277°C. Dobinski and J. Wesolowski[7] found the density exhibited no singularities between 217° and 300°C. The viscosity temperature curve of selenium is given by Dobinski and Wesolowski[8] that of sulfur by

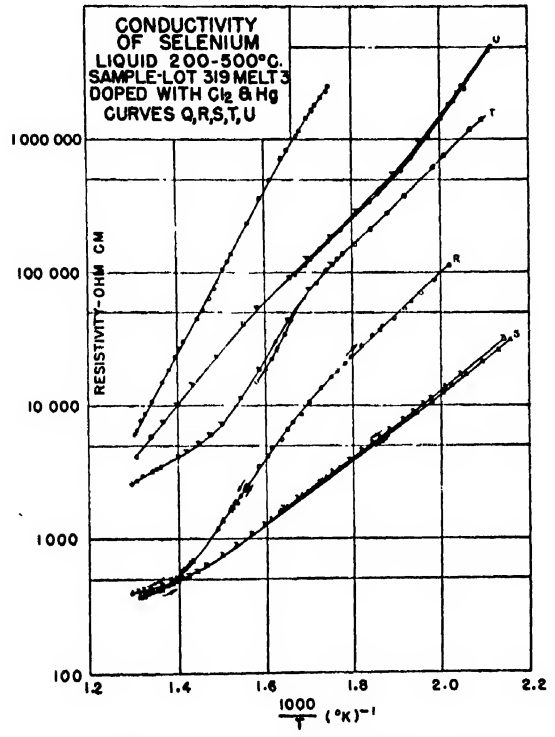

FIG. 7. Resistivity of selenium doped with Hg and Cl_2, lot 319, melt 3.

Bacon and Fanelli.[9] Selenium shows no tendency to form a ring structure at low temperatures as evidenced by the shape of the viscosity curve.

Doped Selenium

The melt of curve *I* was cooled to about 250°C and 1 percent by weight of iodine Se_2I_2(?) was introduced. After a mixing period of one minute, curve *J* was traced. Curve *K* was obtained after a 3½-hour period of heating above 400°C, curve *L* after additional 5 hours, curve *M*

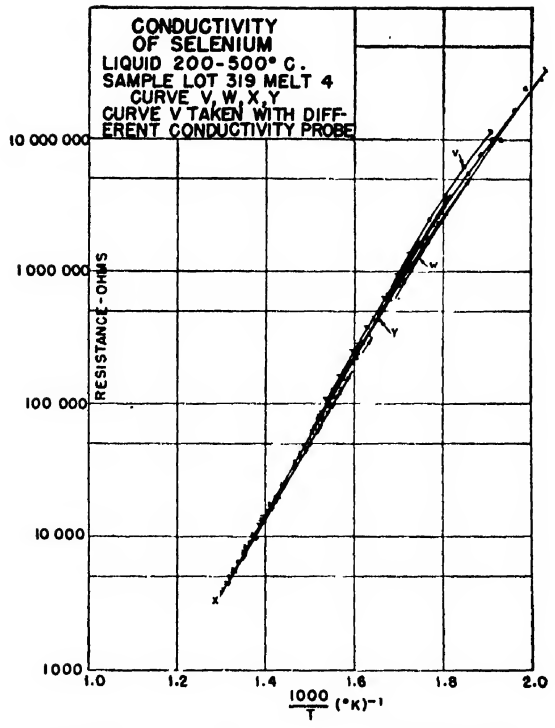

FIG. 8. Resistance of pure selenium, lot 319, melt 4.

after an additional 1¾-hours heating. Table II gives the changes in *A* and *B*. The temperature coefficients are observed to have increased slowly as I_2 was expelled.

0.1 percent mercury as HgSe was added to pure selenium of curve *N* and curve *O* was traced. No change in *A* or *B* was noted. The melt was then heated for 1 hour above 400°C and curve *Q* obtained. Again as indicated in Table III, no definite change in either *A* or *B* was observed.

Melt *M* was then doped with 0.1 percent mercury and immediately retested. Whereas no kinks were evident in curve *M* two appeared in curve *P* (see Table IV). Since conditions were the same in experiments *M* and *P* the changes in temperature coefficients at various temperatures must be attributed to the activity of various compounds of mercury and iodine. Mercury by itself has no effect on temperature coefficients as shown in curves *O* and *Q*. The possible significance of this fact will be discussed later.

The effect on an addition of 1 percent Cl_2 as Se_2Cl_2 to the melt of experiment *Q* is shown in curve *R*. The selenium solidified during addition of Se_2Cl_2 so that run *R* may have been conducted on an inhomogeneous sample. After the melt was heated to 500°C, curve *S* was obtained on cooling. Two temperature coefficients were measured for curve *S*, from 190 to 395°C, 2460, from 395–500°C, 1460. The effect of periods of heating on this melt are shown in Curves *T* and *U*. Different coefficients are noticed in various ranges. Compounds of mercury and chlorine could be active. To check the effect of

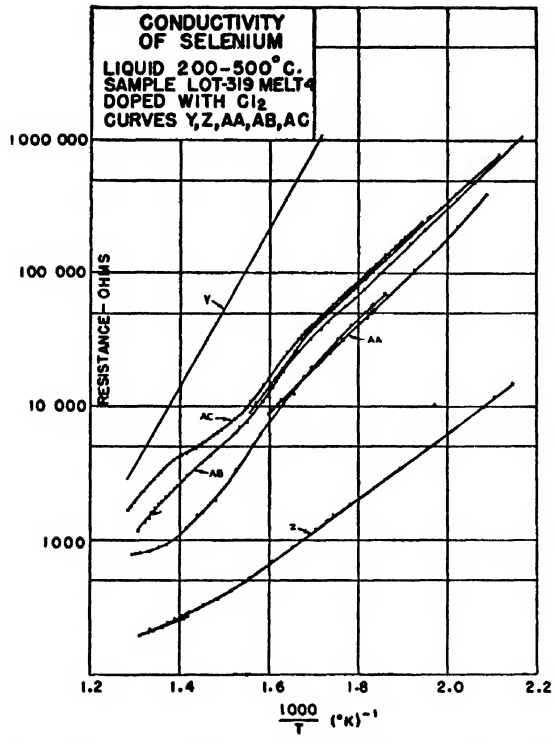

FIG. 9. Resistance of Cl_2 doped selenium, lot 319, melt 4.

chlorine, experiments *Y, Z, AA, AB, AC* were conducted on melts of pure selenium with Cl_2 added as Se_2Cl_2. This time the curve for low slope was obtained immediately. Temperature coefficients were almost identical in curves *S* and *Z*. (See Table V.) (Neither of these melts crystallized on cooling in the oven. This observation is explained in the following manner. Small amounts of impurities act as crystallization centers whereas excessive amounts inhibit the growth of crystals breaking up the continuity of crystallites as in the analogous case of oxygen in molten iron.) Curves *AA, AB, AC* have the same general appearance. In the last two cases a change in temperature coefficient seems to occur about 327°, one at 377° and another at 447°C. Interpretation of the curves is difficult. It is noteworthy that in all cases the resistances of the melts increased steadily with expulsion of chlorine by heating. Various compounds of platinum and chlorine and possibly oxygen influence the temperature coefficient. Experiments were conducted with melts containing 1 percent P. Equilibrium conditions were difficult to attain. A distinct change in temperature coefficient was noted at about 358°C. Below that temperature the value of *B* was 2170, above about 4200. This last figure is not very reliable. It is included to show the direction of the bend and the fact that the original value of *B* was never equaled or exceeded with impurities in the melt. (Melts with phosphorous would not crystallize under any condition. An explanation lies in the netting of molecular

threads caused by the trivalence of the element as discussed in Technical Report No. 9.)[1]

Data on different impurities in selenium is collected in Table VI.

The data indicates that selenium when pure, behaves as an ideal semiconductor in the range of temperatures measured. Non-metal impurities decrease the activation energy of the element in an amount depending on the type of impurity. Note the wide difference between the effect of iodine and chlorine, and to a smaller extent on the amount of impurity (experiments H, I, J, K, L, M). The impurity mercury was chosen as one usually considered to have a radical effect on the electrical properties of selenium. Experiments N, O, Q show that mercury was ineffective in changing the activation energies of the pure melt but was active in combining with the non-metals already in the selenium (curve P). Perhaps the discrepancy between the results of Penin and Astakhov[10] and rectifier manufacturers mentioned in Technical Report No. 9 can be resolved by assuming the experiments of the former were carried out on pure selenium whereas selenium doped with halogens was used commercially.

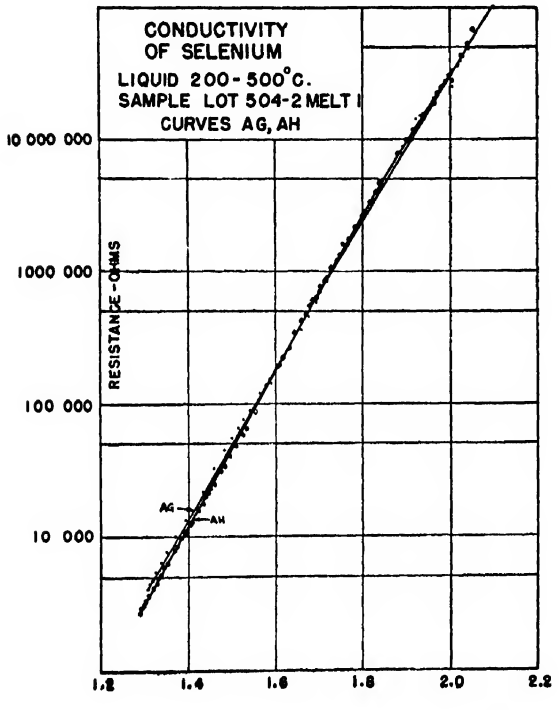

FIG. 11. Resistance of pure selenium, lot 504–2, melt 1.

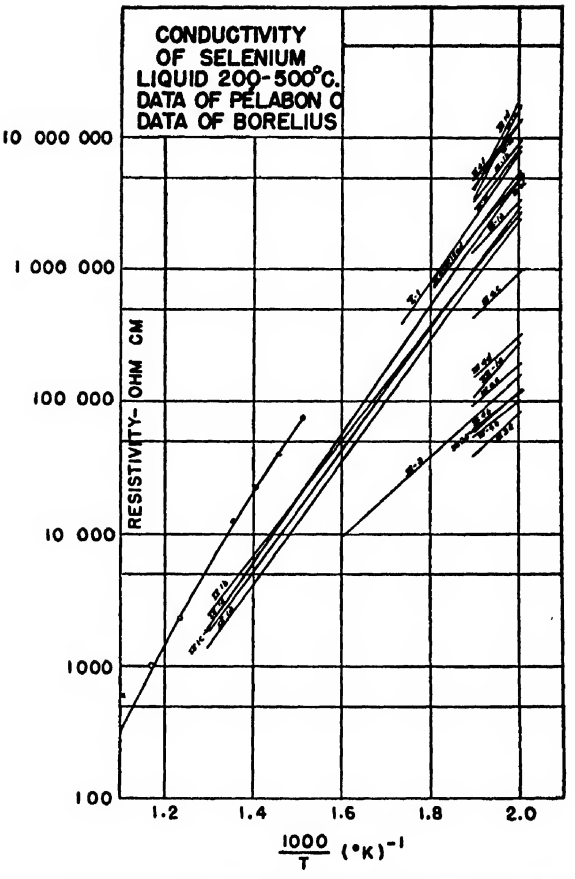

FIG. 12. Resistivity of selenium (data of Pélabon and Borelius).

Melts with metals and non-metals behave in a manner difficult to explain. It is however reasonable to assume that different compounds are stable in different temperature regions and that these compounds should influence the activation energies. There may perhaps be a certain amount of ionic conductivity. However the presence of a large thermoelectric power in liquid selenium and the value of activation energy indicates electronic conduction for the pure semiconductor.

The Specific Heats of MgO, TiO_2, and ZrO_2 at High Temperatures*

JAMES S. ARTHUR
Department of Physics, The University of Pittsburgh, Pittsburgh, Pennsylvania
(Received June 23, 1949)

Mean specific heats were determined from 20°C to 800°C for MgO, TiO_2, and ZrO_2. True specific heats were then calculated assuming that $C_T = A + BT + CT^2$. At 350°C the true specific heats were calculated to be MgO 0.276; TiO_2 0.210; ZrO_2 0.140.

SOME data on the specific heats of oxides in the high temperature range, 20° to 1500°C, are available.[1,2] One of the methods of measuring specific heats employs an adiabatic calorimeter of the type described by Harry Hill and R. M. Bell.[3]

The calorimeter used in obtaining the data listed in this article was patterned after the one used by Hill and Bell with two main changes. An electrolytic, bath type heater was used instead of an electric coil heater in the jacket. The purpose of the heater is to enable the experimenter to match the temperature of the jacket surrounding the calorimeter cup with that of the cup and sample. The electrolyte used was tap water. Advantage is gained in getting more uniform heating and a much shorter reaction time. In addition, the plywood box enclosing the calorimeter cup was lined with aluminum foil to further reduce heat losses.

The calorimeter was calibrated by a small electric heating coil, as described by Hill and Bell.[3]

The heat capacity of the cup was found to increase with temperature in the range 20° to 40°C.

The oxide samples were obtained in powder form and packed into metal foil in the form of cylindrical pellets.[4] The dimensions of the pellets were slightly smaller than the dimensions of the cavity in the calorimeter cup. Aluminum foil was used for temperatures under 600°C and platinum foil when determinations were made at higher temperatures. A mold was used to make the pellets. It consisted of a cylinder composed of two close fitting pieces of hard wood with a brass insert, and a tamping piston made of dowel wood.

A Hoskins electric furnace, type FH204C was used to heat the samples. The temperature was regulated by a Brown electric pyrometer. All high temperature measurements were made with Chromel-alumel or iron-constanton thermocouples.

The methods used to calculate mean specific heat and true specific heat may be found in an article by Wilkes and Wood.[5] Values of mean specific heat are obtained directly from the data recorded and may be written as:

$$C_m = A + B/2(t_2 + t_1) + C/3(t_2^2 + t_2 t_1 + t_1^2), \qquad (1)$$

where C_m = mean specific heat, t_2 = furnace temperature, t_1 = final cup and sample temperature, and A, B, and C

are constants. The true specific heat at any temperature is given by:

$$C_T = A + Bt + Ct^2, \qquad (2)$$

where C_T = true specific heat, t = temperature, and A, B, and C are the same constants as used in (1).

DISCUSSION OF RESULTS

The chief function of this article is to list the mean specific heats of MgO, TiO_2 and ZrO_2 in the range 20°–800°C and the true specific heats for the same oxides. The accuracy of the specific heats is judged to be ±2.0 percent.

MgO has a mean specific heat of 0.246 in the range 25°–200°C and 0.282 in the range 37°–800°C (see Table I). TiO_2 has a mean specific heat of 0.175 in the range 24°–200°C and 0.206 in the range 37°-800°C (see Table II).

ZrO_2 has a mean specific heat of 0.115 in the range 24°–200°C and 0.136 in the range 38°–800°C (see Table III).

Table I shows a comparison of the values of the mean specific heat of MgO obtained by the author with those obtained by G. B. Wilkes using an adiabatic bomb calorimeter. The author's values were consistently higher by approximately 0.3 percent for the same temperature range.

TABLE IV. Values of A, B, and C for MgO, TiO_2, and ZrO_2.

	$C_T = A + Bt + Ct^2$		
Material	A	B	C
MgO	0.2342	0.000124	−0.0000000170
TiO_2	0.1512	0.000245	−0.000000222
ZrO_2	0.0988	0.000173	−0.000000156

TABLE V. True specific heats of MgO, TiO_2, and ZrO_2.

Material	Temperature (°C)	True specific heat (Cal/g-deg. C.)
MgO	200	0.258
	350	0.276
	500	0.292
TiO_2	200	0.191
	350	0.210
	500	0.218
ZrO_2	200	0.127
	350	0.140
	500	0.146

Table IV is a list of the values of the constants A, B, and C which determine the equation of true specific heat in terms of temperature:

$$C_T = A + Bt + Ct^2.$$

Some values of C_T are listed in Table V. The values of true specific heat are accurate for temperature ranges approximately half that of the mean specific heats.

Errors resulting from variation in heat capacity of the cup with temperature are estimated at ±2.0 percent.

Radiation errors were minimized in the following ways: (1) A small refractory furnace was used to transfer the hot sample from the large furnace to the cup; (2) a baffle and guide arrangement was used to guide the sample into the cup and prevent direct heat radiation from the small furnace into the cup; (3) rapid transfers of samples were made, and mainly, (4) the use of the adiabatic heating jacket to keep the cup surroundings at the same temperature as the cup.

The Effect of a Video Filter on the Detection of Pulsed Signals in Noise*

DAVID MIDDLETON
Cruft Laboratory, Harvard University, Cambridge, Massachusetts
(Received November 30, 1949)

The effects of inserting a video filter of finite width on the observability of pulsed signals in random noise are examined. It is found that at match (when the pulse and IF filter are each other's conjugate Fourier transforms) no improvement is gained from such a video: the infinitely wide response yields the optimum results. This is strictly true when the second detector is a quadratic rectifier; (a slight improvement on narrowing the video is noted, however, for strong signals when a half-wave linear rectifier is used). Away from match a video filter does give noticeable improvement when the pulses are overlong, i.e., narrower spectrally than the IF ($\lambda>1$); more noise than signal is then removed by the narrower video filter. The greatest gain over the infinite video is observed for final filters slightly wider than the original pulse. On the other hand, for pulses that are too short ($\lambda<1$) the performance is worsened. The mean maximum signal level is decreased more rapidly than the interfering noise background. In all instances the familiar phenomenon of modulation suppression arises. Two different pulse shapes are considered: (1) Gaussian and (2) rectangular, but for wide videos pulse shape is not a critical factor. Curves showing the output signal-to-noise ratios as a function of the input ratio are included for conditions of match ($\lambda=1$) and mismatch ($\lambda\neq1$).

I. INTRODUCTION AND DISCUSSION

IN an earlier paper[1] the factors governing the reception of pulsed (radar) signals in random noise were discussed, and expressions for the output signal-to-noise ratio in terms of the input ratio were derived for three principal modes of perception: (1) observation of an oscilloscope screen, (2) listening to an harmonic of the pulse repetition frequency (PRF) or (3) noting the mean change in a meter's deflection in the presence and absence of a signal. Here, however, we are concerned with visual reception only, and it is the aim of this paper to examine the effects of inserting a finite video filter in the stage before observation (instead of the infinitely wide, uniform response assumed in the earlier analysis),[1] particularly when the pulse and IF filter are not matched, i.e., are not each other's conjugate Fourier transforms. Recent experiments by Fromm[2] indicate good qualitative agreement with the present theory. Some as yet unpublished,** theoretical discussion of the video filter and extensive experimental investigations, supporting our present conclusions were carried out during the war.[3]

The IF and succeeding stages of the receiver have a critical effect on reception. Coming into the IF is a fluctuating noise voltage and also a signal which is a known function of the time. After filtering and rectification the video amplitude cannot be represented as the simple sum of pure signal and "pure" (i.e., normal random) noise, as there are complicated modulation products generated between the two, especially following a linear detector. If the signal is repeated periodically there will be a certain interval during which the amplitude on the oscilloscope screen is on the average a maximum. Our definition, therefore, of what constitutes a signal in the visual case treated here is *the excess of the average of the amplitude, which we designate as* $s_v(0)_G$, *during this interval, over the mean amplitude* ($=n_v$, the r.m.s. video noise voltage) *in the absence of signal.* The concept of the average is needed because sometimes the noise interferes constructively and sometimes destructively with the signal. The above is called the "simple" criterion for visual detection[1] because, in practice, examination merely of the output ratio $s_v(0)_G/n_v$ neglects certain factors. For example, the effects of the (time) widths of the pulse *versus* the widths of the "blades of grass," or noise, are not considered, and in particular our definition does not take into account the action of pulse repetition: the more frequent the pulse, the more easily the eye integrates (in the limited time at its disposal) to detect the mean position of the pulse or pip with respect to the fluctuating background. To test the simple theory, therefore, we need a device, like the peak-reading meter,[2] which does not depend on PRF, but which gives $s_v(0)_G$ directly. The results are applicable to the radar problem within the limitations described above when the eye and brain constitute the final integrating elements. A table listing the various parameters—λ, Ω, Ω', involving the filter widths, pulse widths and durations, etc., that appear in the analysis—is included at the end of this section. Figure 1 illustrates the two types of pulse treated here and their respective spectra.

Figures 2–4 show the output video signal-to-noise ratio as a function of $\sigma_0^2\lambda$, where σ_0 is defined as the ratio of the r.m.s. maximum signal amplitude to the r.m.s. noise amplitude after passage through an IF filter which is matched to the incoming pulse [Eq. (2.13)]; for the Gaussian pulses and filter λ represents the ratio

* The research reported in this document was made possible through support extended Cruft Laboratory, Harvard University, jointly by the Navy Department (ONR) and the Signal Corps, U. S. Army, under Contract N5ori-76, T. O. 1.

** *Note added in proof:* A similar analysis of the video filter problem is discussed in section 8.7 of reference 3 above. The results of both researches are in close and satisfactory agreement.

[3] J. L. Lawson and G. E. Uhlenbeck, *Threshold Signals*, Book No. 24 (Massachusetts Institute of Technology) Radiation Laboratory Series, McGraw-Hill Book Company, Inc., New York, 1950.

of IF width to pulse width (frequency), cf. Eq. (2.15) and Table I. The factor λ is included to take into account the increased power necessary to give the same value of s_v/n_v at the output when the pulse and filter are no longer matched ($\lambda \neq 1$). Thus, Figs. 2–4 may be compared directly to show the well-known result[1] that at match a given value of the output ratio s_v/n_v (for the same arbitrary video filter width) is always obtained for the least energy per pulse or, equivalently, for the smallest average pulse power. Figures 2–4 also compare the Gaussian and rectangular pulses of initially the same energy [condition (2.23)]. At match for the Gaussian pulses ($\lambda=1$) the rectangular pulse is slightly off match, since our Gaussian IF is no longer the Fourier transform of the rectangular pulse. For this reason $(s_v/n_v)_{\text{rect.},\lambda=1}$ lies somewhat below the values of $(s_v/n_v)_{\text{Gauss.},\lambda=1}$ for the same video filters (same Ω).

Insertion of a finite video filter *at match* gives no improvement in the Gaussian case, provided the signal is weak compared to the noise, i.e., provided that the linear detector is functioning essentially like a quadratic one.[4] When the signals are strong ($\sigma_0^2 > 10$ db), however, a slight improvement is observed (Fig. 3) for video widths of the order of the original pulse width, i.e., $\Omega \sim 1$, 2. This occurs because a video filter helps to decrease the effects of the low frequency ($n \times n$) noise components arising from the higher-order modulation products generated in the linear detector, products which are absent in the output of the square-law rectifier. Insertion of a video filter away from match, however, will give significant improvement when the pulse is sufficiently long, a fact verified experimentally by Fromm.[2] The gain in performance is particularly noticeable when the IF is much greater than the pulse's spectral spread (see, for example, $\lambda=10$, Fig. 4). Too much noise is then passed by the IF along with the signal, and accordingly narrowing the video helps to eliminate some of the added noise products following rectification. The maximum effect occurs for videos slightly broader than the pulse spectrum. Of course, too pronounced a decrease in video width will eventually cut down the maximum signal level more rapidly than the noise, and the system will lose in effectiveness. Such behavior is observed in Figs. 2–4 as $\Omega \to 0$. On the other hand, for an IF narrower than the pulse (say, $\lambda=0.1$, Fig. 2) no improvement is observed: an infinitely wide video still gives the best results. This is because now the maximum signal strength is decreased more rapidly by the insertion of a video filter than is the r.m.s. noise level.

Figure 5(a) shows how the input power required for a given output ratio ($s_v/n_v=0$ db) varies with the pulse or IF band width, for a variety of video responses. The narrower the video the smaller the value of $\bar{\lambda}(\equiv \omega_v/\omega_b)$ at which the mean input power $\bar{P}$ is a minimum. The explanation lies in the fact that for a fixed IF characteristic the longer pulses have fewer significant components, among which correspondingly more of the pulse's energy is distributed; the narrow videos then remove relatively more noise than signal power in such circumstances, since a larger proportion of pulse energy lies in the low frequency harmonics passed by the video filter. The minimum power required for a given output (here $s_v/n_v=0$ db) occurs at match ($\lambda=1$), as predicted earlier. We note, moreover, that pulse shape is not a very critical factor, except when the video filters are very narrow compared to the pulse. Indeed, according to our "simple" criterion, performance at match (for a fixed PRF) is independent of pulse shape; (actually, there is a small modification because visibility of the pulse is somewhat affected by its widths).[3] Long pulses are no easier to detect than short ones in their respective matched conditions, since we observe merely the net increment in signal, which is quite independent of its duration. This is not true, of course, away from match, as Figs. 2 and 4 show: long pulses are then more easily detected than short ones.

Finally, we call attention to the phenomenon of *modulation suppression*, which is particularly noticeable when the signal is comparable to, and less than, the noise, and is characteristic of all nonlinear devices such as the second detector of our present receiver. For ex-

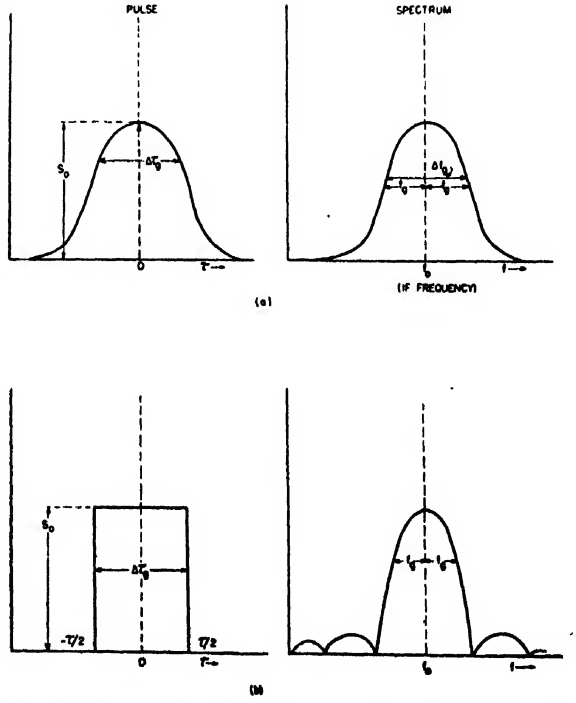

FIG. 1. The wave form and spectrum of (a), a Gaussian pulse, and (b), a rectangular pulse.

[4] This is easily deduced from Eq. (2.16) when $\lambda=1$; only the term $n=0$ in the expression for the noise $\Sigma_n(\Omega')$ (Eq. (2.8)) appears when the detector is a square-law device. We observe that

$$s_v(0)_G/n_v = \sigma_0^2[(\Omega^4+2\Omega^2)/(\Omega^4+2\Omega^2+1)]^{\frac{1}{2}}, \quad (\lambda=1),$$

and clearly the coefficient of σ_0^2 (=a constant) is a maximum when $\Omega \to \infty$, i.e., $\omega_v \to \infty$. This result that the optimum video is one that is indefinitely wide was originally shown by Uhlenbeck (reference 3); see also footnote 19, reference 1, and the footnote following reference 3 above.

ample, when this second detector is the half-wave linear rectifier assumed here, an incoming signal that is weak relative to the noise appears quadratically[5] in the output, instead of linearly; suppression is also noted when the noise is weak, for then the carrier in its turn overwhelms the noise in nonlinear fashion until for sufficiently intense signals the noise becomes relatively ignorable and independent of carrier strength. The envelope, or modulation, is reproduced without distortion. Suppression is evident in Figs. 2–4, where for small signals the slope of the curves is 2, changing to a slope of unity as the input power is increased. Experiment[2] is in good agreement on this point.

II. ANALYSIS

The present theory follows directly from reference 1; we assume explicitly that all filter characteristics are Gaussian. Such responses, while not actually realizeable in practice, are analytically very convenient, and are nevertheless good approximations in most instances,

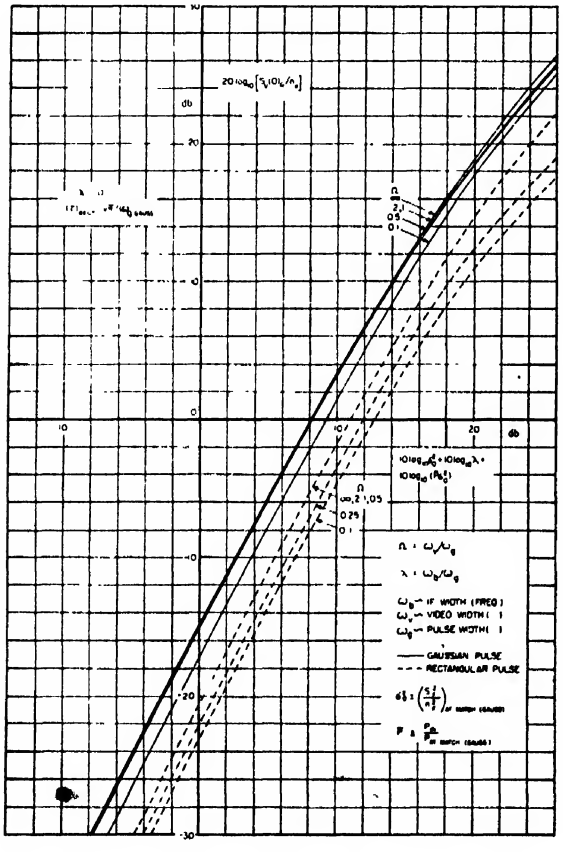

FIG. 2. Output video signal-to-noise ratios for unmatched pulse and IF ($\lambda<1$); same pulse power and peak amplitudes for Gaussian and rectangular pulses entering the IF.

[5] In fact, it has been shown that all half-wave second detectors behave like a quadratic rectifier when the signal is weak compared to the noise. For details see D. Middleton, *Rectification of a Sinusoidally Modulated Carrier in Random Noise*, Proc. I.R.E. 36, 1467 (1948), and Cruft Laboratory Technical Report No. 45, July 1, 1948.

as long as we are not too concerned with frequencies well away from resonance. Two different pulse shapes are considered here: (a) Gaussian and (b) rectangular (see Figs. 1a, 1b), the latter being closer to the particular waveform used in Fromm's work,[2] while the former is a more general shape; pulse shape itself, however, is not a very critical factor in most cases.

Let

$$G_v(\omega)=|G_v(\omega)|e^{-i\omega t_0}, \quad \omega=2\pi f, \quad f>0 \qquad (2.1)$$

be the amplitude response of the inserted video filter; we assume here, and in all our various filters, a phase shift that is linear with frequency—i.e., no phase distortion. The mean-square output noise voltage after rectification is represented by

$$n_v^2=\int_0^\infty W_0(f)df=4\int_0^\infty df\int_0^\infty R_0(t)\cos\omega t dt. \qquad (2.2)$$

Here $W_0(f)$ and $R_0(t)$ are, respectively, the low frequency power spectrum and correlation function after detection, on the assumption of an infinite, uniform video response. If we take account of the finite characteristic of our inserted video filter, (2.2) is modified at once to give

$$n_v^2=\int_0^\infty W_0(f)|G_v(\omega)|^2df=\frac{2}{\pi}\int_0^\infty |G_v(\omega)|^2d\omega \times\int_0^\infty R_0(t)_{(n\times n),\,p=0}\cos\omega t dt. \qquad (2.3)$$

Since the pulsed signal is on only a small fraction of the repetition period, the signal×noise ($s\times n$) products generated in rectification are negligible, and the noise ×noise ($n\times n$) contributions alone are significant; furthermore, the ($n\times n$) noise is essentially unaffected by the presence of such a signal, so that we can safely replace $R_0(t)$ in (2.2) above by $R_0(t)_{(n\times n),\,p=0}$, which is the output correlation function for rectified noise without a signal ($p=0$). The $d-c$ term, corresponding to the constant part of $R_0(t)$, is excluded, since our video filters do not pass the steady component of the detected wave.

For the effect of the video filter on the signal we may write

$$s_v(t)_G=\frac{1}{2\pi}\int_{-\infty}^{\infty}e^{i\omega t}S_v(\omega)G_v(\omega)d\omega, \qquad (2.4)$$

where $S_v(\omega)$ is the Fourier transform of the unfiltered video output, given by $[s_v(t)_{p>0}-s_v(t)_{p=0}]$. For real signals $G_v(\omega)$ is required to be equal to $G_v(-\omega)^*$; $s_v(t)_{p>0}$ and $s_v(t)_{p=0}$ correspond respectively to the r.m.s. increments in video signal (infinite, uniform video filter) when there is a pulse and noise and when there is noise alone. The difference of these two quantities is consequently the mean net increment in the video level due

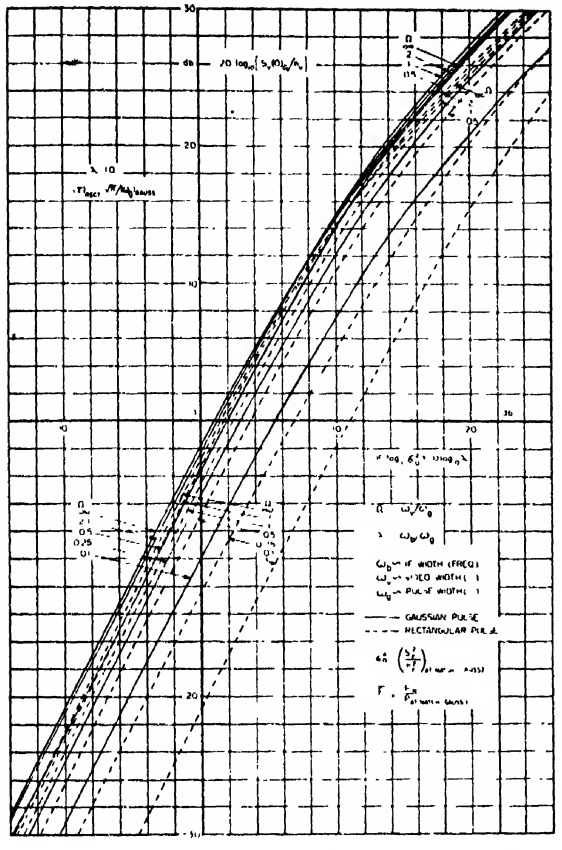

FIG. 3. Output video signal-to-noise ratios for matched pulse and IF; equal pulse power and peak amplitudes for Gaussian and rectangular pulses entering the IF.

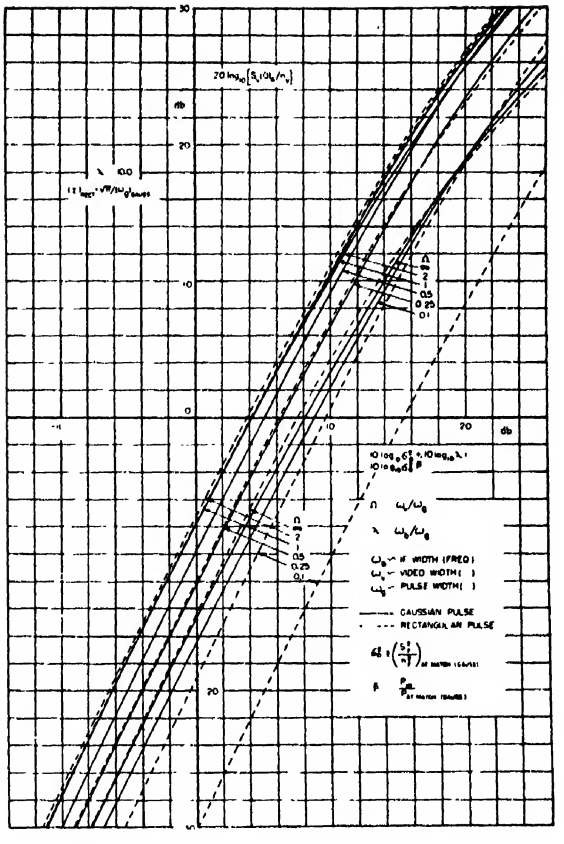

FIG. 4. Output video signal-to-noise ratios for unmatched pulse and IF ($\lambda>1$); same pulse power and peak amplitudes for Gaussian and rectangular pulses entering IF.

to the presence of a signal, corresponding to our definition in Section 1. (The notation here and in what follows is that of reference 1.) With the aid of (2.1) in (2.4) we obtain $s_v(t)_G$, observing that according to our "simple" criterion of visibility we want now the maximum value of $s_v(t)_G$; this corresponds to the maximum of the r.m.s. increment due to signal and noise over the surrounding noise background and is found by setting $t=t_0$, i.e., by selecting our origin on the time-scale so that $t=t_0$ gives a maximum, a gating operation performed automatically by the eye. We have, finally,

$$s_v(0)_G=[s_v(t)_G]_{\max}=\frac{1}{2\pi}\int_{-\infty}^{\infty}d\omega|G_v(\omega)|$$

$$\times\int_{-\infty}^{\infty}[s_v(t')_{p>0}-s_v(t')_{p=0}]e^{-i\omega t'}dt'. \quad (2.5)$$

Let us now calculate some specific examples. We choose $G_F(\omega)$ and $G_v(\omega)$ to be respectively the amplitude filter responses of the IF and video stages of our receiver and represent their moduli by

$$\begin{aligned}|G_F(\omega)|&=e^{-\omega^2/2\omega_b^2}, \quad \omega_b=2\pi f_b,\\ |G_v(\omega)|&=e^{-\omega^2/2\omega_v^2}, \quad \omega_v=2\pi f_v.\end{aligned} \quad (2.6)$$

In both the above instances we have assumed a linear phase dependence with frequency. The various quantities f_b, f_v, etc., are described in Table I.

The low frequency correlation function for the noise following a half-wave linear detector is found to be [cf. Eq. (24), reference 1] exclusive of the steady component,

$$R_0(t)_{(n\times n),\,p=0}=\frac{\beta^2\psi}{8\pi}\sum_{n=0}^{\infty}\mu_n{}^2r_0(t)^{2n+2} \quad (2.7)$$

where

$$\mu_n=\frac{(2n)!}{2^{2n}n!(n+1)!}=\frac{(1/2)_n}{(2)_n},$$

$$r_0(t)=\exp(-\omega_b{}^2t^2/4); \quad \psi=n_F{}^2=\frac{W_0\omega_b}{2\pi^{\frac{1}{2}}}.$$

The quantities W_0 and ψ are the maximum spectral intensity of the noise entering the IF and the mean noise power output of the IF, respectively; $r_0(t)$ is therefore the (normalized) correlation function of the random noise leaving the IF stage; β is a constant (e.g., the dynamic transconductance) of the detector.

Substituting (2.1) and (2.7) into (2.3) and performing the integration yield the mean-square video noise

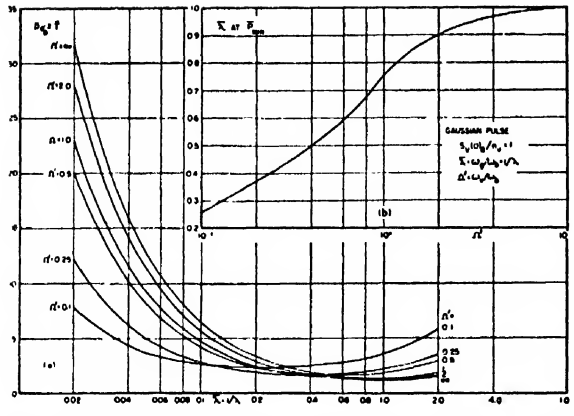

FIG. 5. (a) Average pulse power as a function of pulse length or IF width; (b) minimum average pulse power as a function of the video filter width.

voltage

$$n_v^2=\frac{\beta^2\psi}{8\pi}\sum_n(\Omega')$$

$$=\frac{\beta^2\psi}{8\pi}\sum_{n=0}^{\infty}\mu_n^2\frac{1}{(1+2(n+1)\omega_b^2/\omega_v^2)^{\frac{1}{2}}};$$

$$\Omega'\equiv\omega_v/\omega_b. \tag{2.8}$$

Observe that when the video is infinitely wide, i.e., $\omega_v\to\infty$, the series can be summed to give the familiar value $n_v^2=0.0435\beta^2\psi$, which is our earlier result, Eq. (25), reference 1. Note also that for vanishingly narrow videos ($\omega_v\to 0$) the output vanishes, as one would expect.

For the half-wave linear rectifier considered here, the increment in video signal output is[1,6]

$$s_v(t')_{p>0}-s_v(t')_{p=0}$$

$$=\frac{\beta\psi^{\frac{1}{2}}}{(2\pi)^{\frac{1}{2}}}[{}_1F_1(-\tfrac{1}{2};1;-s_F(t')^2/\psi)-1], \tag{2.9}$$

where ${}_1F_1$ is a confluent hypergeometric function and $s_F(t')$ is the r.m.s. envelope of the carrier after passage through the IF filter. In terms of the original r.m.s. modulation $s_I(t)$ entering the receiver we obtain for $s_F(t')$

$$s_F(t')=\frac{1}{2\pi}\int_{-\infty}^{\infty}G_F(\omega)e^{i\omega t'}d\omega\int_{-\infty}^{\infty}s_I(t)e^{-i\omega t}dt. \tag{2.10}$$

Before considering particular examples we remark that (2.9) is more readily handled if we approximate the hypergeometric function by $x/2-\gamma x^{\frac{1}{2}}$; ($\gamma=0.0763$, $0\leq x\leq 10$) in the manner of reference 1 (p. 962).

Case I. Gaussian Pulse

Here we choose

$$\sqrt{2}s_I(t)=S_0\exp(-\omega_g^2t^2/2), \tag{2.11}$$

where $S_0\equiv$peak value of the envelope and $\omega_g=2\pi f_g$. Then from (2.10) and (2.6) we obtain[7]

$$s_F(t')=s_F\exp(-t'^2b^2/4);\quad b\equiv\sqrt{2}\omega_b\omega_g/(\omega_b^2+\omega_g^2)^{\frac{1}{2}};$$
$$s_F=S_0b/2\omega_g. \tag{2.12}$$

Substituting our results (2.12) into (2.9), with the aid of the approximation for ${}_1F_1$, and applying this to (2.5) enables us to write finally for the maximum average signal

$$s_v(0)_G=\frac{\beta\psi^{\frac{1}{2}}p}{2(2\pi)^{\frac{1}{2}}(1+b^2/\omega_v^2)^{\frac{1}{2}}}$$
$$\times\{1-\gamma'p^{\frac{1}{2}}(1+b^2/\omega_v^2)^{\frac{1}{2}}/(\tfrac{2}{3}+b^2/\omega_v^2)^{\frac{1}{2}}\};$$
$$\gamma'=\gamma(8/3)^{\frac{1}{2}}=0.1246,\quad p\leq 10. \tag{2.13}$$

The quantity p is defined as the mean-square maximum signal output of the IF divided by the mean-square noise amplitude, *viz.*: $p\equiv s_F(t)_{\max.}^2/n_F^2=s_F(0)^2/n_F^2=s_F^2/\psi$. Again we may check (2.13) by noting that as the video is made very wide our signal $s_v(0)_G$ approaches the earlier form, Eq. (25) of reference 1. The desired signal-to-noise ratio $s_v(0)_G/n_v$ follows at once from (2.13) and (2.8). We see from (2.13) that for weak signals the output signal power is proportional to the *square* of the input carrier-to-noise ratio p, an example of modulation suppression discussed in the preceding section. On the other hand, strong signals suppress the noise, so that when $p^2\gg 1$ we obtain from the asymptotic development of ${}_1F_1$ (see Eq. (A3.3) of reference 6) the average video increment

$$s_v(0)_G\backsimeq\frac{\sqrt{2}}{\pi}\beta(\psi p)^{\frac{1}{2}}(1+b^2/2\omega_v^2)^{-\frac{1}{2}},\quad p>20, \tag{2.14}$$

which is now directly proportional to $(p)^{\frac{1}{2}}$. The two expressions (2.13) and (2.14) for the video signal enable us to cover the entire range of values of $s_v(0)_G/n_v$ *vs.* p with a small region of interpolation for $10<p<20$.

At this point it is convenient to introduce a number of parameters

$$\lambda=\omega_b/\omega_g;\quad\Omega=\omega_v/\omega_g;\quad\Omega'=\omega_v/\omega_b=\Omega/\lambda=\Omega\bar{\lambda}. \tag{2.15}$$

The signal-to-noise ratio becomes finally [see (2.8)]

$$\left[\frac{s_v(0)_G}{n_v}\right]_{\text{Gauss}}=\frac{p(1-0.1246(p)^{\frac{1}{2}}[1+2\lambda^2/\Omega^2(1+\lambda^2)]^{\frac{1}{2}}/[\frac{2}{3}+2\lambda^2/\Omega^2(1+\lambda^2)]^{\frac{1}{2}})}{[1+2\lambda^2/\Omega^2(1+\lambda^2)]^{\frac{1}{2}}\{\sum_n(\Omega')\}^{\frac{1}{2}}},\quad p\leq 10, \tag{2.16}$$

[6] D. Middleton, "Some general results in the theory of noise through nonlinear devices," Quart. App. Math. 5, 445 (1948), Section 4 and Appendix A3.

[7] There is a misprint in the expressions for s_F in Eq. (61b) of reference 1; $\sqrt{2}$ should be replaced by 2.

* The widths of the filters and pulses are measured between half-power (or intensity) points—i.e., points at which the intensity is one-half its maximum value.

Ω = [video filter width (freq.)]/[½ pulse width (freq.)]; $\Omega' = \Omega/\lambda = \Omega\bar{\lambda}$.
λ = [IF filter width (freq.)]/[pulse width (freq.)] $= \bar{\lambda}^{-1}$; T = PRF; $\tau \ll T$.

and for strong signals

$$\left[\frac{s_v(0)_G}{n_v}\right]_{\text{Gauss}} \simeq 4(p/\pi)^{\frac{1}{2}}\left\{\left[1+\frac{\lambda^2}{\Omega^2(1+\lambda^2)}\right]\left[\sum_n (\Omega')\right]\right\}^{-\frac{1}{2}}, \quad p>20. \quad (2.17)$$

Figure 3 illustrates $s_v(0)_G/n_v$ when $s_F/n_F = (p)^{\frac{1}{2}}$ is chosen as independent variable in the matched condition $\lambda = 1(\omega_b = \omega_g)$. The effect of the different videos is observed through the quantity Ω. When the pulse and IF filter are not matched ($\lambda \neq 1$) we may represent the ratio p by

$$p = [2\lambda^2/(1+\lambda^2)]\sigma_0^2, \quad (2.18)$$

where σ_0^2 is taken to be $(s_F/n_F)^2$ at match. In terms of the input power to the IF, which is simply the (energy/pulse)$\times$(number of pulses/sec.), we may also write [cf., Eq. (68), reference 1),

$$p = [2\lambda/(1+\lambda^2)]\sigma_0^2 \bar{P}\bar{T}, \quad (2.19)$$

in which $\bar{P} = P_{in}/P_0$ and $\bar{T} = T_{in}/T_0$, the subscript (0) referring to the input power to the IF (P_0) and pulse repetition period (T_0) at match, while P_{in} and T_{in} are these quantities for arbitrary conditions of operation, not necessarily at match. Figures 2 and 4 show $s_v(0)/n_v$ at mismatch, and here we have chosen as our independent variable $\sigma_0^2\lambda$, or $\sigma_0^2\bar{P}\bar{T}$, in order to take into account the added power input necessary to achieve a given output when away from match.

We mention briefly two additional limiting cases: for a fixed pulse width and very wide IF ($\omega_b \to \infty$, $\lambda \to \infty$; $\Omega' \to 0$, $\Omega = \Omega$) s_v/n_v vanishes as λ^{-1}, since $\sigma_0^2 \sim \omega_b^{-1}$, whereas for a fixed IF and a very narrow pulse (in time) ($\omega_g \to \infty$, $\lambda \to 0$, $\Omega' = \Omega'$; $\Omega \to 0$) we find at once that $s_v/n_v \sim \lambda^2$. Thus in both instances the output vanishes; in the former because of the added noise, in the latter because of vanishing signal strength. Similar remarks apply for the rectangular pulse treated below.

Case II. Rectangular Pulse

Here the shape of the signal wave entering the IF is

$$\sqrt{2}s_I(t) = S_0, \quad -\tau/2<t<\tau/2; \quad =0, \quad |t|>|\tau/2|. \quad (2.20)$$

S_0 is again the peak amplitude, and τ measures the duration of the pulse between half-power points. The various IF and video filters are Gaussian as before (cf. Eq. (2.6)]. The envelope of the pulse leaving the IF follows immediately from (2.10) and the result

$$\int_0^\infty \frac{\sin ax}{x}\exp(-bx^2/2)dx = \pi\phi^{(-1)}(a/b^{\frac{1}{2}}) = \frac{\pi}{2}\Theta[a/(2b^{\frac{1}{2}})], \quad (2.21a)$$

where

$$\Theta(x) = \frac{2}{\pi^{\frac{1}{2}}}\int_0^x e^{-t^2}dt \quad (2.21b)$$

is the well-known error function. We have finally

$$s_F(t') = s_F\{\Theta([t'+\tau/2]\omega_b/\sqrt{2}) - \Theta([t'-\tau/2]\omega_b/\sqrt{2})\}/2\Theta(\tau\omega_b/2\sqrt{2}), \quad (2.22)$$

in which

$$s_F = S_0\Theta\left(\frac{\tau\omega_b}{2\sqrt{2}}\right)\Big/\sqrt{2}. \quad (2.22a)$$

In terms of our definition for p we see that

$$p_{\text{rect.}} = (\pi)^{\frac{1}{2}}S_0^2\Theta(\tau\omega_b/2\sqrt{2})^2/W_0\omega_b = 2\Theta\left(\frac{\tau\omega_b}{2\sqrt{2}}\right)^2\sigma_0^2. \quad (2.22b)$$

Compare this with Eq. (2.18) which gives p_{Gauss}; if we make such a comparison on the basis of equal energy/pulse into the IF, i.e.,

$$E_{\text{Gauss}} = E_{\text{rect.}} = \int_{-\infty}^{\infty} s_I(t)^2 dt,$$

the relation between τ and ω_g is found from (2.11) and (2.20) to be

$$\tau=(\pi)^{\frac{1}{2}}/\omega_g. \tag{2.23}$$

Then we have

$$p_{\text{rect.}}=\left(\frac{1+\lambda^2}{\lambda^2}\right)\Theta\left(\frac{\pi^{\frac{1}{2}}\lambda}{2\sqrt{2}}\right)^2 p_{\text{Gauss}}, \quad (\tau=\pi^{\frac{1}{2}}/\omega_g). \tag{2.24}$$

Thus we are able to discuss the case of rectangular pulses in terms of the parameters (2.15) of the wholly Gaussian system.

With (2.22) for $s_F(t')$ we now use our approximation for ${}_1F_1$ but omit the term containing $s_F(t')^3$, as it leads to analytical difficulties out of proportion to the results achieved; our final expression is not seriously affected, since with the aid of the asymptotic development for ${}_1F_1$ we can interpolate with little error in the region not covered by the small-signal result involving $s_F(t')^2$ alone ($p<1$) and so obtain s_v/n_v as a function of $p^{\frac{1}{2}}$ (or $\sigma_0(\lambda)^{\frac{1}{2}}$) over the entire range of these variables; the parallel behavior with the Gaussian pulse aids the interpolation.

The increment in video signal (2.9) is accordingly[8]

$$s_v(0)_G\doteq p\frac{\beta\psi^{\frac{1}{2}}\omega_v}{16\pi}\int_{-\infty}^{\infty}dt'e^{-\omega_v^2t'^2/2}\{\Theta[(t'+\tau/2)\omega_b/\sqrt{2}]$$

$$-\Theta[(t'-\tau/2)\omega_b/\sqrt{2}]\}^2/\Theta^2\left(\frac{\tau\omega_b}{2\sqrt{2}}\right), \quad p<\tfrac{1}{2}. \tag{2.25}$$

The integrand in (2.25) may be evaluated in straightforward manner if we use a contour integral representation of the error function and the related $\phi^{(j)}(x)$, which are specifically

$$\phi^{(j)}(x)=\frac{d^{(j)}}{dx^{(j)}}\frac{e^{-x^2/2}}{(2\pi)^{\frac{1}{2}}}, \quad j=0, 1, \cdots,$$

and are related to the Hermitian polynomials $H_j(x)$ by $(-1)^jH_j(x)e^{-x^2/2}/(2\pi)^{\frac{1}{2}}=\phi^{(j)}(x)$; the $\phi^{(j)}$ are tabulated up to $j=6$ in T. C. Fry's *Probability and Its Engineering Uses* (D. Van Nostrand Company, Inc., New York, 1928), p. 456.

We obtain finally for the video increment[9]

$$s_v(0)_G\doteq\frac{p\beta\psi^{\frac{1}{2}}}{2(2\pi)^{\frac{1}{2}}}\sum_{n=0}^{\infty}\frac{4}{(2n)!(\Omega'^2+1)^{2n}}$$

$$\times\phi^{(2n-1)}\left(\frac{\tau\omega_v}{2(\Omega'^2+1)^{\frac{1}{2}}}\right)^2\Big/\Theta\left(\frac{\tau\omega_b}{2\sqrt{2}}\right)^2, \quad p\leq\tfrac{1}{2}. \tag{2.26}$$

Compare this with the leading term of (2.13) for the Gaussian pulse. Notice that for an infinitely wide video response ($\omega_v\to\infty$), $s_v(0)_G$ reduces to $s_F^2\beta/2(2\pi\psi)^{\frac{1}{2}}$, as we would expect. Pulse shape is no longer significant relative to the video; all harmonics of the envelope are passed when $\omega_v\to\infty$ and only the energy/pulse is important.

The output signal-to-noise ratio for the rectangular pulse is obtained from (2.8) and (2.26) and is

$$\left[\frac{s_v(0)_G}{n_v}\right]_{\text{rect.}}\doteq p\left\{\sum_{n=0}^{\infty}4\phi^{(2n-1)}\left(\frac{\tau\omega_v}{2(\Omega'^2+1)^{\frac{1}{2}}}\right)^2\right.$$

$$\left.\div\Theta^2\left(\frac{\tau\omega_b}{2\sqrt{2}}\right)(2n)!(\Omega'^2+1)^{2n}\right\}\Big/(\textstyle\sum_n(\Omega'))^{\frac{1}{2}},$$

$$p<\tfrac{1}{2}. \tag{2.27}$$

The noise term is unchanged, since only ($n\times n$) products ($p=0$) enter effectively, and the amount of noise power available in the low frequency spectra region after our linear rectifier then depends on IF filter shape alone, cf. (2.7) and (2.8). Again with the help of the contour integral representation of the error function and $\phi^{(j)}(x)$, we find that for large carrier strengths the video signal is

$$[s_v(0)_G]_{\text{rect.}}\backsimeq\frac{\sqrt{2}\beta s_F}{\pi}\Theta\left(\frac{\tau\omega_v}{2(2\Omega'^2+2)^{\frac{1}{2}}}\right)\Big/\Theta\left(\frac{\tau\omega_b}{2\sqrt{2}}\right);$$

$$s_F^2/\psi>20, \tag{2.28}$$

analogous to (2.14). The signal-to-noise ratio is therefore

$$[s_v(0)_G/n_v]_{\text{rect.}}$$

$$\backsimeq 4(p/\pi)^{\frac{1}{2}}\Theta\left(\frac{\tau\omega_v}{2(2\Omega'^2+2)^{\frac{1}{2}}}\right)\Big/\Theta\left(\frac{\tau\omega_b}{2\sqrt{2}}\right)(\textstyle\sum_n(\Omega'))^{\frac{1}{2}},$$

$$p>20, \tag{2.29}$$

a result to be contrasted with (2.17). Figures 2–4 also give (2.27) and (2.29).

ACKNOWLEDGMENT

The author wishes to express his appreciation to Miss Marilyn Lang and Mrs. Roger Stokey, who performed most of the computations in this paper.

[8] p is written p_{Gauss} or $p_{\text{rect.}}$ only when it is not clear from the context which is meant.

[9] The details of the evaluation are given in Technical Report No. 57, Cruft Laboratory, Harvard University (August 10, 1948).

Negative Wire Corona at High Temperature and Pressure

L. R. Koller and H. A. Fremont
Research Laboratory, General Electric Company, Schenectady, New York
(Received December 27, 1949)

The corona characteristics of air and methyl chloride were studied in a modified type of Cottrell precipitator at temperatures from room temperature to 500°C and pressures from 1 to 5 atmospheres. Within this range the corona current is a power function of voltage with gas density as a parameter. This power is independent of density. Values are given for air and methyl chloride.

INTRODUCTION

In the course of the development of a high temperature, high pressure electrostatic precipitator, it was necessary to determine the corona characteristics of air and methyl chloride. These studies were made in a modified type of Cottrell precipitator at temperatures from room temperature to 500°C and pressures from 1 to 5 atmospheres. The wire sizes were varied from 0.005″ to 0.02″ in diameter. Negative wire corona only was investigated.

APPARATUS

A drawing of the precipitator used is shown in Fig. 1. It was originally constructed for the removal of finely divided powder from a process gas stream. It consisted essentially of a wire mounted along the axis of a 2″ diameter tube. The latter was of seamless steel 36″ long and 2″ in diameter. Great care was used in the construction of the unit to remove sharp edges and roughened surfaces.

A drawn tungsten wire was used for the central electrode. It was not given any cleaning or polishing treatment. No significant pitting or corrosion of the wire was observed during the tests.

The wire was mounted in a bayonet-like fixture at the bottom and spring loaded by means of a tungsten spring at the top. The ends were fastened by ball and socket joints formed by fusing the ends of the wire to small balls about 50 mils in diameter. This eliminated any sharp projecting ends of wire. The purpose of the bayonet fixture was to leave the bottom part of the equipment free for both visual observation of the wire during operation, and also to simplify removal of any powder precipitated when the unit was used as a precipitator.

Zirconium silicate insulators similar to submarine insulators were supplied by the Locke Insulator Company. The leakage over these insulators was negligible in the range of currents investigated.

The unit was wrapped with nichrome wire and insulated with pipe lagging so that it could be heated electrically. Temperatures were determined by three chromel alumel thermocouples peened into the metal and equally spaced along the 2″ pipe.

The electrical circuit is shown in Fig. 2. It consisted of a voltage doubler capable of supplying 25×10^{-3} amps at 40 kv. The positive terminal of the power supply was connected to the precipitator shell which was grounded, and the negative side was connected to the wire. The voltage was controlled by means of a variac in the primary of the high voltage transformer. Voltage (average) was measured on a voltmeter consisting of a microammeter with a 30 megohm series resistance. In order to limit the current in case of arc over an 8013A kenetron, with its emission limited by operating the filament at reduced temperature was included in the high potential side of the line.

The precipitator was assembled with piping containing a flow indicator, pressure gauge and throttle valve. With this arrangement it was possible to introduce various gases at pressures up to 5 atmospheres and make measurements with a small steady flow of gas through the tube. The gas flow was introduced at the upper end of the precipitator as shown in Fig. 1.

PROCEDURE AND PRELIMINARY TESTS

Preliminary tests were made in air at 1 atmosphere. For these tests the end of the unit was sealed with a

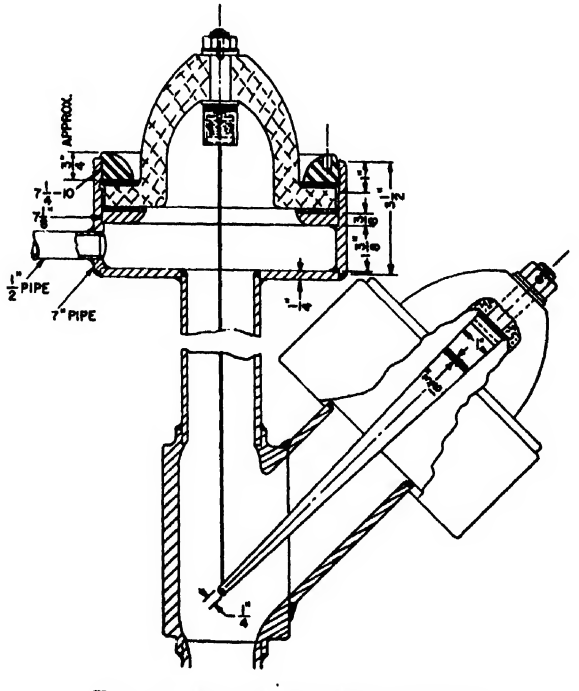

Fig. 1. Design of electrostatic precipitator.

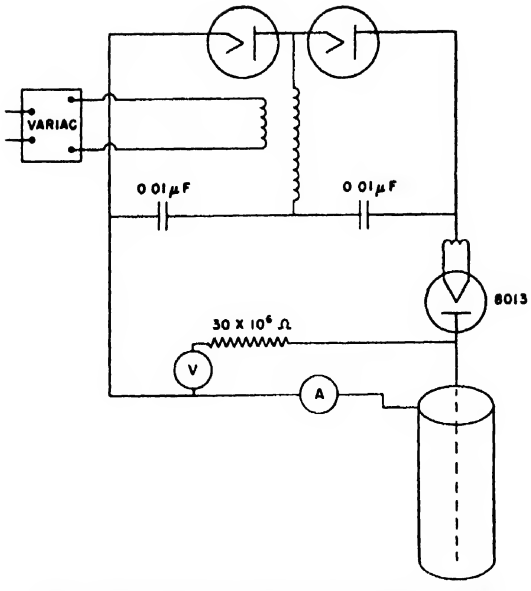

FIG. 2. Electrical circuit for corona measurements.

sheet of $\frac{1}{8}$" transparent cellulose acetate. This made it possible to observe the corona visually by looking in through the end of the tube along the wire.

Voltage was applied to the precipitator and gradually increased while the wire was observed through the open end of the tube. Corona was first noticed around 6000 volts and increased in intensity with increasing voltage. It appeared to be quite uniform along the wire, and there was no tendency to spark or arc over at the ends of the wire or over the insulators. As the voltage was increased still further, the wire was seen to vibrate. At 30 kv, corresponding to a current of about 10 ma spark-over generally took place near the middle of the wire. This may have been due to the close approach to the wall as a result of the vibration.

RESULTS

Typical volt ampere characteristics at 1 atmosphere and room temperature are shown in Fig. 3 for air, for a mixture of air and approximately 19 percent of CCl_4 by volume and an atmosphere of pure CH_3Cl. These curves show a shift toward higher voltage in going from air to CCl_4 to CH_3Cl as well as a decrease in slope. They illustrate the well-known effect of halogens in suppressing corona.

An extensive series of measurements was made first in air and later in CH_3Cl at pressures from 1 to 5 atmosphere and temperatures from room temperature to 300°C. The temperatures chosen were room temperature, 100°C, 200°C and 300°C. At each of these temperatures the volt ampere characteristics were measured at 1, 2, 3 and 4 atmospheres pressure with a small flow of gas through the tube. Figures 4 and 5 show the original observations. The curves at any one temperature show a shift towards higher voltages and a decrease in slope as the pressure is increased.

It was found that over the range of corona currents from 0.1×10^{-3} to 1×10^{-3} amp. the volt ampere characteristics gave straight lines when plotted on log-log paper. It seemed reasonable to assume that temperature and pressure had no effect on the discharge other than their effect on the density of the gas, that is the number of molecules between the electrodes. Thus the characteristics of the discharge should be uniquely determined by the mass of the gas between the electrodes.[1] Accordingly, at any given current the voltage should be a function of the gas density rather than of the temperature and pressure. To test this, values of voltage at a given current were plotted as a function of the density of the gas, taking the density at room temperature and 1 atmosphere as unity. The family of curves for air and methyl chloride are shown in Figs. 6 and 7, respectively. These figures show that at any given current the values of voltage plotted as a function of density fall on a smooth curve within the limits of the experimental error regardless of the temperature and pressure at which the measurements were made. The agreement is good except for the measurements at room temperature which depart considerably from the curve at the lower currents.

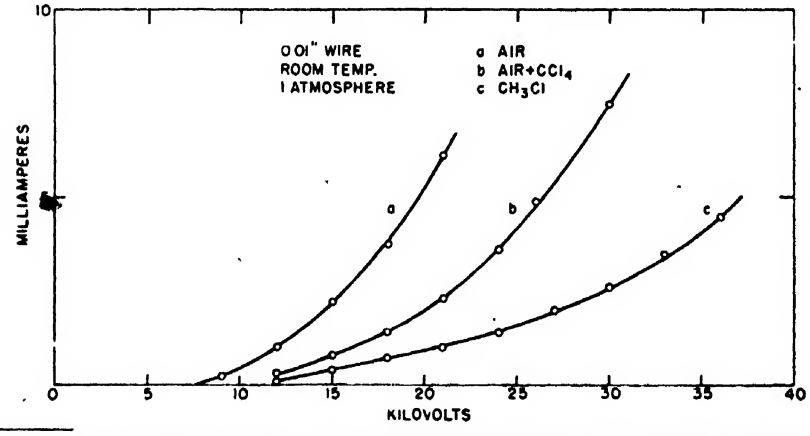

FIG. 3. Corona characteristics in various gases.

[1] Pauthenier and Rousse [Comptes Rendus 225, 1293 (1947)], show that the critical gradient for the threshold of the corona effect is a function of the specific mass of air.

All of these measurements are in a range of voltages well above the corona starting voltage. The theoretical starting voltage calculated from the equation

$$v = 33.9 g r_i \log(r_a/r_i)[1-(0.295/g r_i)],^{2}$$

where v = corona starting voltage in kv, r_a = radius of outer cylinder in cm, r_i = radius of wire in cm, g = air density taking air at stated conditions = 1 is also shown in Fig. 7.

From the curves of Figs. 6 and 7 it is possible to read off the voltages as a function of current with gas density as a parameter. When plotted on log-log paper

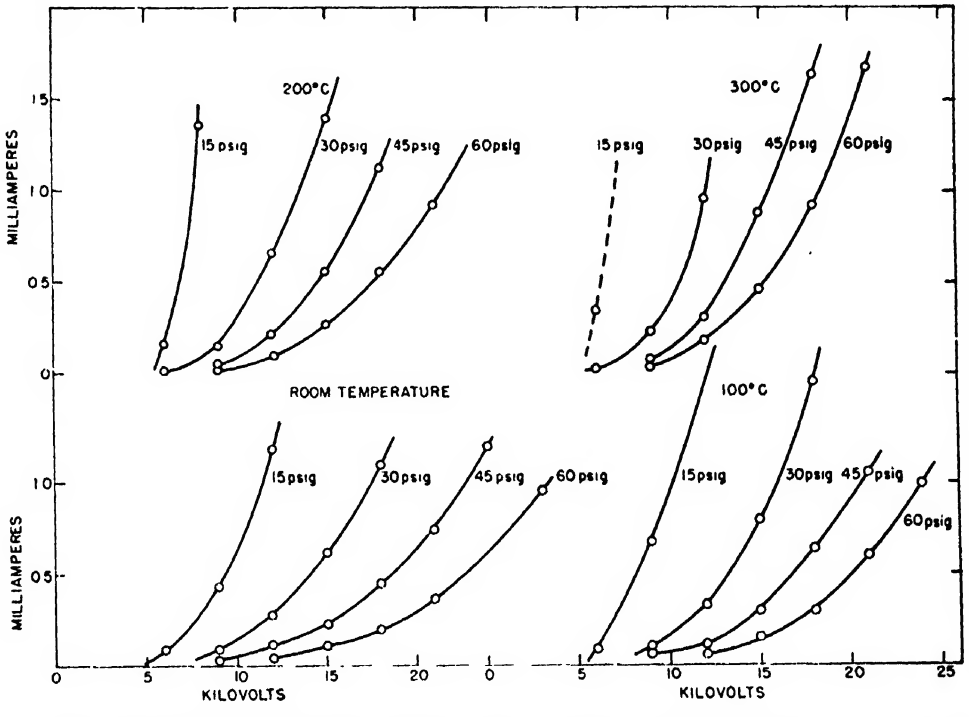

FIG. 4. Corona characteristics of 0.01" wire in air.

TABLE I. Values of log A and K for air and methyl chloride.

d	Air	CH_3Cl	Air	CH_3Cl
	log A	log A	K	K
1	4.5	3.5	4.2	2.8
2	5.2	4.1	4.2	2.8
3	5.7	4.4	4.2	2.8
4	6.05	4.7	4.2	2.8

these volt ampere characteristics are straight lines, all having the same slope. They may be represented by an equation

$$\log i = \log A + K \log V$$

where i = current in milliamperes, V = voltage in kilovolts, A = a constant, K = a constant. They show that the current increases with the same power of the voltage at all values of density. This power is 4.2 for air and 2.8 for methyl chloride. The constants for different values of gas density are shown in Table I.

A series of measurements was carried out in air at various pressures at room temperature to determine the effect of wire size on corona characteristics. Measurements were made using tungsten wires 0.005″ and 0.02″ in diameter respectively to compare with measurements previously made with 0.01″ wire. These measurements showed that for currents of about 0.1×10^{-3} amps the effect of wire diameter on corona voltage was negligible. At 1×10^{-3} amp. the voltage increased about 3 kilovolts as the wire diameter was increased from 0.005″ to 0.02″. The gain in mechanical strength obtained by using a large diameter wire probably more than compensates for the small increase in voltage.

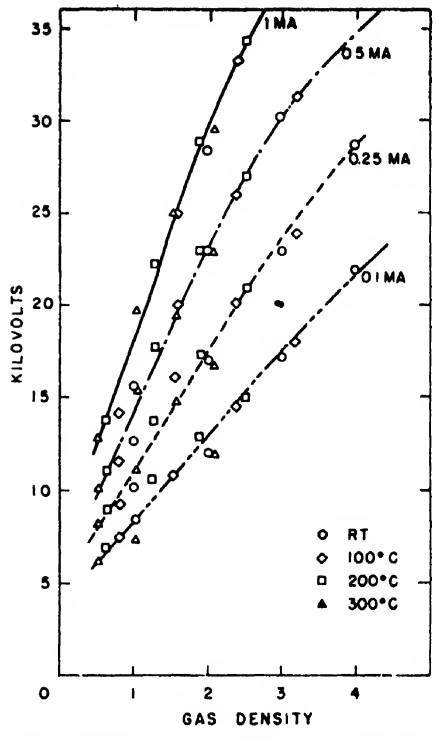

FIG. 7. Corona characteristics as a function of methyl chloride density for 0.01″ wire.

SUMMARY

The volt ampere characteristics of a corona discharge in a Cottrell precipitator are uniquely determined by the mass of gas between the electrodes and are independent of the temperature and pressure of the gas.

The corona current is a power function of the voltage. The power is independent of the gas density. Values of the power are given for air and methyl chloride.

Variations in corona characteristics with wire sizes are small at voltages above the corona starting voltage.

The Radiation from a Transverse Rectangular Slot in a Circular Cylinder*

SAMUEL SILVER AND WILLIAM K. SAUNDERS
Division of Electrical Engineering and the Antenna Laboratory, University of California, Berkeley, California
(Received January 27, 1950)

General results obtained previously for slots of arbitrary shape are applied to the case of a transverse rectangular slot in a circular cylinder. It is shown that the principal transverse plane pattern of such a slot in which the excitation has only a circumferential tangential electric field component is the same as the pattern generated by an infinite axial slot with the same circumferential excitation. Theoretical and experimental curves are given for the narrow-width half-wave-length slot.

I. INTRODUCTION

IN a previous paper[1] we developed general expressions for the external field produced by a slot of arbitrary shape in the wall of a circular cylindrical wave guide, on the assumption that the tangential electric field in the slot is a prescribed function. The present paper deals with the application of these results to the particularly simple configuration of a transverse rectangular slot: a slot that, on development of the cylinder into a plane, becomes a rectangle with boundaries respectively transverse and parallel to the axis of the cylinder. This configuration has been investigated by others by methods that differ from ours and are of less general applicability: C. H. Papas[2] has obtained expressions for the field for the case when the tangential electric field in the slot has only an axial component. G. Sinclair[3] has treated the case of a narrow rectangular slot, oriented arbitrarily on the surface of the cylinder, in which the tangential electric field is transverse to the slot axis.

The results given in this paper are restricted to the far-zone field of the slot; for this region the integrations can be performed and calculations can be made with relative ease. The computations have been made for the especially important case of a narrow slot having an axial extent of a half-wave-length. Experimental patterns have also been obtained. The data that are given here are for two values of cylinder radius that are likely to be used in microwave antenna designs.

II. THE FIELD DISTRIBUTION IN THE SLOT

The slot configuration and the various coordinates to be used are shown in Fig. 1. The slot is bounded axially by the planes $z=\pm l/2$ and in azimuth by the planes $\phi=\pm\phi_0$; or, in the notation used in I, we have for the boundaries of the slot

$$z_1=-l/2;\quad z_2=+l/2;\quad \phi_1(z)=-\phi_0;\quad \phi_2(z)=+\phi_0.$$

In formulating possible tangential electric field distributions in the slot we are guided by the consideration that at the boundaries of the slot the component of the distribution that is tangential to the boundary must be zero. In general, the excitation of the slot may be conceived as a superposition of many modes of field distribution each of which satisfies the fundamental requirement. This is analogous to the general excitation of a thin wire antenna which may be synthesized by superposition of characteristic sinusoidal distributions that satisfy the requirement that the current be zero at the ends.

The geometry of the configuration suggests that in each of the fundamental modes of excitation the field components are separable functions of ϕ and z; thus,

$$E_\phi(a,\phi,z)=f_1(\phi,z)=F_1(\phi)G_1(z), \tag{1a}$$

$$E_z(a,\phi,z)=f_2(\phi,z)=F_2(\phi)G_2(z). \tag{1b}$$

With the boundary condition at the edges of the slot in mind we are led to postulate that

$$G_1(z)=\begin{cases}\sin(p\pi z/l) & p, \text{ even integer},\\ \cos(p\pi z/l) & p, \text{ odd integer};\end{cases} \tag{2a}$$

$$F_2(\phi)=\begin{cases}\sin(p\pi\phi/2\phi_0) & p, \text{ even},\\ \cos(p\pi\phi/2\phi_0) & p, \text{ odd}.\end{cases} \tag{2b}$$

The functions $F_1(\phi)$ and $G_2(z)$ are not so clearly indicated. Certain forms are suggested for them by the point of view that the slot is a very shallow section of wave guide, in consequence of which the field configuration is like that over the cross section of a wave guide. On this basis we should have

$$F_1(\phi)=\begin{cases}\cos(q\pi\phi/2\phi_0) & q, \text{ even},\\ \sin(q\pi\phi/2\phi_0) & q, \text{ odd};\end{cases} \tag{3a}$$

$$G_2(z)=\begin{cases}\cos(q\pi z/l) & q, \text{ even},\\ \sin(q\pi z/l) & q, \text{ odd}.\end{cases} \tag{3b}$$

The limitations of the wave guide picture must be realized. It provides no basis for relating E_ϕ^{pq} to E_z^{pq} in the slot in the manner that they are related in the corresponding rectangular wave guide. Furthermore, there is some question as to whether the field components are bounded; infinities may exist at points on the slot

boundaries at which the field component is normal to the edge.[4]

III. THE FAR-ZONE FIELD

The general expressions for the far-zone field are given in the set of Eqs. (23) in I. In the present case, for a single mode of E_ϕ and E_z in the slot, the electric field components are

$$E_\theta = -\frac{1}{2\pi^2}\frac{e^{-jkR}}{R}\sum_{n=-\infty}^{\infty}\left\{\frac{(j^{n+1}e^{-jn\phi})}{\sin\theta H_n^{(2)}(ka\sin\theta)} \times \int_{-l/2}^{l/2} G_2(\xi)e^{jk\xi\cos\theta}d\xi \int_{-\phi_0}^{\phi_0} F_2(\beta)e^{jn\beta}d\beta\right\}, \quad (4a)$$

$$E_\phi = \frac{1}{2\pi^2}\frac{e^{-jkR}}{R}\sum_{n=-\infty}^{\infty}\left[\frac{j^n e^{-jn\phi}}{H_n^{(2)\prime}(ka\sin\theta)} \times \left\{\int_{-l/2}^{l/2} G_1(\xi)e^{jk\xi\cos\theta}d\xi \int_{-\phi_0}^{\phi_0} F_1(\beta)e^{jn\beta}d\beta + \frac{n\cot\theta}{ka\sin\theta}\int_{-l/2}^{l/2} G_2(\xi)e^{jk\xi\cos\theta}d\xi \times \int_{-\phi_0}^{\phi_0} F_2(\beta)e^{jn\beta}d\beta\right\}\right]. \quad (4b)$$

It will be observed that there is a striking difference between the fields produced by the respective modes of excitation in which there is no E_z-component in the slot and in which there is no E_ϕ-component in the slot. In the former case, when $F_2 = G_2 = 0$, the radiation field is linearly polarized having only an E_ϕ-component. In the latter case, where $F_1 = G_1 = 0$, the radiation field has both an E_ϕ- and E_z-component and, except in certain special planes, is elliptically polarized in general. These results can be correlated with the fact that the slot can be set into equivalence with a magnetic current sheet,[5] the direction of the current associated with a given tangential electric field component being transverse to that component.

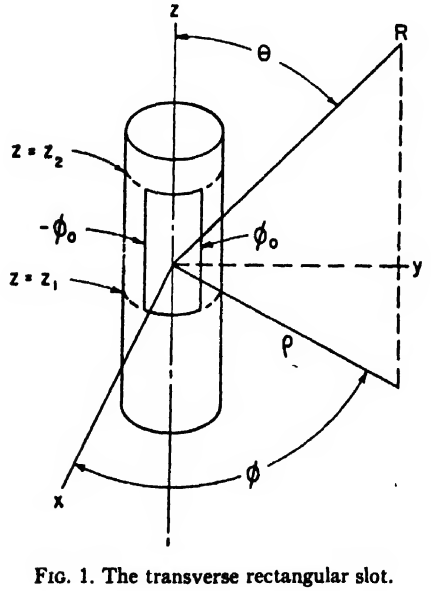

FIG. 1. The transverse rectangular slot.

There are further points of interest to be noted for the case where the tangential electric field in the slot has only an E_ϕ-component. The far-zone field is given by Eq. (4b) with F_2 and G_2 set equal to zero; on introduction of self-compensating factors of $\sin\theta$ in the appropriate places, we have

$$E_\phi = \frac{1}{2\pi^2}\frac{e^{-jkR}}{R}\int_{-l/2}^{l/2} G_1(\xi)\sin\theta e^{jk\xi\cos\theta}d\xi \times \sum_{n=-\infty}^{\infty}\frac{(j^n e^{-jn\phi})}{\sin\theta H_n^{(2)\prime}(ka\sin\theta)}\int_{-\phi_0}^{\phi_0} F_1(\beta)e^{jn\beta}d\beta. \quad (5)$$

The integral over ξ is just the space factor of a wire antenna carrying a "magnetic current" of linear density $G_1(z)$; except for the polarization it is the same as that of an electric current having the same distribution. The summation expresses the effect of the cylinder and the transverse distribution function.

Consider now the principal transverse plane, $\theta = \pi/2$. In this plane

$$E_\phi = \left[\frac{1}{2\pi^2}\frac{e^{-jkR}}{R}\int_{-l/2}^{l/2} G_1(\xi)d\xi\right]\sum_{n=-\infty}^{\infty}\frac{j^n e^{-jn\phi}}{H_n^{(2)\prime}(ka)} \times \int_{-\phi_0}^{\phi_0} F_1(\beta)e^{jn\beta}d\beta. \quad (6)$$

The bracketed term is constant with respect to ϕ; the radiation pattern in this plane is, therefore, given by the summation alone. The latter, except for constants which do not affect the pattern, is exactly the far-zone field (in the two-dimensional sense) produced by an infinite axial slot of width $2\phi_0$ in which the excitation is constant along the slot axis, directed transverse thereto, with a transverse distribution $F_1(\phi)$. Thus we have the general result that the pattern in the plane $\theta = \pi/2$ produced by a rectangular slot having only E_ϕ-excitation is independent of the axial distribution of E_ϕ and is the same

180	0.5343	0.4918	0.4509	0.4230	0.3973	0.3801	0.3693	0.3627	0.3612

as that produced by an infinite axial slot having the same transverse distribution. This provides a rigorous basis for the conjecture of Sinclair,[6] Papas and King[7] and others that such a relationship exists in the case of a narrow rectangular slot in which $F_1(\phi)$ is a constant.

IV. THE NARROW RECTANGULAR SLOT

When the transverse dimension, $2a$, of the slot is small compared with the wave-length and the slot length, the significant mode of excitation is that in which there is only an E_ϕ-component that is uniform across the slot and has a sinusoidal distribution along its length. Such a slot is of particular interest because of its practical applications; the element a half-wave-length long is used extensively in microwave antennas.

It is customary to express the transverse characteristic $F_1(\phi)$ in terms of a voltage V; thus we have for the excitation

$$F_1(\phi)G_1(z) = (V/2a\phi_0)G_1(z). \tag{7}$$

On substituting into Eq. (5) we find the far-zone field to

[6] G. Sinclair, Proc. I.R.E. **36**, 1487 (1948).

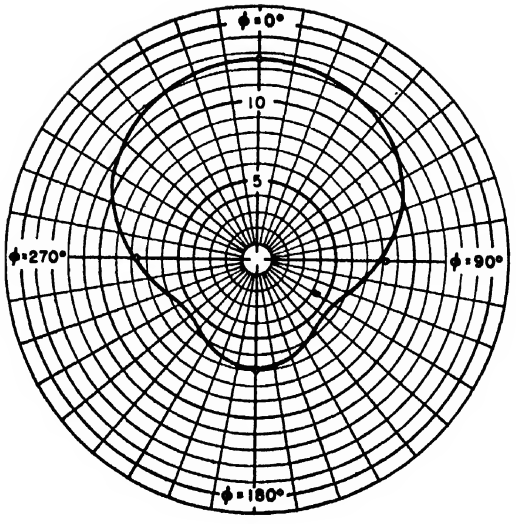
(b)



(c)

FIG. 2. Radiation pattern ($|E|$) of the narrow half-wave slot; $ka=0.8$; (a) principal H-plane ($\phi=0, \pi$); (b) H-plane ($\phi=\pm\pi/2$); (c) principal E-plane ($\theta=\pi/2$). Solid line is the theoretical curve.

be

$$E_\phi=\frac{V}{2\pi^2 a}\frac{e^{-jkR}}{R}\int_{-l/2}^{l/2}G_1(\xi)\sin\theta e^{jk\xi\cos\theta}d\xi \times\sum_{n=-\infty}^{\infty}\frac{j^n e^{-jn\phi}}{\sin\theta H_n^{(2)\prime}(ka\sin\theta)}\frac{\sin n\phi_0}{n\phi_0}. \quad (8)$$

If ϕ_0 is sufficiently small, $\sin n\phi_0/n\phi_0\approx 1$ over the range of values of n for which the terms of the series are significant. This can be seen in Table I which shows the dependence on ka of the number of terms required for five figure accuracy and the associated value of ϕ_0 for which $\sin n\phi_0/n\phi_0\geq 0.9$ over the range of n. From a practical standpoint, therefore, we can ignore the $\sin n\phi_0/n\phi_0$ variation. Combining terms of positive and negative n, we can write finally for the radiation field of the narrow slot

$$E_\phi=\frac{V}{2\pi^2 a}\frac{e^{-jkR}}{R}\int_{-l/2}^{l/2}G_1(\xi)\sin\theta e^{jk\xi\cos\theta}d\xi \times\sum_{n=0}^{\infty}\frac{j^n\epsilon_n\cos n\phi}{\sin\theta H_n^{(2)\prime}(ka\sin\theta)};\quad \begin{cases}\epsilon_n=1, & n=0,\\ =2, & n>0.\end{cases} \quad (9)$$

In its reduced form the series is a space factor dependent on the cylinder alone. With the series tabulated as a function of ka, θ, and ϕ the computation of the field produced by narrow axial slots becomes a simple straightforward task. Tables II and III give the function in a $10°\times 10°$ mesh in θ and ϕ for two values of ka used in our experimental work. The latter correspond to values that are likely to be used for microwave antennas.

The Half-Wave-Length Slot

When the length of the slot is $\lambda/2$, $G_1(z)=\cos(\pi z/l)$ and the far-zone field is

$$E_\phi=\frac{V}{2\pi^2 a}\frac{e^{-jkR}}{R}\left[\frac{\cos(\pi/2\cos\theta)}{\sin\theta}\right]\times\sum_{n=0}^{\infty}\frac{j^n\epsilon_n\cos n\phi}{\sin\theta H_n^{(2)\prime}(ka\sin\theta)}. \quad (10)$$

The bracketed term will be recognized to be the space factor of a half-wave-length wire antenna. The effect of the cylinder can be seen in the patterns shown in Figs. 2 and 3. Figures (2a) and (3a) are principal H-plane patterns ($\phi=0, \pi$); the dashed line is one quadrant of the pattern of the half-wave radiator in free-space. It is seen that the main lobe of the slot pattern is closer to the half-wave radiator pattern in the case of the larger cylinder than in the case of the smaller one. The corre-

FIG. 3. Radiation pattern ($|E|$) of the narrow half-wave slot; $ka=2.5$; (a) principal H-plane ($\phi=0, \pi$); (b) H-plane ($\phi=\pm\pi/2$); (c) principal E-plane ($\theta=\pi/2$).

spondence may be expected to increase with increasing cylinder radius, for the pattern of a corresponding slot in an infinite plane sheet is just that of the half-wave radiator. The principal transverse patterns ($\theta=\pi/2$) are given in Figs. (2c) and (3c).

The circles are the experimental points. The excellent agreement between the measured and theoretical values shown here was also obtained in the many other patterns that were investigated.[8] Figure 2 pertains to a probe-fed slot of width 0.006 in. cut in the wall of a $\frac{5}{16}$ in. O.D. coaxial line. The operating wave-length of 3.12 cm was chosen so that the value of ka would coincide with one of those for which transverse plane patterns were measured by Sinclair[6] in his study of the relation between the finite slot and the infinite slot. The computed pattern shown in Fig. (2c) will be found to be in excellent agreement with Sinclair's data and the pattern of an infinite slot.

The patterns in Fig. 3 were obtained for a slot of width .012 in. cut into the wall of a circular wave guide of O.D. 1 in. The circular wave guide was fed by way of a standard type of transition section from a rectangular wave guide and the slot was cut along the extended center line of the narrow side of the rectangular guide. The operating wave-length was 3.2 cm.

V. ACKNOWLEDGMENTS

We take pleasure in expressing our appreciation to Mr. J. Priedigkeit of the Antenna Laboratory for his assistance with the measurements. The work was supported in part by the Bureau of Ships under Contract No-bsr-39401 with the University.

The Thermal Conductivity of Soils

ANDREW GEMANT
Research Department, The Detroit Edison Company, Detroit, Michigan
(Received January 31, 1950)

The thermal conductivity of soils of varying moisture content is calculated on a physical basis. The results of this computation are, in a range of moisture contents from 5 to 25 percent, in agreement with experimental data in the literature. The influence of soil composition on conductivity is also explained by the theory. The use for practical purposes of an average resistivity value of 60 to 70 thermal ohms appears justified in the light of this analysis.

THE thermal conductivity of soils is an essential factor in determining the heat dissipation in various industrial installations in the ground. Such installations are, among others, underground high voltage cable lines, steam lines, and cross-country oil pipe lines.

For the design and operation of such installations a knowledge of the conductivity of the soil is necessary. The value varies with the composition of the soil, whether sand, loam, or clay, but primarily it depends on the moisture content and thus varies with the season. Pertinent data referring to various soils are presented by Nelson.[1]

For many purposes, particularly in the cable field, it is customary to use average values. An often used value for the resistivity has been 120 thermal ohms, whereas in recent years a value of 80 is more frequently used. Recent determinations by Sanderson, Sticher, and McGrath[2] indicate that still lower values, about 60 thermal ohms, might be justified.

Because of the importance of soil conductivity, it was thought of interest to calculate its value on a physical basis. Such a computation might also indicate the right order of magnitude of the average figures to be used for practical purposes.

For the following considerations both thermal conductivities λ and resistivities ρ will occur. The former is usually expressed in cal./cm sec. °C, the latter in cm °C/watt, or thermal ohms. In these units

$$\rho = 0.239/\lambda. \tag{1}$$

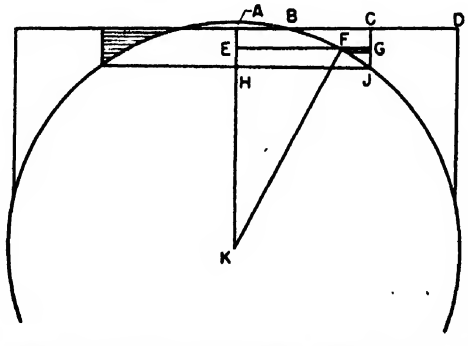

FIG. 1. Assumed geometric arrangement of solid grains and water in soil.

As mentioned, λ increases with increasing moisture content. For dry soil, λ is in the order 0.0007, increasing with increasing moisture content up to about 0.005. An apparent paradox may be mentioned at this point. One would expect that, since water increases the thermal conductivity, water itself should have a conductivity higher than soaked soil. This, however, is not the case, λ for water being 0.0014.

This apparent contradiction can be explained in the following manner. Dry soil has a low conductivity because air, a poor thermal conductor, separates the solid grains of the soil. If one adds water to the soil, hence gradually replacing the air by water, the conductivity increases. Finally, we arrive at soil saturated with water. Of the two components of such a system, the solid has a higher conductivity than the liquid; hence replacing the solid by the liquid will result in lower conductivity. The statement above, namely, that the solid component of soils is a better thermal conductor than water, is corroborated by data, as will be shown below.

The calculation of the conductivity of composite structures[3,4] can be carried out with a greater or smaller degree of rigorousness. Absolute rigorousness is impossible because of the irregularity of the shape and distribution of the grains. For the present purpose an approximate calculation was deemed sufficient.

The soil is assumed as being composed of solid spherical particles of radius $KF=r$ (Fig. 1). In reality, the grains are more likely to be oblate ellipsoids. The arrangement of the spheres is assumed such that each sphere touches six neighbors. In reality, the packing will be closer; our arrangement, however, does not deviate too much from reality, since it yields a porosity of 43 percent against about 38, found experimentally. If the spheres were to touch at a geometrical point only, the resistivity of dry soil would be close to that of air which is contrary to experience. The spheres, therefore, are assumed to be chipped and contact over the circular areas of radius $AB=a$. For the sake of simplicity the length $AK=AD$ is termed unity; the cubical volume housing the chipped sphere is then 8. The actual grain size is not involved in the following calculations.

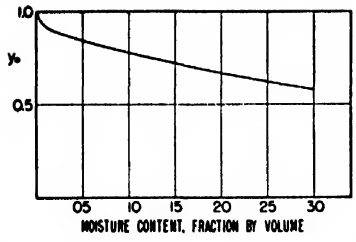

FIG. 2. Thickness of water layer between grains as a function of moisture content.

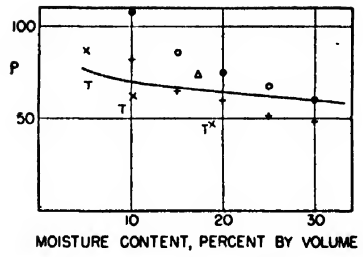

FIG. 3. Resistivity of soil *vs.* moisture content. (Solid line is calculated, points are experimental data from literature.)

If moisture is present, it will, owing to capillarity,[5] be located around the circles of radius a, occupying a wedge-shaped ring, the cross section of which is BCJ, shown also by the cross-hatched area in Fig. 1. The volume of the ring increases with increasing moisture content. If h, the moisture content, designates the ratio of water volume to total volume, then the volume of the ring BCJ equals $8h/6=1.33h$.

Any point F on the sphere is characterized by its coordinates $EF=x$ and $EK=y$. The water reaches down to point J, characterized by its coordinates $HJ=x_0$ and $KH=y_0$. Obviously, y_0 is a function of the moisture content h, and for the subsequent derivation this correlation is needed. Its calculation is straightforward, as shown.

The volume of an infinitesimally thin ring-shaped layer (Fig. 1), the cross section of which is shown at FG, is given by $\pi(x_0^2-x^2)dy$, or, because of

$$x^2+y^2=r^2, \quad \pi(y^2-y_0^2)dy.$$

The volume of the total ring is given by

$$\pi\int_{y_0}^{1}(y^2-y_0^2)dy.$$

Solving the integral, one obtains:

$$1.33h=\pi(0.33-y_0^2+0.67y_0^3). \tag{2}$$

For moisture contents over about 0.2 the formula is not strictly correct, since there will be an overlapping of the neighboring ring-shaped water pools.

Figure 2 is a graphical presentation of Eq. (2) for moisture contents up to 0.30. It may be noted that $(1-y_0)$ is a measure of the thickness of the water layer between grains. Use will be made later of this graph.

The thermal resistivity is computed by taking AK as the direction of heat flow and integrating the resistance of infinitesimally thin layers normal to the y axis. Since the flow lines are not parallel to y but diverge below y_0, this method is approximate.

Consider again the elementary layer at F. If the conductivity of the solid phase is λ_s and that of the water λ_w, the resistance of the inner circle is

$$dy/(\pi x^2\lambda_s)$$

and that of the outer ring

$$dy/[\pi(x_0^2-x^2)\lambda_w].$$

The resistance of both together is obtained by adding the conductances and taking the reciprocal of the sum. By replacing x by y, and considering that $r^2=1+a^2$, one obtains

$$dy/[\pi(f^2-g^2y^2)],$$

where

$$f^2=(1+a^2)\lambda_s-y_0^2\lambda_w \tag{3}$$

and

$$g^2=\lambda_s-\lambda_w. \tag{4}$$

The resistance of all layers between $y=1$ and y_0 is then:

$$\frac{1}{\pi}\int_{y_0}^{1}\frac{dy}{f^2-g^2y^2}=\frac{1}{2\pi fg}\log\frac{(f+g)(f-gy_0)}{(f-g)(f+gy_0)}. \tag{5}$$

Disregarding chipping at four points of the "equator" of our sphere, the resistance of all layers between $y=y_0$ and 0 is obtained as

$$\frac{1}{2\pi f'g'}\log\frac{f'+g'y_0}{f'-g'y_0}, \tag{6}$$

where

$$f'^2=(1+a^2)\lambda_s \tag{7}$$

and

$$g'^2=\lambda_s. \tag{8}$$

The resistance of all layers between $y=0$ and 1 is given by the sum of (5) and (6). Since the cross-sectional area of this volume is 4, the resistivity of the structure is four times greater. Thus

$$\frac{1}{\lambda}=\frac{2}{\pi fg}\log\frac{(f+g)(f-gy_0)}{(f-g)(f+gy_0)}+\frac{2}{\pi f'g'}\log\frac{f'+g'y_0}{f'-g'y_0}. \tag{9}$$

In the derivation above, the conductance of the air phase was neglected, as well as the conductance of the four water rings located at four points of the "equator" of our sphere.

For the numerical calculations which follow, numerical values of λ_s, λ_w, and a are required. The value of

TABLE I. Influence of composition on conductivity of soils. Density = 1.75; moisture content = 17.5 percent.

Soil	ρ observed ohms	λ_s cal./cm sec. °C	ρ calculated ohms
Sand	46	0.014	50
Sandy loam	69	0.010	66
Silt loam	99	0.0058	101

y_0 can be read from Fig. 2 if the moisture content of the soil is known.

Although the chief constituent of soils is silica, the conductivity of pure quartz crystals is not an appropriate choice for λ_s, since the grains of soils are not composed of pure quartz crystallites. Closer to reality is probably quartzite, a compact rock composed of quartz; still better perhaps, quartz-schist, a metamorphosed rock essentially of quartz; or sandstone, a rock essentially of sand and some natural cement. The conductivity of quartzite[6] is 0.014, that of quartz-schist[7] 0.0097, and that of sandstone[7] 0.011. As an average of the last two data, $\lambda_s = 0.010$ was taken. The value of λ_w, as mentioned earlier, is 0.0014.

Concerning the radius a of the circle of contact, its value can be computed from the conductivity of dry soil, λ_d, a representative value of which is 0.00066. For this case, $1/\lambda_d$ is given by the second term of Eq. (9) with $y_0 = 1$. If, now, $a \ll 1$, the corresponding equation reduces to

$$\frac{1}{\lambda_d} = \frac{2}{\pi \lambda_s} \log \frac{4}{a^2}, \tag{10}$$

from which, with $\lambda_s = 0.010$, one obtains $a = 2 \times 10^{-5}$. The area of contact is very small compared with the grain dimension, and may be neglected in the numerical computation; in other words, unity can be substituted for $(1+a^2)$ in Eqs. (3) and (7).

Equation (9) now can be used for numerical computation of the conductivity λ of soils of varying moisture content. The result, in a range of $h = 0.05$ to 0.3, that is 5 to 30 percent by volume of moisture, is shown by the curve of Fig. 3. The ordinates are ρ in thermal ohms, calculated from λ by Eq. (1).

For the sake of comparison with the calculated curve, experimental data of Krischer[6] on two samples of soil are plotted on Fig. 3. The soils measured were loamy sand of average grain size 0.085 cm. The crosses in Fig. 3 refer to a sample of density (dry) 1.6 and 38 percent porosity, the circles to a sample of density 1.7 and 34 percent porosity. In addition, a value indicated by a triangle obtained by Sanderson *et al.*[2] is plotted.

[6] O. Krischer, Beihefte z. Gesundheits—Ing. Series I, No. 33 (1934).

[7] H. A. Nancarrow, Proc. Phys. Soc. 45, 447 (1933).

A few pertinent data taken from a recent paper by M. S. Kersten[8] are also plotted on Fig. 3. They refer to a sandy soil of density 1.7 and 37 percent porosity (X) and of density 1.8 and 34 percent porosity (T).

Above five percent moisture content, the agreement between experimental and calculated data is good; below five percent, experimental data are higher. The calculation involves rather specific assumptions as to the geometry of contact points between grains; for low moisture contents where the contacts become increasingly significant, the calculation becomes less reliable. The moisture range of greatest practical importance is between 5 and 25 percent, and for this range the calculation corroborates the experimental figures rather well. If the present calculation were carried out for oblate ellipsoids, instead of spheres, or for grains bounded partly by planes, the agreement in the low moisture content range might perhaps be improved.

The influence of the composition of the soil on conductivity, according to Kersten's observations, is such that λ increases in the sequence clay—loam—sand. Soils of constant density and moisture content must be chosen for such a comparison. Table I gives in the first column the designation of the soil and in column 2 the resistivity in ohms, as found by Kersten.[8]

According to the theory given, the influence of the composition is represented by λ_s which for a sandy loam, as discussed, is 0.010. Sand is essentially quartz for which the conductivity of quartzite, 0.014, is appropriate. Silt loam consists to a large extent of kaolin which is essentially finely divided feldspar, aluminum silicate. For feldspar,[9] $\lambda_s = 0.0058$. These values are listed in the third column of Table I. The resistivities, as calculated from Eq. (9), are given in column 4; the agreement with the observed data is satisfactory.

In practical instances the conductivity of the sequence clay—loam—sand may be reversed, clay having the highest conductivity. This is not in contradiction with the data given in Table I, which refers to the same moisture content. The reversal is caused by the varying ability of soils in retaining moisture. Thus sand, having large grains, passes water easily and has, as a rule, a low moisture content; hence, a resistivity of 80 ohms or more will result. Clay, on the other hand, has very fine pores, water is easily retained and the moisture content, as a rule, is high; the resistivity may be as low as 60 or even 50 ohms. The average soil, being a sandy loam of a water content of about 20 percent, has, according to Fig. 3, a resistivity of 60 to 70 thermal ohms.

Theory of Blind Navigation by Dynamical Measurements

J. J. GILVARRY, S. H. BROWNE,* AND I. K. WILLIAMS
The Rand Corporation, Santa Monica, California
(Received February 1, 1950)

The differential equation is considered which determines the position of a vehicle from dynamical measurements of the non-gravitational acceleration **b** made internally. Three linear approximations to the gravitational field **g**(r) of the earth, which lead to explicit solutions of this equation, are considered and their limitations are discussed. An interval-wise solution (linear continuation) for trajectories of extended range is described, which is based on such linear approximations and has definite advantages in this application. The theory is applied to the trajectory of the German A10 vehicle.

CURRENT developments in rocket and jet propulsion have made blind navigation a matter of practical importance. This paper discusses the theory of blind navigation by means of dynamical measurements (measurements of forces or accelerations) made on a proof body in a reference frame internal to a vehicle. Instrumentally, such measurements are made by an accelerometer in a reference frame provided by gyroscopic or other means. A navigation system essentially of the type considered was used in the German V2. In the following discussion, the vehicle will be idealized as a windowless box.

Under the assumption of local uniformity of the gravitational field, the information derivable from the accelerometer is limited[1] by the applicability of Einstein's equivalence principle. In fact, this limitation was recognized by the investigator[2] who built the first (consciously-designed) accelerometer.

I. THE g-CORRECTION EQUATION

The accelerometer reference frame Q will be taken non-rotating for convenience, with origin at a point Q in the box. If $\mathbf{R}$ is the radius vector of the point Q referred to an inertial reference frame O, then the acceleration $d^2\mathbf{R}/dt^2$ of this point must consist of two parts: a part $\mathbf{g}$ due to the local gravitational acceleration in space, and a part $\mathbf{b}$ due to the operation of non-gravitational forces. Thus one has

$$d^2\mathbf{R}/dt^2=\mathbf{g}+\mathbf{b}. \tag{1}$$

If $\boldsymbol{\rho}$ is the radius vector in the frame Q of the proof body and m is its mass, the equation of motion of this body in the inertial frame O is

$$d^2(\mathbf{R}+\boldsymbol{\rho})/dt^2=\mathbf{g}+\mathbf{L}/m, \tag{2}$$

where $\mathbf{L}$ is the force on the proof body linking it to the frame Q. Subtraction of (1) from (2) yields

$$d^2\boldsymbol{\rho}/dt^2-\mathbf{L}/m=-\mathbf{b} \tag{3}$$

for the equation of motion of the proof body in the observer's frame Q. If the quantity on the left-hand side in Eq. (3) is defined as the reading of the accelerometer, it follows that an accelerometer reads the negative of the acceleration of the origin of its associated reference frame due to non-gravitational forces. From the method of derivation, it is clear that Eq. (3) holds independently of variation of mass, rotation, or non-rigidity of the box.

In Eq. (1) only the term $\mathbf{b}$ is susceptible to physical measurement in the box, and the observer can integrate the differential equation to yield his position vector $\mathbf{R}(t)$ only if he knows the functional form of $\mathbf{g}$ in its dependence on position coordinates and also the initial position and velocity of the box. When the term $\mathbf{g}$ is replaced by the function specifying its dependence on position coordinates in space, and the term $\mathbf{b}$ is considered a function $\mathbf{b}(t)$ of time, Eq. (1) will be referred to as the g-correction equation.

For motion of the box in the earth's neighborhood, the inertial frame O can be taken as approximately geocentric. It is convenient to select an initial point O_0 with radius vector $\mathbf{R}_0$ which, in general, is outside the earth's surface and on the curve of motion C (Fig. 1). The gravitational field corresponding to a spherical earth is

$$\mathbf{g}=-g_0(R_0^2/R^3)\mathbf{R}, \tag{4}$$

if g_0 is the value of g at O_0. The g-correction equation then becomes

$$d^2\mathbf{R}/dt^2+g_0(R_0^2/R^3)\mathbf{R}=\mathbf{b}(t). \tag{5}$$

The sphere S_0 (Fig. 1) through O_0 and concentric with the earth will be referred to as the reference sphere. For an initial point on the actual (approximately spheroidal) earth, the radius and surface gravitation of the reference sphere can be taken as the mean radius R_e and mean gravitational acceleration g_e over the earth's surface, which are defined[3] in first approximation by

$$R_e=(2/3)R_{eq}+(1/3)R_{pol}, \tag{6a}$$

$$g_e=(2/3)g_{eq}+(1/3)g_{pol}, \tag{6b}$$

where R_{eq} and R_{pol} are the equatorial and polar radii

[3] G. G. Stokes, Camb. and Dubl. Math. J. 4, 194 (1849); Trans. Camb. Phil. Soc. 8, 672 (1849); also *Mathematical and Physical Papers* (Cambridge University Press, Cambridge, 1883), Vol. II, p. 104.

respectively of the earth, and g_{eq} and g_{pol} are the corresponding gravitational accelerations. The radius R_e is, in first approximation, equal to the radius of the earth's sphere of equal volume, and defines an equivalent sphere S_e (Fig. 1) with surface gravity g_e for the earth.[4] Equation (5) is valid in a geocentric frame O' fixed in the rotating earth if the centrifugal and Coriolis accelerations (and the latitude-dependent component of $\mathbf{g}$) can be neglected.[5]

Let a Cartesian frame O_0 (Fig. 1) be defined with origin at the initial point of motion, such that the z-axis is vertical, the x-axis is horizontal in the plane determined by the z-axis and the initial velocity vector $\mathbf{v}_0$, and the y-axis is selected to make the frame right-handed. It will be assumed for simplicity in what follows that the initial velocity $\mathbf{v}_0$ is non-vanishing unless otherwise stated (and hence the convention above defines the direction of the x-axis except when the initial velocity is in the vertical direction). If $\mathbf{r}=x\mathbf{i}+y\mathbf{j}+z\mathbf{k}$ is the radius vector of the box in the frame O_0, Eq. (5) becomes

$$d^2\mathbf{r}/dt^2+\omega_0^2(R_0/R)^3(R_0\mathbf{k}+\mathbf{r})=\mathbf{b}(t), \tag{7}$$

where the parameter ω_0 is defined by

$$\omega_0=(g_0/R_0)^{\frac{1}{2}}, \tag{8}$$

and

$$R=[x^2+y^2+(z+R_0)^2]^{\frac{1}{2}}, \tag{9}$$

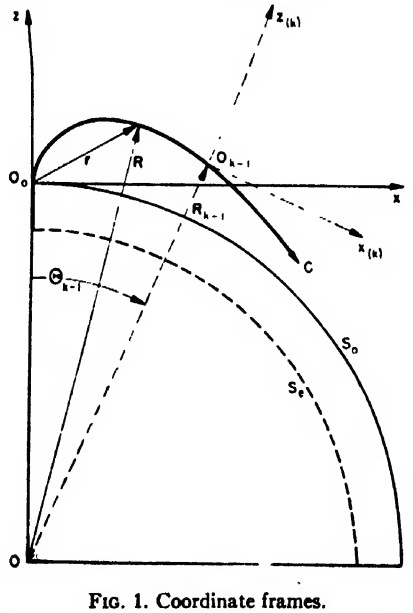

FIG. 1. Coordinate frames.

[4] The equality of volumes follows on the assumption that squares and higher powers of the ellipticity $e=(R_{eq}-R_{pol})/R_{eq}$ are negligible compared to unity. If the density of the earth's crust is assumed constant, R_e is likewise the radius of the earth's sphere of equivalent mass. Hence, Eq. (4) with $R_0=R_e$ and $g_0=g_e$ yields the correct asymptotic value GM/R^2 (G=gravitational constant, M=mass of the earth) of g at large distances from the earth.

[5] Equation (5) likewise ignores a slight perturbation due to lunar and solar attraction (similar in origin to the perturbations producing tides). The corresponding effect for artillery shells is discussed in F. R. Moulton, *New Methods in Exterior Ballistics* (University of Chicago Press, Chicago, 1926), p. 19.

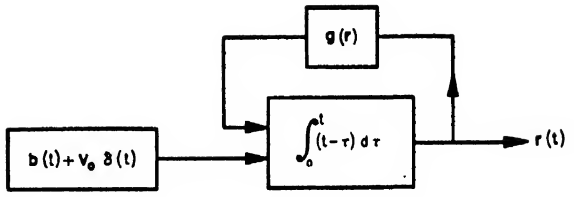

FIG. 2. Computer diagram.

with $\mathbf{b}=b_x\mathbf{i}+b_y\mathbf{j}+b_z\mathbf{k}$. The initial conditions are $\mathbf{r}_0=0$ and $\mathbf{v}_0=v_{x,0}\mathbf{i}+v_{z,0}\mathbf{k}$.

Equation (7) can be formulated as an integral equation

$$\mathbf{r}=\mathbf{v}_0t+\int_0^t(t-\tau)[\mathbf{b}(\tau)+\mathbf{g}(\mathbf{r})]d\tau, \tag{10}$$

in which $\mathbf{g}(\mathbf{r})$ is $\mathbf{g}$ of (4) with its dependence on components of $\mathbf{r}$ represented symbolically, and the cubature operator $\int_0^t(t-\tau)d\tau$ performs the operation of double integration with respect to time (as integration by parts verifies). From the standpoint of an automatic computer in the box, the sequence of operations shown diagrammatically in Fig. 2 yields the position vector $\mathbf{r}(t)$ from $\mathbf{b}(t)$ (the initial velocity $\mathbf{v}_0$ has been put in symbolically by means of the Dirac δ-function, $\delta(t)$, which is singular at $t=0$).

From the standpoint of determining $\mathbf{r}(t)$ as a closed solution in the time, Eq. (7) poses serious difficulties since $\mathbf{b}(t)$ is an arbitrary function of time and the equation is non-linear in $\mathbf{r}$. In the general case, integrals of energy and angular momentum cannot be found except as purely formal expressions Hence, the classical method of using integrals of the motion to reduce the order of the component differential equations is not possible in general. Exact solutions in some particular cases are available; if $\mathbf{b}$ is zero, for example, Eq. (7) reduces to the differential equation of an elliptical free-flight trajectory. In practical cases, however, $\mathbf{b}$ and $\mathbf{g}$ are of comparable magnitude over the trajectory as a whole (see Fig. 4), so that perturbation methods are not generally useful. Resort can be made to various numerical and iterative methods. A difference method due to Hartree,[6] which avoids intermediate computation of the velocities, can be mentioned. The integral equation, (10), can be identified in coordinate formulation with a system of non-linear Volterra integral equations of the second kind[7] to yield a general solution by iteration. Although iterative solutions have obvious limitations, a solution of this type has been applied[8] as a computational method for specific $\mathbf{b}(t)$.

In the practical problem of computer design, the non-linear $\mathbf{g}$-term of Eq. (7) presents design complications. Furthermore, a suitable approximation for $\mathbf{g}$ may be sufficient on trajectories of restricted range, or when

[6] D. R. Hartree, Mem. Manch. Lit. Phil. Soc. 77, 91 (1932).

[7] V. Volterra, *Leçons sur les Equations Intégrales* (Gauthier-Villars, Paris, 1913), p. 90.

[8] E. T. Benedikt, Phys. Rev. 74, 1213(A) (1948).

the motion is constrained to a particular surface (see Section 2). The simplest such approximation consists in replacing $\mathbf{g}$ by its constant value $-g_0\mathbf{k}$ at O_0, which yields the zero-order solution

$$\mathbf{r}=\mathbf{v}_0t-(g_0t^2/2)\mathbf{k}+\int_0^t(t-\tau)\mathbf{b}(\tau)d\tau, \qquad (11)$$

valid in a restricted neighborhood of the origin. The remainder of this paper will consider the problem of replacing $\mathbf{g}$ by linear approximations. These linear approximations will be made the basis of an interval-wise solution having certain advantages.

II. THE SPHERICAL SOLUTION

The g-correction equation, (7), has a simple and exact solution when the vehicle is constrained to move on the surface of a sphere concentric with the earth, and the corresponding solution will be referred to as a spherical solution. The sphere of motion will be taken as the reference sphere of radius R_0, on which the outward-drawn unit normal is $\mathbf{R}/R_0$ or $\mathbf{k}+\mathbf{r}/R_0$. The condition on $\mathbf{b}$ for motion on S_0 is

$$\mathbf{b}\cdot(R_0\mathbf{k}+\mathbf{r})=g_0R_0^2/R-v^2, \qquad (12)$$

which is necessary and sufficient if the initial velocity vector is tangent to S_0 at $O_0(\mathbf{v}_0=v_0\mathbf{i})$. Physically, Eq. (12) states (when divided by R) that the radial component of $\mathbf{b}$ equals the gravitational acceleration less the centrifugal acceleration on a sphere of radius R. In practice, the condition (12) can be met by means of an altimeter (of atmospheric-pressure or radar type) used to control independently the altitude of the vehicle relative to the earth. The field $\mathbf{g}_s$ on the surface of S_0 is

$$\mathbf{g}_s=-g_0\mathbf{k}-\omega_0^2\mathbf{r}, \qquad (13)$$

which will be referred to as the spherical field.

The g-correction equation in the spherical case is

$$d^2\mathbf{r}/dt^2+\omega_0^2\mathbf{r}=\mathbf{b}-g_0\mathbf{k}. \qquad (14)$$

The solution of Eq. (14) subject to the condition (12) on $\mathbf{b}$ is

$$\mathbf{r}=[(\sin\omega_0t)/\omega_0]\mathbf{v}_0-[2R_0\sin^2\omega_0t/2]\mathbf{k}+(1/\omega_0)\int_0^t\mathbf{b}(\tau)\sin\omega_0(t-\tau)d\tau, \qquad (15)$$

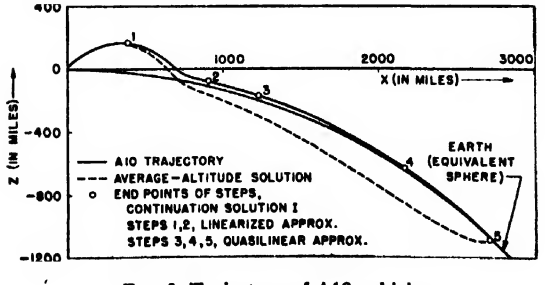

FIG. 3. Trajectory of A10 vehicle.

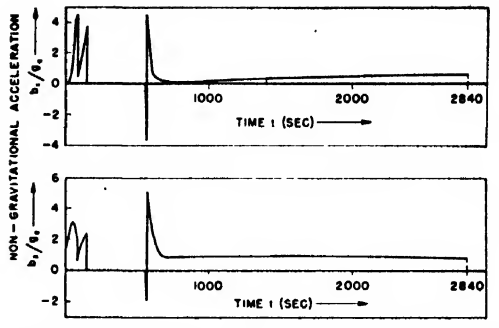

FIG. 4. Non-gravitational accelerations b_x and b_z on A10 vehicle in terms of g_e (surface gravity on equivalent sphere).

with the restriction that $\mathbf{v}_0=v_0\mathbf{i}$. If the sine functions appearing in the spherical solution are replaced by the leading terms of their Taylor expansions, the spherical solution (15) reduces to the zero-order solution (11).

As a trivial example of the spherical solution, consider a box moving on the surface of the reference sphere S_0 and such that $\mathbf{b}=0$. From Eq. (12), the speed $v_{s,0}$ is a constant

$$v_{s,0}=(g_0R_0)^{\frac{1}{2}}. \qquad (16)$$

Equation (15) in this case corresponds to a circle of radius R_0 described with the constant angular velocity ω_0 and the period

$$T_0=2\pi(R_0/g_0)^{\frac{1}{2}}, \qquad (17)$$

which is approximately 84.4 min. for an origin on the equivalent sphere S_e. Hence, this special case corresponds physically to the motion of a satellite around the earth in a circular orbit, and the speed $v_{s,0}$ will be referred to as the satellite (or circular) speed corresponding to the radius R_0.

When the constraining condition (12) is not satisfied exactly at all times, the altitude,

$$h=R-R_0, \qquad (18)$$

of the vehicle relative to the reference sphere S_0 is nonvanishing, and the spherical solution (15) yields a corresponding error. If $\delta_s\mathbf{r}$ is the true solution of Eq. (7) less the spherical solution of (15) for a given $\mathbf{b}$, then one has

$$d^2\delta_s\mathbf{r}/dt^2+\omega_0^2\delta_s\mathbf{r}=g_0\xi(\mathbf{k}+\mathbf{r}/R_0), \qquad (19)$$

where the error parameter ξ is defined by

$$\xi=1-(R_0/R)^3\sim 3h/R_0, \qquad (20)$$

and the approximation indicated is valid for $h\ll R_0$. The quantity $\xi(\mathbf{k}+\mathbf{r}/R_0)$ is the gradient of a harmonic function, and hence its magnitude assumes a maximum value on the boundary of any closed region of space (not including the center of the earth) considered. Thus, if a uniform bound H on the absolute value of h is known, then

$$M=(1-H/R_0)^{-2}-(1-H/R_0)\sim 3H/R_0 \qquad (21)$$

is a uniform bound on $|\xi(\mathbf{k}+\mathbf{r}/R_0)|$ for $H<R_0$, and hence one can show that

$$|\delta_s\mathbf{r}| \leqslant 2g_0M\sin^2\omega_0t/2, \quad (t\leqslant T_0/2), \tag{22}$$

if no error exists in the knowledge of initial conditions (the direction of $\mathbf{v}_0$ is now unrestricted). Since $|\delta_s\mathbf{r}|$ vanishes as $M\to 0$ (or $H\to 0$), the spherical solution (15) is a valid approximation in the large (or "on the average") for motion which is closely spherical, within the limitations of (22) or a closer error bound.

Over a trajectory of extended range, the spherical solution is not useful if significant systematic variations of altitude exist. The difficulty usually cannot be avoided by taking an average R corresponding to an average altitude in the $\mathbf{g}$-term of Eq. (7); this point can be illustrated by an example. Figure 3 shows the trajectory (solid curve) of the German A10 vehicle,[9,10] which is extreme in its altitude variation (185 mi.), and Fig. 4 shows the non-gravitational accelerations[11] b_x and b_z for this vehicle as a function of time. For this trajectory, a solution of the g-correction equation is shown in Fig. 3 (dashed curve) which corresponds to an average altitude of 16.9 mi. (i.e., R was taken as $R_e+16.9$ mi. in the $\mathbf{g}$-term of Eq. (7)). This particular average-altitude solution yields a negligible error at the terminal point of the motion but defines a trajectory passing under the earth's surface.

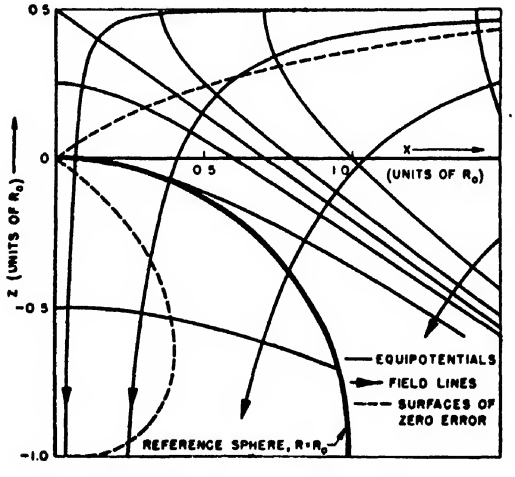

FIG. 5. Linearized field diagram.

[10] J. M. J. Kooy and J. W. H. Uytenbogaart, *Ballistics of the Future* (McGraw-Hill Book Co., Inc., New York, 1946), p. 399.

[11] Only a limited amount of information is available on the A10 (this vehicle was proposed but never built, and was to consist essentially of a winged V2 equipped with a booster rocket). The trajectory of Fig. 3 fits the A10 as closely as the available information permits. The quantities b_x and b_z were determined by differentiation from the assumed trajectory. Of the peaks in each curve of Fig. 4, the first two correspond to release of the booster and power cut-off in that order, and the ones at 560 seconds correspond to re-entry into appreciable atmosphere. Rotation of the earth and latitude variation of g have been completely neglected in the data of Figs. 3 and 4.

III. THE LINEARIZED APPROXIMATION

It is clear from the preceding discussion that the essential problem in connection with the g-correction equation exists when significant variations in altitude above the earth occur. This section discusses an approximate analytic solution which is superior to the zero-order approximation (11) when variations in altitude above the earth occur.

The field $\mathbf{g}(\mathbf{r})$ of (4) can be expanded about the origin O_0 to yield

$$\mathbf{g}(\mathbf{r}) = -g_0\mathbf{k}-\omega_0^2[\mathbf{r}-3(\mathbf{k}\cdot\mathbf{r})\mathbf{k}]-(3\omega_0^2/2R_0) \times\{[5(\mathbf{k}\cdot\mathbf{r})^2-\mathbf{r}^2]\mathbf{k}-2(\mathbf{k}\cdot\mathbf{r})\mathbf{r}\}+\cdots. \tag{23}$$

If only linear terms are retained in the Taylor expansion (23), the corresponding field $\mathbf{g}_L$, defined by

$$\mathbf{g}_L(\mathbf{r}) = -g_0\mathbf{k}-\omega_0^2[x\mathbf{i}+y\mathbf{j}-2z\mathbf{k}], \tag{24}$$

will be referred to as the linearized field. Under this approximation for $\mathbf{g}$, the coordinate formulation of the g-correction equation becomes

$$\ddot{x}+\omega_0^2x = b_x, \tag{25a}$$

$$\ddot{z}-2\omega_0^2z = b_z-g_0, \tag{25b}$$

with the y-equation symmetric to that in x. These differential equations, which are valid in some neighborhood of the origin, will be referred to as the linearized equations.

The linearized solution will be taken as

$$x = (v_{x,0}/\omega_0)\sin\omega_0t+(1/\omega_0) \times\int_0^t b_x(\tau)\sin\omega_0(t-\tau)d\tau, \tag{26a}$$

$$y = (1/\omega_0)\int_0^t b_y(\tau)\sin\omega_0(t-\tau)d\tau, \tag{26b}$$

$$z = (v_{z,0}/2^{\frac{1}{2}}\omega_0)\sinh 2^{\frac{1}{2}}\omega_0t-R_0\sinh^2\omega_0t/2^{\frac{1}{2}} +(1/2^{\frac{1}{2}}\omega_0)\int_0^t b_z(\tau)\sinh 2^{\frac{1}{2}}\omega_0(t-\tau)d\tau. \tag{26c}$$

The case of a flat earth corresponds to $R_0\to\infty$, or equivalently $\omega_0\to 0$. Equations (26) reduce directly to the zero-order solution (11) for a flat earth as $\omega_0\to 0$ if note is taken of the limits $(\sin u)/u\to 1$, $(\sinh u)/u\to 1$ as $u\to 0$.

The linearized field $\mathbf{g}_L$ is symmetric about the z-axis. In the meridian x, z plane, the equipotentials of the linearized field are defined by

$$(z-R_0/2)^2-x^2/2 = \text{const.}, \tag{27}$$

and the field lines are given by

$$x^2(z-R_0/2) = \text{const.} \tag{28}$$

Hence, the equipotentials form in the x, z plane a family of concentric hyperbolas and their conjugates

asymptotic to the lines $x^2=2(z-R_0/2)^2$ through the center of symmetry $(0, R_0/2)$ of the field. The linearized field diagram is shown in Fig. 5 (solid curves, field lines indicated by arrows). On the horizontal plane $z=R_0/2$, the z-component of the linearized field vanishes and above this plane the field becomes repulsive. The field diagram of Fig. 5 yields a qualitative index of the extent of the neighborhood of the origin in which the linearized equations provide a practical approximation.

In discussing the degree of approximation of the linearized solution, the error vector $\delta_L\mathbf{r}$ with components $\delta_L x$, $\delta_L y$, $\delta_L z$ will represent the true less the linearized solution. By subtracting the linearized equations, (25), from the corresponding component equations of (7), one obtains (omitting the equation for $\delta_L y$ symmetric to that in $\delta_L x$)

$$d^2\delta_L x/dt^2+\omega_0^2\delta_L x=\omega_0^2\xi x, \tag{29a}$$

$$d^2\delta_L z/dt^2-2\omega_0^2\delta_L z=\omega_0^2\zeta R_0, \tag{29b}$$

where ξ is given by (20) and the error parameter ζ is defined by

$$\zeta=1-2z/R_0-(1+z/R_0)(R_0/R)^3\sim 3(r^2-3z^2)/2R_0^2. \tag{30}$$

Physically, the right-hand sides of Eqs. (29a) and (29b) are the accelerations neglected by $\mathbf{g}_L$ on the x- and z-axes respectively. If bounds $\max(|\xi x|)$ and $\max(|\zeta R_0|)$ are known from sources other than the linearized solution itself, then one has

$$|\delta_L x|\leqslant 2\max(|\xi x|)\sin^2\omega_0 t/2, \quad (t\leqslant T_0/2); \tag{31a}$$

$$|\delta_L z|\leqslant \max(|\zeta R_0|)\sinh^2\omega_0 t/2^{\frac{1}{2}}. \tag{31b}$$

Both ξx and ζR_0 are harmonic functions, so their maximum and minimum values must be on the boundary of any closed region of space (not containing the center of the earth) considered.

It follows from (29) that the linearized x- and z-solutions are exact for motion of the box on surfaces such that $\xi x=0$ and $\zeta=0$ respectively. If one disregards the trivial locus represented by the z-axis, the reference sphere $R=R_0$ is (from Eq. (20)) the surface of zero error $\xi=0$ for the linearized x-solution (and for the linearized y-solution, by symmetry). The surface defined by $\zeta=0$ is a surface of revolution about the z-axis, and consists of two sheets intersecting the origin O_0 which are shown (dashed curves) in x, z coordinates on the linearized field diagram of Fig. 5. The upper open branch in Fig. 5 is asymptotic to the line $z=R_0/2$, and the upper and lower branches behave in the neighborhood of the origin O_0 as segments (for x positive) of the two straight lines $x^2=2z^2$. It is seen that no surface exists on which all components of the linearized solution are exact.

The leading term of the Taylor expansion of the error $\delta_L\mathbf{r}$ is given by

$$\delta_L\mathbf{r}=R_0[2v_{x,0}v_{z,0}\mathbf{i}+(v_{z,0}^2-2v_{x,0}^2)\mathbf{k}]\times(\omega_0 t)^4/4v_{e,0}^2+\cdots, \tag{32}$$

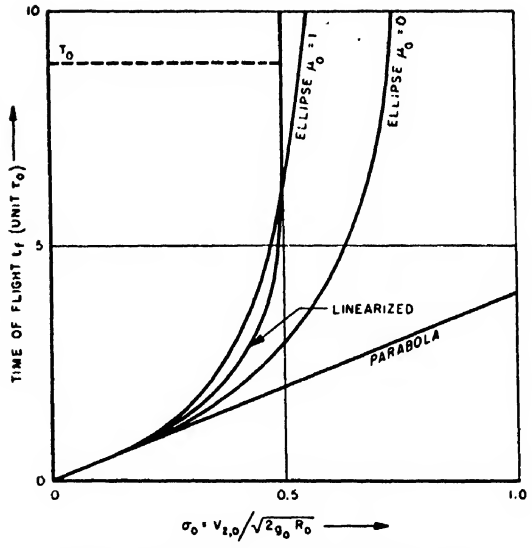

FIG. 6. Times of flight to horizontal plane $z=0$ (ballistic case, $\mathbf{b}=0$).

where $v_{e,0}$ is the escape (or parabolic) speed

$$v_{e,0}=(2g_0R_0)^{\frac{1}{2}}. \tag{33}$$

The leading terms of $\delta_L x$ and $\delta_L z$ vanish for motions initially tangent to the corresponding surfaces of zero error, respectively, and hence never vanish simultaneously. For $v_0\neq 0$ the absolute error $|\delta_L\mathbf{r}|=O(t^4)$ is never of order higher than t^4, and thus the Taylor expansion of the linearized solution agrees with the true Taylor expansion of $\mathbf{r}$ through terms of order t^3, as compared to the zero-order solution (11), which agrees through terms of order t^2. Since the arc length s on the curve of motion satisfies $s=O(t)$ when $v_0\neq 0$, the linearized trajectory has contact of order not less than the third with the actual trajectory at the origin, and hence the linearized solution is essentially an osculating approximation.

For the case $\mathbf{b}=0$ (ballistic trajectory), the linearized trajectory can be compared with the exact solution representing an ellipse in space and with the corresponding parabola. It is convenient to introduce the dimensionless parameters

$$\mu_0=v_{x,0}/(g_0R_0)^{\frac{1}{2}}, \quad \sigma_0=v_{z,0}/(2g_0R_0)^{\frac{1}{2}}, \tag{34}$$

for the initial velocities, where the denominators in μ_0 and σ_0 are, respectively, the satellite speed $v_{s,0}$ of (16) and the escape speed $v_{e,0}$ of (33) (one has $\sigma_0^2+\mu_0^2/2\leqslant 1$ if $v_0\leqslant v_{e,0}$). The linearized solution for $\mathbf{b}=0$ can be written

$$x=R_0\mu_0\sin\omega_0 t, \tag{35a}$$

$$z=(R_0/2)[1-(1-4\sigma_0^2)^{\frac{1}{2}}\cosh(t/\tau_0-\tanh^{-1}2\sigma_0)], \tag{35b}$$

in which the parameter τ_0 is

$$\tau_0=1/2^{\frac{1}{2}}\omega_0, \tag{36}$$

and it is assumed that $|\sigma_0|<1/2$. If $\sigma_0=1/2$, the z-solu-

tion becomes

$$z=(R_0/2)[1-e^{-t/\tau_0}], \tag{37}$$

and hence the trajectory defined by the linearized solution approaches the plane $z=R_0/2$ asymptotically as $t\to\infty$. The time constant τ_0 for z to reach the fraction $1-1/e$ of its asymptotic value in this case is approximately 9.5 min. for an initial point O_0 on the surface of the equivalent sphere S_e. For $\sigma_0>1/2$, the linearized trajectory crosses the plane $z=R_0/2$ and is unbounded in z; thus the linearized approximation implies an escape speed $v_{e,0}/2$ which is one-half the true value (33) on an inverse-square field. For $0<\sigma_0<1/2$, the time of flight t_f corresponding to intersection with the x,y plane,

$$t_f=2\tau_0 \tanh^{-1}2\sigma_0, \tag{38}$$

is compared in Fig. 6 with the corresponding time of flight $4\sigma_0\tau_0$ for a parabola, and, for a few values of μ_0, with the corresponding time of flight on an inverse-square field.

In Fig. 7, linearized trajectories from Eqs. (35) are shown (solid curves) in two families ($\sigma_0=0.3$ and $\mu_0=0.2$). From Eq. (35a) one notes that all the linearized trajectories for $\mathbf{b}=0$ intersect the z-axis at time $t=T_0/2$. For σ_0 small and thus t_f small relative to $T_0/2$ (as in the family $\sigma_0=0.3$), this intersection point is far below the x,y plane, and above this plane, the linearized trajectories show a fairly close resemblance in the large to the corresponding ellipses (dashed curves). The intersection with the z-axis is at the origin O_0 for $t_f=T_0/2$, which fixes a critical value $(\tanh\pi/2^{1/2})/2=0.488$ of σ_0 at which the upward and downward branches of the linearized trajectory above the x,y plane coincide. It is clear that for σ_0 close to $1/2$, the linearized trajectories for $\mathbf{b}=0$ are a very poor approximation in the large to the corresponding ellipses, although they are superior to the corresponding parabolas (dot-and-dashed curves) in a neighborhood of the origin.

IV. THE QUASILINEAR APPROXIMATION

The linearized approximation is based on the assumption that the gravitational acceleration $\mathbf{g}$ is a slowly varying function of position. This section discusses a linear approximation based on the additional assumptions that the radius of curvature of the trajectory is large and is a slowly varying function. The approximation will be referred to as the quasilinear approximation. For simplicity, only motion confined to the vertical x,z plane will be considered.

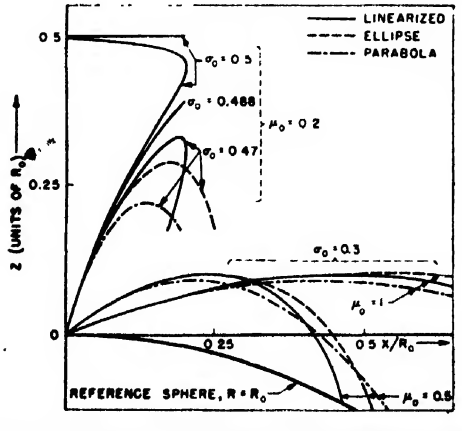

FIG. 7. Comparison of linearized trajectories with ellipses and parabolas (ballistic case, $\mathbf{b}=0$).

If the curve of motion is an analytic curve at the origin O_0, the radius vector $\mathbf{r}$ to a point on the curve can be expanded in the series[12]

$$\mathbf{r}=\alpha_0 s+(\beta_0/2\rho_0)s^2+\cdots, \tag{39}$$

where s is the arc length on the curve, α_0 and β_0 are the unit tangent and unit principal normal at O_0 respectively, and ρ_0 is the radius of curvature at O_0. The terms of order s^3 and higher in (39) involve first and higher derivatives with respect to s and powers above the first of the curvature $1/\rho$. If the series (39) for $\mathbf{r}$ is substituted in (23) for $\mathbf{g}(\mathbf{r})$, one obtains

$$\mathbf{g}(\mathbf{r})=-g_0\mathbf{k}-\omega_0^2[\alpha_0-3(\alpha_0\cdot\mathbf{k})\mathbf{k}]s - \frac{3\omega_0^2}{2}\left\{\frac{\beta_0/3-(\beta_0\cdot\mathbf{k})\mathbf{k}}{\rho_0} + \frac{[5(\alpha_0\cdot\mathbf{k})^2-1]\mathbf{k}-2(\alpha_0\cdot\mathbf{k})\alpha_0}{R_0}\right\}s^2+\cdots, \tag{40}$$

where the terms given explicitly represent $\mathbf{g}$ under the assumption that terms of order s^3 or higher are negligible. Consider the canonical coordinates x_1 and x_2 (defined as coordinates in the direction of α_0 and β_0 respectively) of the curve at the origin. The coordinates x_1 and x_2 are given in terms of x and z by

$$\begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix}=\begin{bmatrix} \alpha_{x,0} & \alpha_{z,0} \\ \beta_{x,0} & \beta_{z,0} \end{bmatrix}\begin{Bmatrix} x \\ z \end{Bmatrix}, \tag{41}$$

where the elements of the direction-cosine matrix are components of α_0 and β_0; these coordinates are likewise given by

$$x_1=s, \quad x_2=s^2/2\rho_0, \tag{42}$$

from (39) under the approximation that terms of order s^3 or higher are negligible. By comparison of (41) and (42), one has the approximation

$$s=\alpha_{x,0}x+\alpha_{z,0}z, \tag{43a}$$

$$s^2=2\rho_0[\beta_{x,0}x+\beta_{z,0}z], \tag{43b}$$

which expresses both s and s^2 linearly in terms of x and z. Under the substitution (43), the terms given explicitly in (40) yield the quasilinear field $\mathbf{g}_Q$ defined (in matrix notation) by

$$\mathbf{g}_Q=-\begin{Bmatrix} 0 \\ g_0 \end{Bmatrix}-\omega_0^2\mathbf{A}_0\begin{Bmatrix} x \\ z \end{Bmatrix} \tag{44}$$

[12] W. C. Graustein, *Differential Geometry* (Macmillan Company, Inc., New York, 1947), p. 39.

where the coefficient matrix $\mathbf{A}_0$ is

$$\mathbf{A}_0=\begin{bmatrix}1-6\alpha_{x,0}\alpha_{z,0}\beta_{x,0}\rho_0/R_0 & 6\alpha_{x,0}\alpha_{z,0}\beta_{z,0}\rho_0/R_0\\ 3\beta_{x,0}(3\alpha_{z,0}^2-1)\rho_0/R_0 & -2+3\beta_{z,0}(3\alpha_{z,0}^2-1)\rho_0/R_0\end{bmatrix}. \tag{45}$$

The parameters entering the coefficient matrix $\mathbf{A}_0$ can be evaluated directly from the initial conditions of the motion. From standard formulas,[12] one has

$$\boldsymbol{\alpha}_0=\frac{\mathbf{v}_0}{v_0},\quad \boldsymbol{\beta}_0=\frac{\mathbf{v}_0\times(\mathbf{b}_0-g_0\mathbf{k})}{|\mathbf{v}_0\times(\mathbf{b}_0-g_0\mathbf{k})|}\times\frac{\mathbf{v}_0}{v_0}, \tag{46}$$

and

$$\rho_0=v_0^3/|\mathbf{v}_0\times(\mathbf{b}_0-g_0\mathbf{k})|, \tag{47}$$

where $\mathbf{b}_0$ is the initial value of $\mathbf{b}$ and it is assumed that $\mathbf{v}_0$ is non-vanishing. The corresponding quasilinear equations of motion are given by

$$\begin{Bmatrix}\ddot{x}\\ \ddot{z}\end{Bmatrix}+\omega_0^2\mathbf{A}_0\begin{Bmatrix}x\\ z\end{Bmatrix}=\begin{Bmatrix}b_x\\ b_z-g_0\end{Bmatrix}. \tag{48}$$

Solutions of the system (48) can be obtained directly by the use of the Laplace transform.

The quasilinear approximation represented by Eqs. (48) yields a transition from the linearized approximation (25) to the spherical approximation (14). The linearized equations assume that terms of the type $(x/R_0)^2$ in the Taylor expansion of $\mathbf{g}$ are negligible compared to terms of type x/R_0, which is equivalent to assuming $(s/R_0)^2\ll s/R_0$. From Eqs. (43) this condition requires that $\rho_0\ll R_0$, and one notes that Eqs. (48) reduce to the linearized equations (25) when $\rho_0\to 0$. The spherical solution (15) for motion in the x,z plane presupposes $\boldsymbol{\alpha}_0=\mathbf{i}$ and $\boldsymbol{\beta}_0=-\mathbf{k}$ at the origin; if note is taken of the constraining condition (12) on $\mathbf{b}_0$, Eq. (47) yields $\rho_0=R_0$. With these values of the parameters, Eqs. (48) reduce directly to the spherical equation, (14), of motion.

Since the terms in the Taylor expansion of $\mathbf{g}$ neglected by $\mathbf{g}_Q$ are of order s^3, and $s=O(t)$ when $\mathbf{v}_0\neq 0$, it follows that the absolute error $|\delta_Q\mathbf{r}|$ of the quasilinear solution is such that $|\delta_Q\mathbf{r}|=O(t^5)$ in general. Thus, the Taylor expansion of the quasilinear solution agrees with the true Taylor expansion of $\mathbf{r}$ through terms of order t^4 in general, as compared to the linearized solution (26), which agrees through terms of order t^3 at most. The quasilinear trajectory has contact of order not less than the fourth with the actual trajectory at the origin, and accordingly is an osculating approximation in general.

One can define error parameters for the quasilinear equations analogous to ξ and ζ in the linearized case, which fix surfaces of zero error for the component equations of (48). By this means one can show that the surfaces of zero error for both components coincide, and the quasilinear system (48) is exact if and only if the motion is constrained to the reference sphere S_0 (condition (12) holds), in which case the quasilinear system reduces to the spherical equation, (14). When $\rho_0\sim R_0$, the surfaces of zero error for both components are nearly in coincidence, and the quasilinear solution provides an approximation which is markedly superior to the linearized. When ρ_0 is small relative to R_0, the quasilinear trajectory differs only slightly from the linearized, and may yield only a small margin of gain. These results are illustrated by Fig. 8, which compares the quasilinear trajectories for the ballistic case ($\mathbf{b}=0$) with the corresponding ellipses and linearized trajectories when $\sigma_0=0$.

In passing, it can be noted that generalization of this quasilinear approximation to three dimensions is easily made (by assuming that the torsion of the curve of motion is likewise a slowly varying function).

V. LINEAR CONTINUATION

When significant variations of altitude above the earth occur on a trajectory of extended range, it is clear that none of the linear approximations given for $\mathbf{g}(\mathbf{r})$ are satisfactory in the large. In this case, the g-correction equation, (7), can always be solved by a step-by-step procedure in which the non-linear gravitational term over any interval of time is replaced by a constant value corresponding to the interval, as determined from the solution of the equation for times up to the interval in question. The solution in any interval is given by a suitable modification of the zero-order solution (11), and the solution is continued from interval to interval by identifying the initial conditions of one interval with the terminal conditions of the preceding interval. Such a method will be referred to as zero-order continuation, and, while always applicable, has the disadvantage of requiring a large number of steps for an extended range.

To reduce the number of steps required, the gravitational acceleration over any interval of time can be

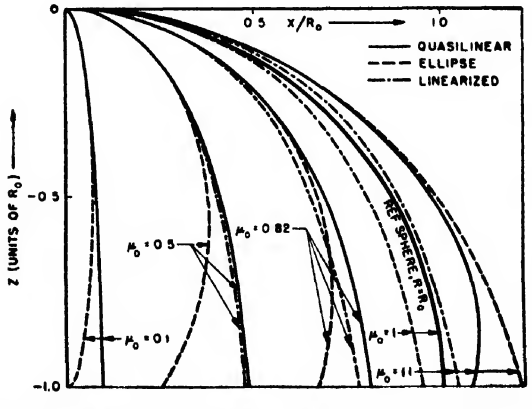

FIG. 8. Comparison of quasilinear trajectories with ellipses and linearized trajectories (ballistic case, $\mathbf{b}=0$).

TABLE I. Results of continuation solutions.

Solution	Step solution	Number of steps	Error $\|\delta r\|$ (mi.)
I	Linearized and quasilinear*	5	20
II	Linearized	39	46
III	Zero-order	39	254

* As specified in Fig. 3.

replaced by a linear approximation whose constants are determined by the solution up to the interval. The most advantageous approximation is the quasilinear. The initial conditions for any interval are again taken as the computed terminal conditions of the preceding interval. Such a method of solution will be referred to as linear continuation.

For simplicity, let the motion be plane with an initial point O_0 on the surface of the equivalent sphere S_e, and let the components of $\mathbf{b}$ be measured parallel to the axes x, z of the frame O_0. Let the total range, O to t_n of t, be divided into n intervals, t_{k-1} to t_k $(k=1, \cdots, n)$ with $t_0=0$. The computed terminal point O_{k-1} in the $(k-1)$th interval determines a frame $x_{(k)}$, $z_{(k)}$ with parameters R_{k-1}, Θ_{k-1} for the kth interval, as in Fig. 1 $(\Theta_0=0)$. In the frame O_{k-1} (which is introduced for computational convenience), the theory of the preceding sections for the frame O_0 can be applied to define the pertinent parameters g_{k-1}, ω_{k-1}, $\mathbf{A}_{k-1}$ by interchange of subscripts. If $\mathbf{B}_{k-1}$ designates the direction-cosine matrix

$$\mathbf{B}_{k-1}=\begin{bmatrix} \cos\Theta_{k-1} & \sin\Theta_{k-1} \\ -\sin\Theta_{k-1} & \cos\Theta_{k-1} \end{bmatrix}, \tag{49}$$

the g-correction equation in the kth interval when referred to the O_{k-1} frame is

$$\begin{Bmatrix} \ddot{x}_{(k)} \\ \ddot{z}_{(k)} \end{Bmatrix} + \omega_{k-1}^2 \mathbf{A}_{k-1} \begin{Bmatrix} x_{(k)} \\ z_{(k)} \end{Bmatrix} = \mathbf{B}_{k-1}' \begin{Bmatrix} b_x \\ b_z \end{Bmatrix} - \begin{Bmatrix} 0 \\ g_{k-1} \end{Bmatrix}, \tag{50}$$

where $\mathbf{B}_{k-1}'$ is the transpose of $\mathbf{B}_{k-1}$. The formulation (50) corresponds to the use of a quasilinear approximation, which reduces to a linearized or spherical approximation in the special cases

$$\mathbf{A}_{k-1}=\begin{bmatrix} 1 & 0 \\ 0 & -2 \end{bmatrix}, \quad \mathbf{A}_{k-1}=\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \tag{51}$$

respectively. The g-correction equation in the kth interval is then

$$\begin{Bmatrix} \ddot{x} \\ \ddot{z} \end{Bmatrix} + \omega_{k-1}^2 \mathbf{B}_{k-1}\mathbf{A}_{k-1}\mathbf{B}_{k-1}' \begin{Bmatrix} x \\ z \end{Bmatrix} = \begin{Bmatrix} b_x \\ b_z \end{Bmatrix} - \mathbf{B}_{k-1} \begin{Bmatrix} 0 \\ g_{k-1} \end{Bmatrix} \tag{52}$$

when referred to the O_0 frame.

In practice, it is found that linear continuation yields a considerable reduction in number of intervals as compared with zero-order continuation for the same terminal error. This fact appears by comparison of solutions I and II with solution III in Table I, which shows the results of three different continuation solutions carried out for the A10 trajectory. Solution I was based on the use of quasilinear approximations in the intervals (as specified in Fig. 3) where $\rho \sim R_0$; comparison of the results with those of solution II brings out the superiority of the quasilinear over the linearized approximation under this condition. In carrying out these computations, the $\mathbf{b}$-function (Fig. 4) was tabulated to four decimal places (after round-off) in units of g_e from the assumed trajectory (consisting of segments of analytic curves). Checks indicated that the rounding-off process in $\mathbf{b}$ introduced an error $|\delta\mathbf{r}|$ which amounted to <3 mi. for the solutions of Table I, which shows that the entries in the table for $|\delta\mathbf{r}|$ are significant for comparison of the approximations to $\mathbf{g}$.

It should be emphasized that the computations yielding Table I are of academic nature, due to neglect of the latitude-dependent component of $\mathbf{g}$ and of the centrifugal and Coriolis terms in the kinetic reaction of the g-correction equation. The sum of the first two of these acceleration terms varies over a range of $0.005g_e$ from the equator to the pole on the earth's surface. The systematic errors due to neglect of the variation of these terms on the A10 trajectory have been calculated approximately by a perturbation method for the case when the plane of motion coincides with the earth's equatorial plane (the error is then in this plane likewise). In this case the effect of variation of centrifugal reaction ($|\delta\mathbf{r}| \sim 30$ mi.) and of Coriolis reaction ($|\delta\mathbf{r}| \sim 700$ mi.) is extreme. These errors are larger by orders of magnitude than the upper limit ($|\delta\mathbf{r}| < 3$ mi.) to the round-off error found above for the data of Table I. Hence, the method of computation leading to Table I, in the particular form used, has only a limited practical validity for the A10 trajectory (except as an approximation in the roughly constant plane of motion for a trajectory in the neighborhood of a pole, where the Coriolis deflection is transverse).

It is clear from these considerations that the step solution in linear continuation must be modified on trajectories of extended range, in general, to include terms corresponding to the variation of the latitude-dependent component of $\mathbf{g}$, the variation of the centrifugal reaction, and the Coriolis reaction. The fact that these terms are considerably smaller than the main radial term of $\mathbf{g}$ materially simplifies the problem, which will not be attempted here because of the detail involved.

The advantage of linear continuation over numerical methods such as the Runge-Kutta process consists in the fact that the length of step or the integration interval is fixed by the variation of the slowly varying $\mathbf{g}$-function. From such error bounds as (22) or (31), one can estimate the number of steps required for a given terminal accuracy. In methods of the Runge-Kutta type, however, the integration interval is fixed by the

variation of the rapidly varying b-term, and the possible interval is considerably smaller. Linear continuation yields a reasonable compromise between the conflicting demands of a small number of steps and simplicity of the step solution.

In conclusion the authors wish to acknowledge many helpful discussions of this problem with Dr. W. C. Randels of Northrop Aircraft Corporation, Dr. R. Isaacs of The Rand Corporation, and Prof. T. Dantzig of the Rand consulting staff. Thanks are due also to Mrs. M. Irving and Mrs. J. Griffith for the computational work.

Diffraction Pattern in a Circular Aperture Measured in the Microwave Region

C. L. Andrews
General Electric Research Laboratory, The Knolls, Schenectady, New York
(Received February 2, 1950)

Measurements were made of the diffraction patterns of circular apertures from one to eight wave-lengths in diameter in the planes of the apertures and in the neighborhood of the apertures when a plane polarized electromagnetic wave was incident upon them. From Thomas Young's theory that the diffraction pattern is an interference pattern between the incident plane wave and wavelets from the edge of the aperture, the positions of maximum intensity have been predicted in the neighborhood of the aperture and the values of the intensities over the apertures checked with experiment.

INTRODUCTION

DIFFRACTION of light waves has been explained by Thomas Young as interference between the geometrically propagated incident wave and Huygen's wavelets caused by disturbance at the edge of the diffracting screen. Young's explanation was dropped promptly for Fresnel's theory that the diffraction pattern of a plane screen is the resultant of interfering wavelets from every point in any open portion of the infinitely extended plane of the screen. Lacking experimental facts, Fresnel made the simple assumption that the wave reaching the aperture of the screen was unperturbed. On the basis of Green's theorem and Fresnel's assumptions, Kirchoff developed a more exact theory of diffraction. A hundred years after Young and Fresnel, Rubinowicz[1] showed that Kirchoff's surface integral for the determination of the disturbance at a point on the opposite side of the aperture from the source may be transformed into two terms, one for the geometrically propagated wave through the aperture, and the other a line integral around the edge of the aperture. Thus Rubinowicz gave us two mathematically equivalent ways of thinking of diffraction by an aperture, one to think of intensity at a point in the diffraction pattern as the sum of all the effects from every point in the aperture and the other to think of diffraction as an edge effect.

Recently microwaves by their convenient length have provided a means of measuring the diffraction pattern in the plane of an aperture and on the sides toward and away from the source. It has been emphasized that the sharpest part of the diffraction pattern of an aperture is in the plane of the aperture itself.[2] Although this fact was recognized through measurements of microwave intensities in apertures, it could have been observed with light.

If the elementary apparatus for study of diffraction of light by a single slit is employed, the aperture may be opened to uncover a half dozen Fresnel strips relative to the point of observation. If the eye piece is then moved slowly toward the slit and at the same time the slit is diminished in width, so that the same number of dark bands is always observed, then, when the eye piece is finally focused on the plane of the aperture, sharp black lines are seen, each separated by a wavelength.

These simple observations with light are mentioned that the reader may confirm a fact of diffraction that has not been noted in the textbooks. The experimental work reported in this paper was performed with microwaves which provide the most precise means of measuring the diffraction patterns near apertures of the order of a few wave-lengths in diameter.

The assumption by Fresnel of constant intensity across the aperture, or more recent assumptions of constant intensity over most of a large aperture with tapering off only at the edge, have justification only in that they may be used in calculating correct intensities in the diffraction pattern beyond the aperture. The assumptions do not agree with experiment.

Thomas Young's theory of diffraction correctly predicts the positions of maximum and minimum intensity on the sides of the aperture toward and away from the source and in the plane of the aperture itself. Young assumed that the diffraction pattern of an aperture is the interference pattern between a geometrically propagated wave through the aperture and reradiated wavelets from the edge of the aperture. Thus the diffraction pattern of a slit is simply the interference pattern of three waves, the geometrically propagated wave through

[1] Rubinowicz, Ann. d. Phys. 53, 257 (1917).
[2] C. L. Andrews, Phys. Rev. 71, 777 (1947).

the slit and two cylindrical waves from the edges. The interference pattern of a plane wave and a cylindrical wave is a family of parabolas with their common principal focus at the edge, and their focal lengths an odd number of quarter wave-lengths. The interference pattern of the three waves in the plane perpendicular to the edges is not a set of curves but an array of points where the two families of parabolas intersect as shown in Fig. 1, the points where all three waves are in phase. Where the parabolas intersect at small angles the contours of intensity are elongated loops but near the aperture where the parabolas intersect nearly perpendicularly the contours are nearly circular and the gradients of intensity largest. Figure 1 gives the points of maximum intensity in the diffraction pattern of a slit three wave-lengths wide. Whether points A and B be positions of two long rods or the edges of a slit or the edges of a circular aperture upon which a plane polarized wave is incident, this simple theory of Thomas Young predicts closely the positions of maximum intensity in the magnetic plane between two parallel lines from the source through A and B. As the slit edges are separated the two families of parabolas move with them while the peaks of intensity move forward through the aperture from the standing wave region to the Fresnel region.

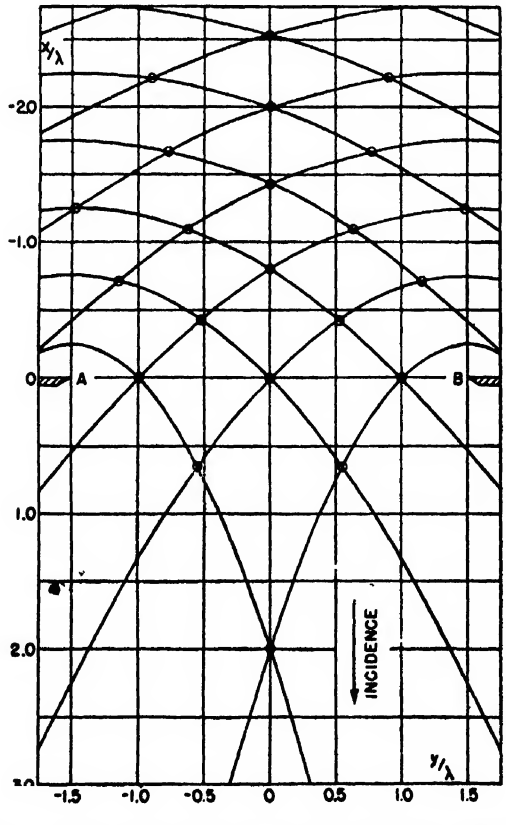

FIG. 1. Diagram for determination of positions of maximum intensity in the diffraction pattern in the magnetic plane of a circular aperture when a plane polarized wave is incident normally.

APPARATUS

The experimental arrangement was similar to that described previously.[1] The wave-length was reduced from 12.8 cm to 8.0 cm. A special triode oscillator was built for the purpose.[3] The parabolic reflector was 4 ft. (122 cm) in diameter. The equipment was set up out-of-doors on a roof to avoid reflections from walls and the distance from source to diffracting screen increased to 75 ft. (23 meters). The centers of the parabolic reflector and diffracting screen were 5 ft. above the roof. The block of the optical bench was driven by motor and screw at the rate of two wave-lengths per minute and the intensities recorded on a recording galvanometer (General Electric Photoelectric Recorder) with a sensitivity of 10 microamperes full scale and a period of 0.83 second.

There were two major sources of error (1) the lack of constancy of intensity in the cross section of the incident unperturbed beam, (2) the finite size of the antenna of the probe and the leads from the probe to the recorder. The automatic recorder made the search for sources of error simpler. The greatest variations of intensity of the unperturbed beam over a width of four wave-lengths were four percent and over a width of eight wave-lengths 10 percent. The crystal itself, Sylvania IN23B, with the brass tip of its capsule removed was used as dipole so that no coaxial lines would have to be employed to

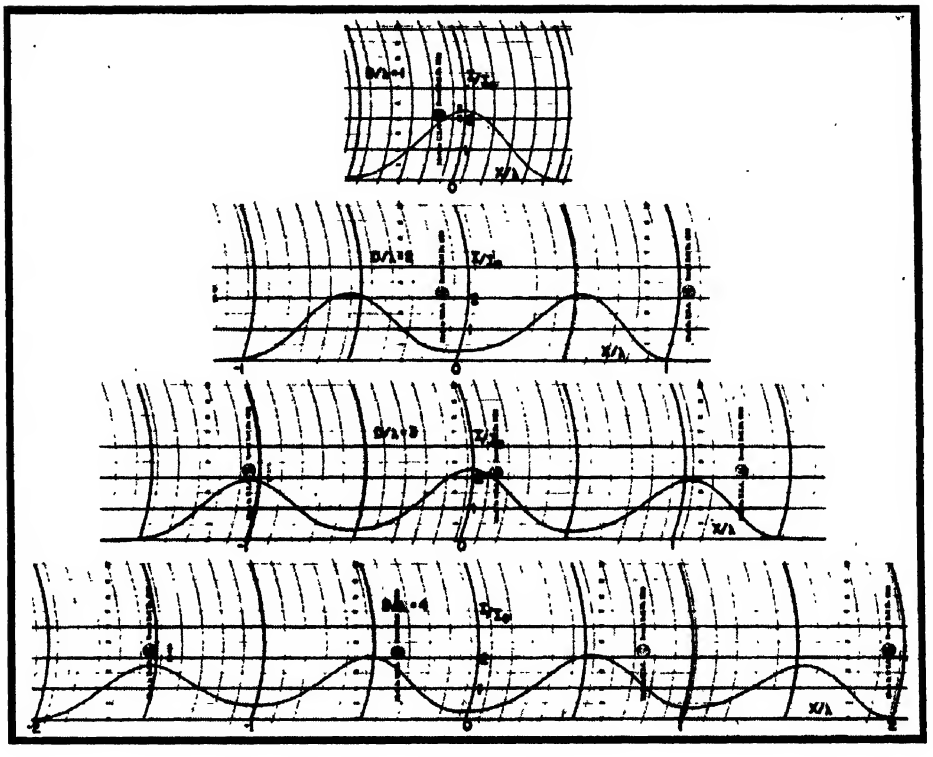

FIG. 3. Recorded graphs of intensity of radiation along magnetic diameters of circular apertures 1, 2, 3, and 4 wave-lengths in diameter.

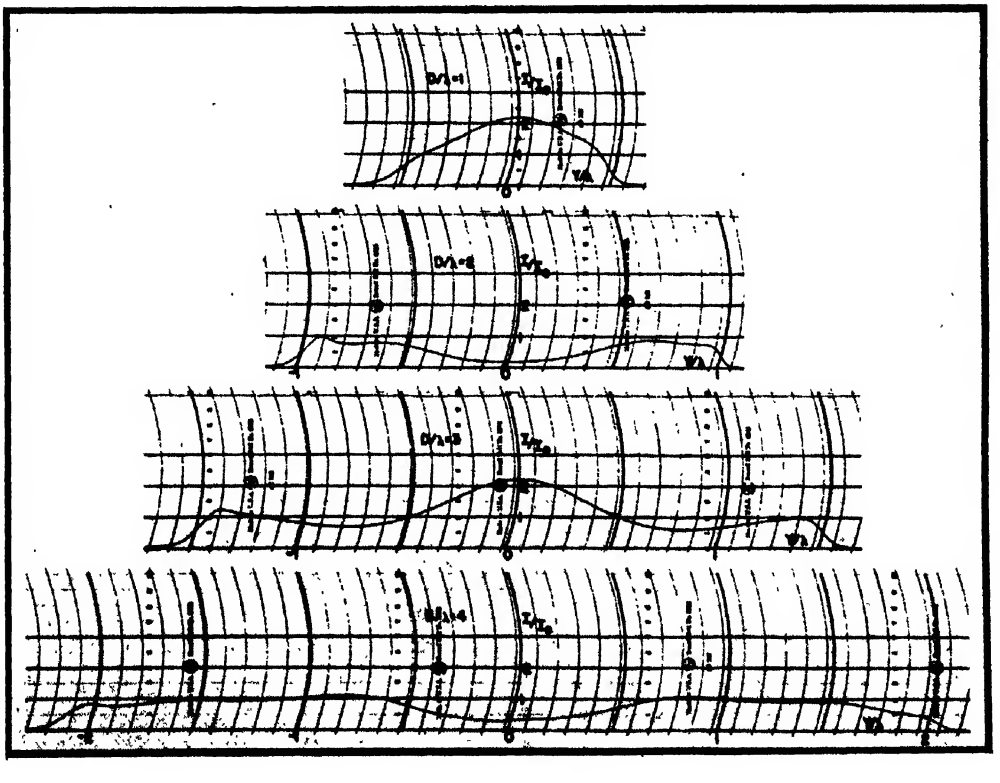

FIG. 4. Recorded graphs of intensity of radiation along electric diameters of circular apertures 1, 2, 3, and 4 wave-lengths in diameter.

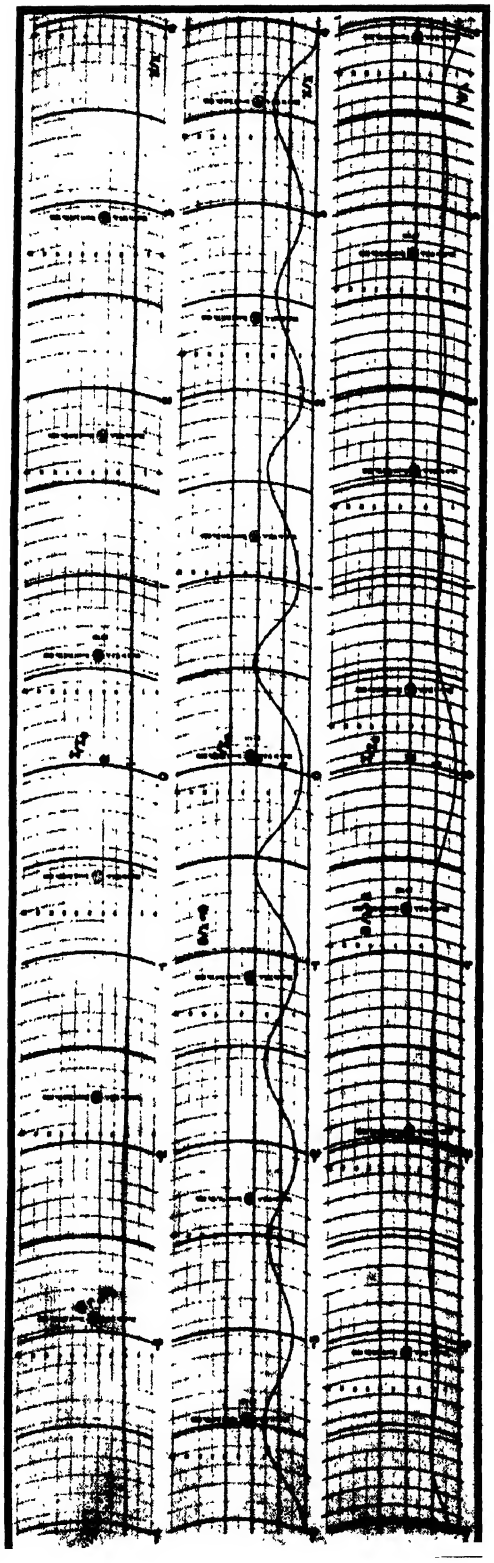

FIG. 5. Intensity of radiation of the unperturbed beam and along magnetic and electric diameters of circular apertures eight wave-lengths in diameter.

disturb the field. A fine twisted lead of No. 23 wire was attached with soft solder to the ends of the capsule of the sealed silicon crystal and extended in the direction of propagation for three meters and guyed by strings and rubber bands. Thence it extended out of the beam perpendicularly to the electric field.

The errors caused by the finite size of the antenna were estimated in two ways:

(1) By comparing records of the same diffraction patterns as the length of the probe was reduced.

(2) By studying the diffraction patterns of rods varying from 0.5 to 0.1 wave-length.

When the antenna was reduced from 0.25 to 0.20 wave-length, the patterns were not altered noticeably except when the probe was closer than a quarter wave-length to the edge of an aperture. Likewise, it was noted that rods of 0.2 wave-length long had negligible effects on the field at distances greater than one-quarter wave-length.

It was estimated that the greatest source of error in all patterns shown in the following graphs was the variation of intensity in the cross section of the unperturbed beam except at points within an eighth wave-length of an edge on the H diameter or a quarter wave-length of an edge on the E diameter where the largest error was caused by the finite size of the probe.

EXPERIMENTAL RESULTS

In Fig. 2 the circles indicate experimental data of intensity of radiation I relative to the intensity I_0 of the unperturbed beams taken along the axes of circular apertures in metal screens 1, 2, 3, and 4 wave-lengths in diameter. f/λ is the distance in wave-lengths along the axis measured from the plane of the aperture in the direction of propagation. The crosses are experimental data taken from the results of Severin[5] for wave-lengths of 6 and 10 cm. Severin coated the front and back of his metal screen with a "paint" that reduced reflections to 10 percent of the metallic reflection. Near the aperture data are the same for the reflecting and absorbing screen. The curves of Fig. 2 are plots of the calculations from Kirchoff's theory.[6] Note that the best agreement with experiment is at the center of the aperture. If the assumptions of Kirchoff's theory were not conflicting and if the solution were correct then the solution should yield the original assumption of an unperturbed beam in the plane of the aperture. Therefore, we shall ignore the origins of Kirchoff's expression and consider it as a semi-empirical formula. The disagreement with experimental data on the side toward the source may be expected because of reflection from the mirror surface on the back side of the screen.

Note that when the aperture is an odd number of wave-lengths in diameter I/I_0 at the center is 2.25. When the diameter is an even number of wave-lengths, I/I_0 is 0.25.

[6] See reference 1, Eq. (4) and Fig. 1.

Figure 3 is of recorded graphs of the intensity along the magnetic diameters of circular apertures 1, 2, 3, and 4 wave-lengths in diameter when a plane polarized beam is incident normally on the screen.

Figure 4 is a similar record of intensities along the electric diameters. Note that the measurements along the electric diameters are not dependable closer than a quarter wave-length from the edge. It may be noted that whatever the length of the dipole probe the recorded intensity begins to drop as soon as one end of the dipole probe goes behind the screen and drops to zero when the probe is completely hidden from the source.

Figure 5 is a recording of the intensity of the unperturbed beam and the intensities along the magnetic and electric diameters of an aperture eight wave-lengths in diameter.

A search for a meaningful empirical expression to describe the patterns resulted in

$$(u/u_0)_v = 1 - \frac{1}{2\pi} \oint \epsilon^{i\beta} \cos\theta \cos\gamma (ds/r), \qquad (1)$$

$$(u/u_0)_h = -\frac{1}{2\pi} \oint \epsilon^{i\beta} \cos\theta \sin\gamma (ds/r), \qquad (2)$$

u is the complex amplitude of the resulting wave at point P of Fig. 6 in terms of u_0, the amplitude of the incident wave. The subscripts v and h indicate vertical and horizontal components. The term unity is for the vertically polarized incident beam. The negative sign indicates the reversal of phase of the reradiated wavelet from the edge. ds is an element of edge and r its distance from point P. β is the phase angle, $2\pi r/\lambda$. Multiplication by $\cos\theta$ resolves the component of the amplitude of the incident wave parallel to the element of edge ds. $\cos\gamma$ and $\sin\gamma$ resolve the amplitude of the wavelet from ds arriving at P into vertical and horizontal components. Since the expression contains ideas clearly expressed by Thomas Young, we shall call it Young's Circuital Form for determining the diffraction pattern in the plane of an aperture in a flat screen when a plane polarized transverse wave is incident normally on the plane of the aperture.

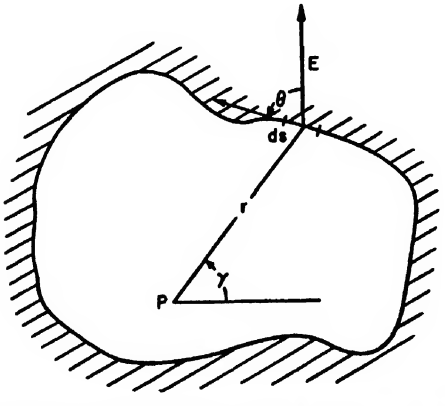

FIG. 6. Aperture in screen upon which a vertically polarized beam is incident normally.

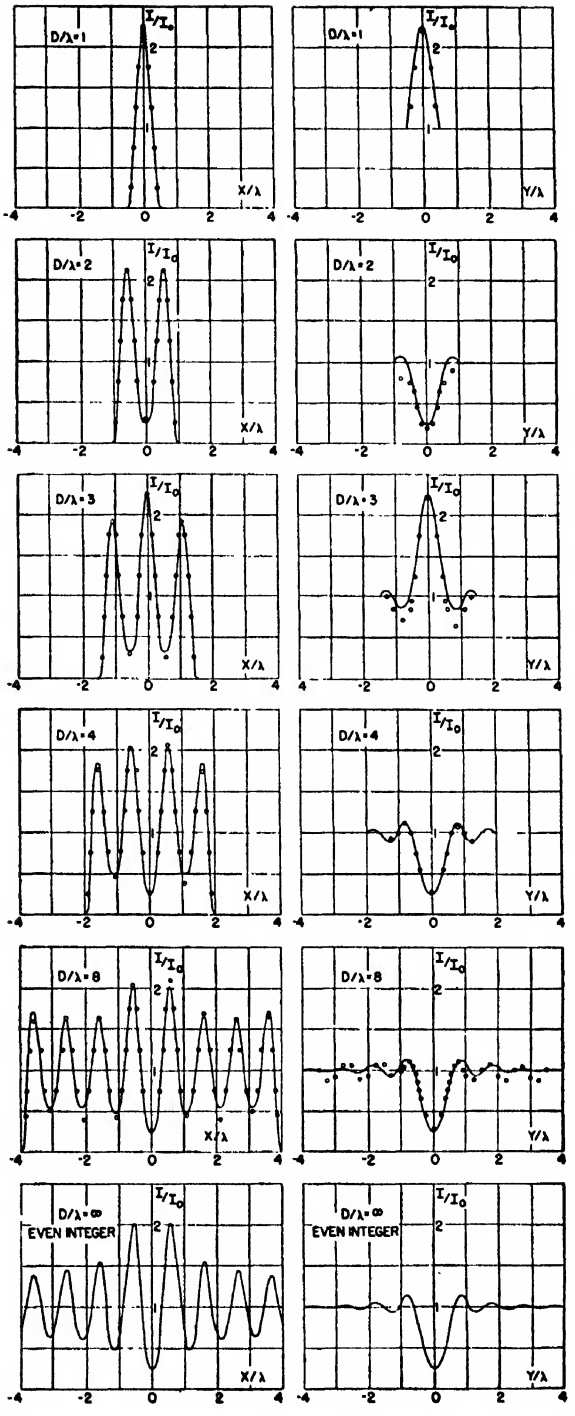

FIG. 7. Computed intensities of radiation along magnetic and electric diameters of circular apertures 1, 2, 3, 4, 8 and an infinite even integer number of wave-lengths in diameter. The circles indicate experimental data from Figs. 3, 4, and 5.

If the aperture is a circle of radius R and x and y are

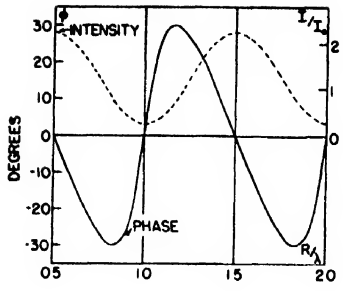

FIG. 8. Phase and intensity of radiation at center of circular aperture *versus* diameter.

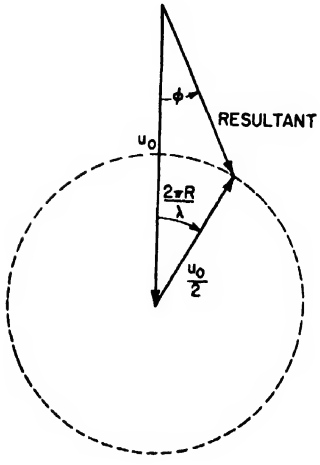

FIG. 9. Vector diagram for determination of phase and amplitude at center of circular aperture one wave-length in diameter or greater.

the cartesian coordinates taken along the horizontal and vertical diameters from the center to express the position P, then

$$(u/u_0)_v = 1 - \frac{1}{2\pi} \oint \epsilon^{i\beta} (R/r)^2 (\cos^2\theta - (x/R)\cos\theta) d\theta, \quad (3)$$

$$(u/u_0)_h = -\frac{1}{2\pi} \oint \epsilon^{i\beta} (R/r)^2 \times (\sin\theta\cos\theta - (y/R)\cos\theta) d\theta. \quad (4)$$

All of the independent variables may be expressed in terms of any one of them. We were not able to integrate the expressions but evaluated the integrals for points along the magnetic and electric axes by dividing the circle into ten degree steps and adding vectorially. Some cases were checked by dividing the aperture into two degree steps.

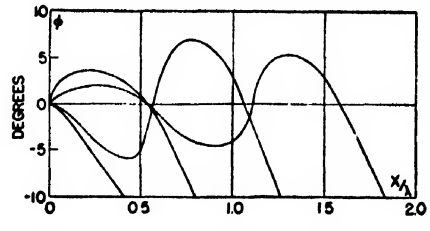

FIG. 10. Phases along the magnetic diameter of apertures 1, 2, 3, and 4 wave-lengths in diameter.

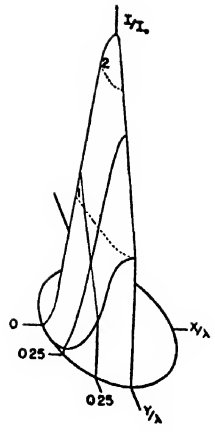

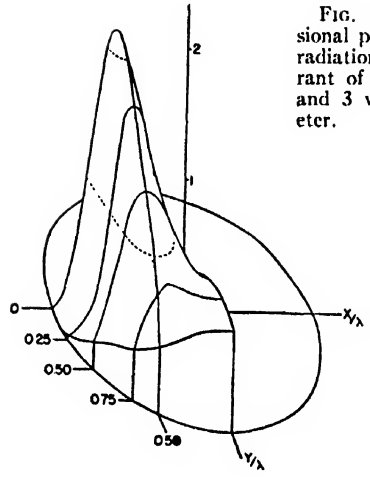

FIG. 11. Three dimensional plots of intensity of radiation over one quadrant of apertures of 1, 2, and 3 wave-lengths diameter.

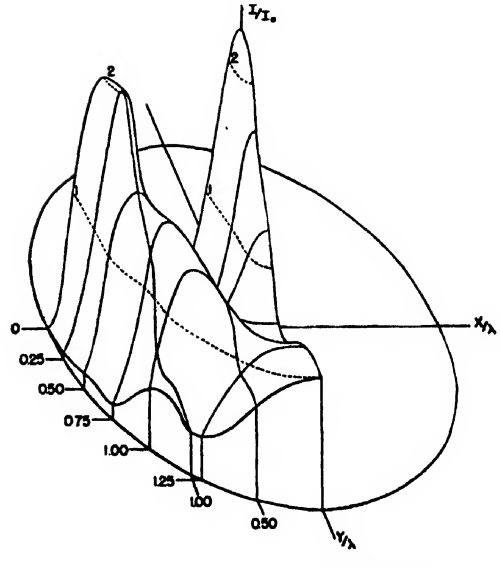

The two columns of curves in Fig. 7 are of the computed intensities of radiation along magnetic and electric diameters of circular apertures 1, 2, 3, 4, 8 and an infinite even integer number of wave-lengths in diameter. The circles indicate experimental data from the curves of Figs. 3, 4, and 5.

Two features other than the general agreement of the data and calculations are to be noted. For both the experimental and calculated curves (1) the peaks are narrower than the valleys (2) the maxima and minima do not lie at exactly integer half wave-lengths from the center but slightly beyond those positions.

At the center of the circular aperture the phase ϕ alternates with increasing radius between 30° and −30° by a saw-toothed relation indicated by Fig. 8. A plot of I/I_0 *versus* R/λ is given with coordinates on the right to indicate that, when the intensity differs most from that of the incident beam, the phase is the same as that of the incident beam.

At the center

$$I/I_0 = 5/4 - \cos 2\pi R/\lambda, \tag{5}$$

$$\tan\phi = \frac{\frac{1}{2}\sin 2\pi R/\lambda}{1-\frac{1}{2}\cos 2\pi R/\lambda}. \tag{6}$$

Equations (5) and (6) are seen to follow from the vector diagram of Fig. 9.

Equations (5) and (6) are a special case of Kirchoff's expression[6] for the amplitude and phase on the axis provided $R/\lambda > \frac{1}{2}$. For smaller radii the point of observation may be chosen on the axis near the center on the side of the screen away from the source. Small apertures have not been treated experimentally. They will require a smaller probe than the cases reported here.

Figure 10 is a plot of phases along the *II* diameter for diameters of 1, 2, 3, and 4 wave-lengths. The calculations of these angles may be in error by as much as 0.5 degree. The phase angles are small and where the intensity is a maximum the phase is the same as that of the incident beam. The largest phase angles occur where the intensity is approaching zero at the edge. Thus with good approximation one may assume constant phase over the aperture when applying Huygens' principle to calculate the diffraction pattern beyond the aperture. Smythe's[7] method of the double current sheet will be readily applicable. However, the approximation of constant phase is justified only when the diameter of the aperture is an integer number of wave-lengths.

If, for apertures an integer number of wave-lengths wide, one considers the positions of maximum intensity, Fig. 8, as line sources, then the Fraunhaufer diffraction pattern is easily calculated vectorially and is the same as that calculated by zone or strip methods from the assumption of constant phase and intensity over the aperture.

Figure 11 is of three-dimensional plots of intensity over one quadrant of apertures of one, two and three wave-lengths in diameter from experimental data.

CONCLUSION

In view of these experimental observations the classical treatment of diffraction is in need of review. Although there have been many volumes of theory written on diffraction, there have been comparatively few experimental results reported in sixty years. Microwaves now provide a precise means of measurement of diffraction patterns near apertures.

Young's theory of diffraction yields the diffraction pattern in the plane of a circular aperture.

The Retrograde Motion of the Arc Cathode Spot

C. J. GALLAGHER
General Electric Research Laboratory, Schenectady, New York
(Received February 6, 1950)

The motion of the cathode spot in a direction opposite to that predicted by Ampère's law depends on the arc current, gas pressure, kind of gas, and magnetic field strength. Studies of the effects of these variables have been made, including measurements of velocity and the critical pressure at which reversal of motion occurs. The phenomena observed have not been clearly explained by any of the pictures presented to date. The existence of the retrograde motion indicates very strongly that the positive-ion space charge outside the cathode is all important in determining the mechanism of current transfer.

IN the low pressure arc the cathode spot, when subjected to a transverse magnetic field, may move in a direction opposite to that which Ampère's law predicts.[1,2] The direction and speed of this retrograde motion are determined by: (1) gas pressure, (2) magnetic field strength, (3) arc current, and (4) kind of gas. It is not certain at this writing whether or not the cathode material has any appreciable effect. This paper will describe some experiments in which the above variables were investigated as to their effect on the motion.

The first series of experiments is concerned with a low pressure mercury arc, using a mercury pool cathode. The geometry of the tubes used was such that the cathode was ring-shaped. The tube was placed in the gap of an electromagnet with an annular structure as shown in Fig. 1. The magnetic field was radial, so that the current entering the cathode spot was always perpendicular to the field. Both tube and magnet were immersed in oil, which was cooled by circulating through a heat exchanger to provide a steady stream of oil cooler than the bath itself. This stream was directed against the wall of the tube and thus determined the condensing temperature of the mercury inside. The condensing temperature could be considered the same as that of the stream, except for the small thermal drop in the glass wall of the tube. The tube was operated at a line voltage of 250 v d.c. with a variable series resistance to regulate the current.

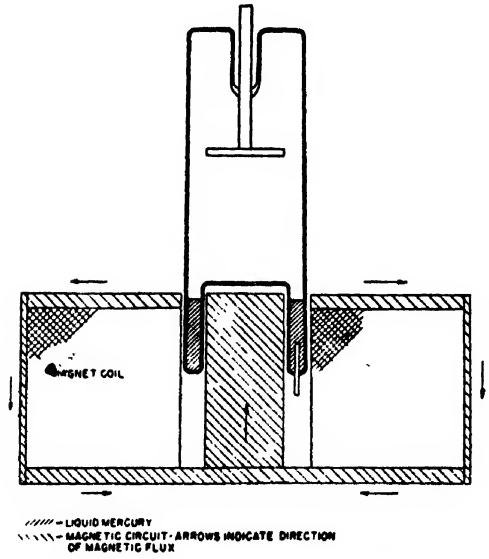

FIG. 1. Mercury pool tube in radial magnetic field.

The velocity of the spot was obtained from the frequency of rotation. The light from the region of the spot was transmitted through the oil by a glass rod and then allowed to fall on a photo-multiplier tube, the output of which was applied to the vertical plates of an oscilloscope. A sine wave of known frequency was applied to the horizontal plates and varied until a one to one Lissajou pattern was obtained. The method was not effective below about 20 c.p.s. because of random fluctuations in the position of the path of the spot over the mercury surface. At high speeds, the spot stayed against the wall of the tube so that very regular patterns could be obtained.

The velocity of the spot as a function of magnetic field, arc current, and pressure is shown in Figs. 2, 3, and 4, respectively. As shown in Fig. 2, the velocity varies almost linearly with magnetic field over the middle range, with an exponential-like variation at low fields. The slopes of the linear portions of the curves appear to be independent of current. At high fields, above 3000 gauss, the results are somewhat uncertain. It was found that the points could not be reproduced with any great accuracy. The voltage across the arc at high magnetic fields is high and may cause instability, although the arc voltage did not show any unusual fluctuations in this region such as might be expected if the arc were unstable. In Fig. 3, the same data are replotted, but with arc current as the independent variable. There is a definite leveling-off point for each value of field, with the constant velocity region setting in at smaller values of current as the field is increased.

The velocity of the spot depends on the pressure, decreasing as the pressure increases. In fact, if the pressure is sufficiently increased, the spot can be made to slow down to zero velocity and then reverse its motion. The pressure at which reversal occurs depends on the magnetic field and the current, as shown in Fig. 4. The reversing pressure as a function of magnetic field is shown for different arc currents. In general, less field

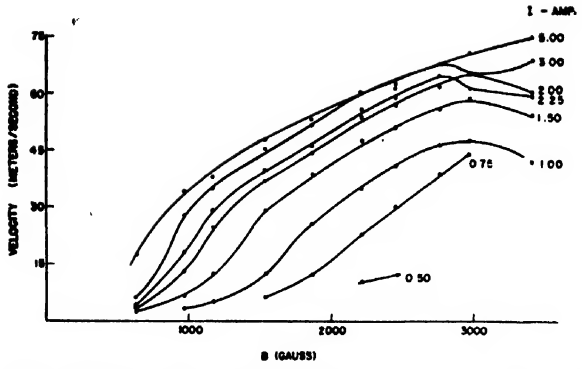

FIG. 2. Velocity of cathode spot on Hg pool *vs.* magnetic field for various arc currents. Pressure = 0.7μ.

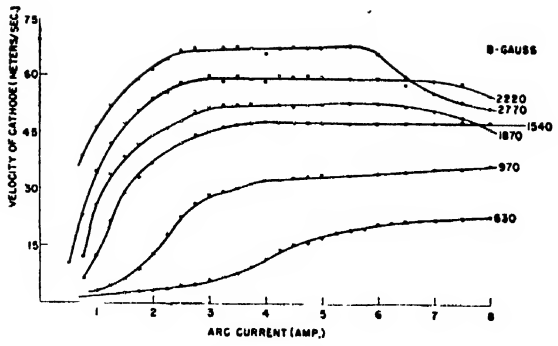

FIG. 3. Velocity of cathode spot on Hg pool *vs.* arc current for various magnetic fields. Pressure = 0.7μ.

is required to reverse the spot at high currents than at low. This suggests that the point of reversal represents a condition of balance between the forces acting on the spot and the forces acting on the column, since it has been observed that the column always tries to move in the "correct" direction.

The appearance of the rotating discharge is shown in the series of pictures in Fig. 5. These are moving pictures, taken at high speed (4000 frames per second). The arc was moving at a speed of about 75 meters per second, with a current of 3.5 amp. The column can be seen extending from the spot away from the direction of motion. The lower image is due to reflection in the magnet surface. The pictures reveal an interesting phenomenon in that occasionally there appears a large dark space between the column and the glow at the cathode. Evidence of this is beginning to appear in the second frame, with a larger gap showing in the third. The dark region has been filled with glowing gas again in the two final pictures. Examination of the complete film indicates that these gaps are randomly distributed in time with no apparent periodicity. Note that the glow of the cathode persists, regardless of the column behavior.

The phenomenon of retrograde motion and reversal was observed with many other gas and electrode combinations. Gases used included nitrogen, oxygen, hydrogen, carbon dioxide, helium, and argon, with electrodes of copper, carbon, tungsten, molybdenum, aluminum, nickel, and cadmium. There was found to be very little, if any, effect of electrode material on the reversing pressure. The principal effect of the electrode appeared to be in determining the stability of the arc. It was not possible to establish arcs at these currents between electrodes which had been carefully cleaned and outgassed. It was necessary in all cases to operate with metals which were oxidized to some extent.

The reversing pressure was sharply affected by the kind of gas used. The results obtained are shown in Fig. 6. The arc current was adjusted to 4 amp. and the magnetic field kept at a low value of about 100 gauss. There is a wide range in reversing pressures, ranging from about 1 cm for mercury to 16 cm for helium, with other gases lying in between. As Fig. 6 shows, there is some correlation between the reversing pressure and the first resonance potential of the gas. The first resonance potential may be taken as a rough measure of the voltage drop between the cathode and the column (the "cathode drop"). The first resonance potential is probably a better choice than the ionization potential because of the possibility of ionization occurring in several steps rather than a single ionizing collision. The probability of step-wise ionization is high where the current density is large. The current density at the arc cathode spot may be greater than 50,000 amp. per cm².[3]

It will be noted that mercury exhibits the lowest reversing pressures. For every other gas investigated, the reversing pressures were higher. In fact, retrograde motion can be observed at pressures as high as atmospheric, depending on the kind of gas, the current, and magnetic field strength. In argon with oxidized tungsten electrode, as shown in Fig. 7, the reversing pressure can be as high as 60 cm Hg, and as low as 5 cm Hg. It will be noted that the effect of current and magnetic field on the reversing pressure is, in general, the same as found in mercury, i.e., the reversing pressure is greater fields or smaller currents.

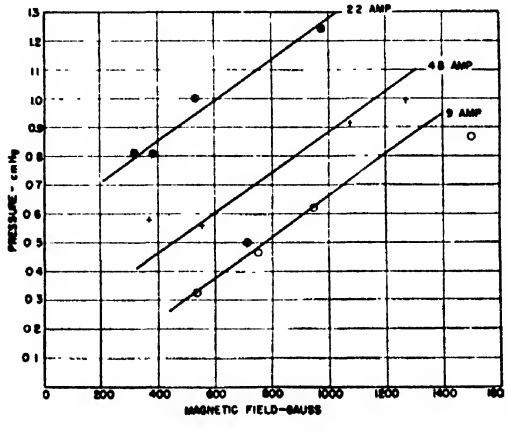

FIG. 4. Reversing pressure *vs.* magnetic field in mercury pool tube.

[3] J. D. Cobine and C. J. Gallagher, Phys. Rev. 74, 1524 (1948).

There is at present no adequate explanation for the phenomena described here. A complete theory would undoubtedly require a knowledge of the mechanism of current transfer at the arc cathode, since the action of the magnetic field must be either at the cathode surface or else at the region of high ion density immediately outside it. If one rules out the Righi-LeDuc effect, as originally proposed by Smith,[2] and other similar effects (Hall, Ettingshausen, and Nernst effects,[4] there remains only the effect of the magnetic field on electron trajectories as the primary physical phenomenon. The electrons involved are probably those emitted by the cathode. The direct effect of the magnetic field on the paths of positive ions is probably quite small, at least in comparison with the change in electron paths. However, the electron trajectories are bent in a direction opposite to the retrograde motion, so that the motion itself is a secondary effect. A simple calculation of the motion of a single electron in crossed electric and magnetic fields indicates that the particle is deflected only a small amount before colliding. This is especially true at higher pressures where the mean free path is short. Bending the electron paths would certainly shift the center of gravity of the positive ion space charge outside

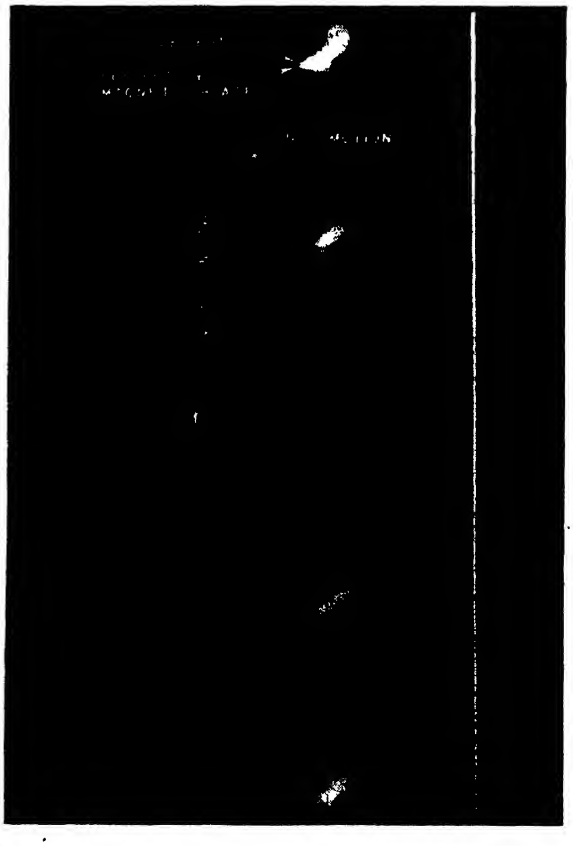

FIG. 5. High speed pictures of cathode spot moving on Hg pool (4000 frames per second).

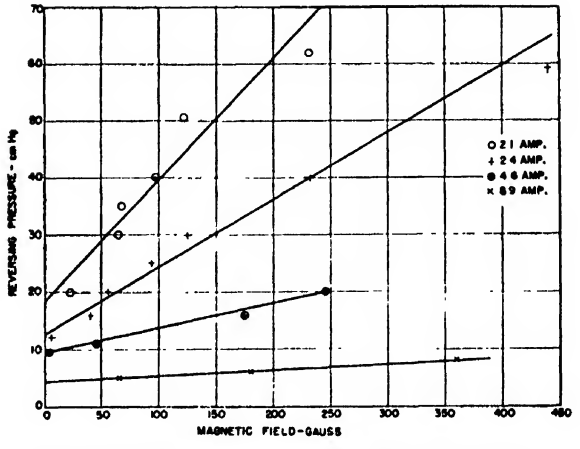

FIG. 7. Reversing pressure *vs.* magnetic field oxidized tungsten in argon.

the cathode, since these ions are probably formed by collisions with emitted electrons. Longini[5] makes a plausible case for a net space-charge shift in the retrograde direction by considering that the positive-ion space charge is shifted less than the electron space charge. It is not clear from his picture how reversal can occur, or why the direction of motion depends on the pressure, the current, or the magnetic field. Himler and Cohn[6] have offered a less plausible explanation by considering the electrons to be emitted from the cathode in all directions, with those emitted in the "correct" direction being returned to the cathode without contributing to the current. Those emitted in the retrograde direction would produce a positive-ion space charge in that direction which would produce a field sufficient to extract more electrons from the cathode. It does not seem possible that there can be any such

[5] R. L. Longini, Phys. Rev. 72, 184 (1947); 71, 642 (1947).
[6] G. J. Himler and G. I. Cohn, Elec. Eng. 67, 1148 (December, 1948).

random distribution in directions of emission, at least, not with the spread that this picture would require.

Both of the above pictures point to the position of the positive-ion space charge as the important factor in determining the position of the cathode spot which in turn means that the emission process depends on the positive ions. That this must be so seems to be borne out by two experimental observations. First, there is the fact that the velocity of the spot is of the order of the probable thermal velocity of the gas atoms (or ions). In fact, it was not possible to get velocities quite as high as thermal velocity. Unless the electric fields are very distorted, the motions of the ions parallel to the cathode will be determined by the thermal velocities. A second evidence of the importance of the position of the positive ions is the observations by Smith,[7] and also by Cobine and Gallagher,[8] that the cathode spot does not exhibit retrograde motion if the cathode is heated to a temperature high enough to support thermionic emission. In this case, the positive-ion space charge is no longer required except to accelerate electrons which have already been emitted, so that the position of the space charge is less important in determining the positions of the cathode spot. These observations are not conclusive, but they do indicate that the positive-ion space charge plays an important role in determining the motion of the spot, and, hence, in maintaining current transfer at the cathode surface.

Transonic Potential Flow of a Compressible Fluid*

W. R. Sears
Cornell University, Ithaca, New York
(Received February 20, 1950)

Even under the assumptions of irrotational, isentropic flow, which have been found generally useful for subsonic and supersonic cases, the equations of gas flow are relatively intractable for mixed, transonic situations. Approximate methods of solution used by a number of investigators are reviewed briefly, as well as the hodograph technique, which yields exact solutions of the equations for plane flow. It is pointed out that all the methods predict smooth, potential mixed flows involving imbedded regions of supersonic speed and both acceleration and deceleration through the speed of sound. There is no experimental verification of the existence of such flows.

Three possible explanations for this sharp discrepancy between experiment and perfect-fluid theory have been advanced; namely, (a) effects of viscosity, (b) non-existence of neighboring solutions, and (c) temporal instability. These are reviewed in turn. None has led to a complete explanation, to date. Kuo's stability calculations are described briefly. His results indicate that stable, smooth, mixed flows may exist if certain conditions are satisfied.

1. METHODS OF CALCULATING TRANSONIC POTENTIAL FLOW

MUCH of our progress in the theory of compressible fluid flows is based on the compatible assumptions of irrotational flow and isentropic changes of state. These approximations are justifiable, in many situations, because a gas of small viscosity in purely subsonic flow, or in flow involving only straight or weak shocks, does flow nearly isentropically and irrotationally. Thus, for many subsonic and supersonic flows, the results of potential-flow theories are in good agreement with experimental observations. We are concerned here with the validity of those assumptions in cases of transonic flow.

Even for steady plane flows that are inviscid, isentropic, and irrotational the differential equations that describe the flow patterns are non-linear, and therefore do not yield, directly, to standard and general mathematical methods of solution. To be sure, these equations can be made linear, by the simple approximation of neglecting the non-linear terms, and are still useful to describe situations occurring at low speeds and again at moderately high speeds, but not near the speed of sound. When the gas takes on speeds close to the sonic speed, relative to a solid obstacle or the walls of a channel, the same essential non-linearity appears in the equation of continuity that is so clearly demonstrated at the throat of a Laval nozzle. The familiar "linearized theory" then fails.

The engineer has not been completely unable to cope with this difficulty. Recognizing the essential non-linearity and the formidable mathematical difficulty of his problem, he has, with some success, taken recourse to such dependable methods as purely numerical computation and series expansion.

G. I. Taylor,[1] for example, in 1930 assumed the velocity potential to be expanded in a double power series in the Cartesian coordinates x and y,

$$\phi = a_1x + a_2x^2 + c_2y^2 + a_3x^3 + c_3xy^2 + a_4x^4 + c_4x^2y^2 + e_4y^4 + \cdots. \quad (1)$$

* An invited paper delivered at the meeting of the American Physical Society at Columbia University, February 4, 1950.

[1] G. I. Taylor, "The flow of air at high speeds past curved surfaces," Aero. Res. Comm. Reports and Memo. No. 1381, London (1930).

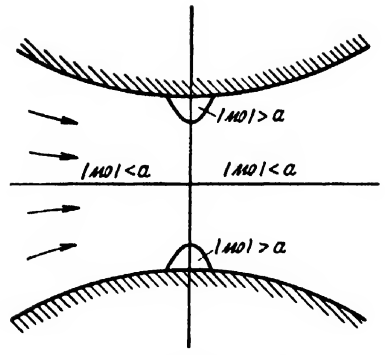

FIG. 1. Transonic potential flow through nozzle, according to calculation of Taylor (see reference 1).

He then proceeded to calculate numerical solutions to the non-linear equations, for the case of plane flow through a symmetrical nozzle. This procedure led to solutions involving both subsonic and supersonic speeds, which will be described later.

Using an entirely different approach, following Prandtl and Ackeret, a number of writers have imagined the velocity potential (or the stream function) to be expanded in powers of a thickness parameter τ, for a family of flow patterns produced around a family of slender cylindrical objects:

$$\phi = U\{x + \tau\phi_1 + \tau^2\phi_2 + \cdots\}. \qquad (2)$$

For example, the parameter τ might be the thickness ratio, for a family of symmetrical airfoils, or the camber, for a family of circular-arc profiles. This results in an iteration procedure by which the successive coefficients of τ^n are calculated from the knowledge of the preceding ones, and in fact the first approximation is precisely the result of the "linearized," or Prandtl-Glauert theory mentioned above. Although the convergence of this process has never been established theoretically, the numerical work appears to converge very satisfactorily, at least at low Mach numbers, and there is no apparent difficulty in producing flows of the transonic type; that is, having both supersonic and subsonic local speeds. The most important work along this line was done by Carl Kaplan[2] in America and by H. Görtler[3] in Germany.

Howard Emmons,[4] in 1946, undertook to attack the problem purely numerically. Approximating to the differential equations of plane motion by differences, he applied the relaxation technique successfully, making the switch from subsonic to supersonic conditions when necessary, and finally, if necessary, introducing shock waves.

More recently, Theodore von Kármán,[5] and, independently, G. Guderley,[6] discovered that a perturbation theory of a different sort, again for slender bodies, could be made for the transonic regime. In this theory it is assumed that every velocity represents a small perturbation of a uniform parallel stream at sonic speed a^*. The resulting equation for the perturbation velocity

potential $\phi(x, y)$ is

$$\frac{\partial^2\phi}{\partial y^2}=\frac{\gamma+1}{a^*}\frac{\partial\phi}{\partial x}\frac{\partial^2\phi}{\partial x^2}, \tag{3}$$

where γ denotes the isentropic exponent. This is typically non-linear and exhibits the characteristic change-over from elliptic to hyperbolic type at the speed of sound. The discovery that underlies this theory is that, for a slender body of thickness ratio τ, the partial derivatives have the following relative orders of magnitude:

$$\left.\begin{aligned}&\partial(\ )/\partial x=O(1),\quad \partial(\ )/\partial y=O(\tau^{\frac{1}{3}}),\\ \text{while}\qquad &\phi=O(\tau^{\frac{2}{3}}).\end{aligned}\right\} \tag{4}$$

Moreover, both von Kármán and Guderley pointed out the similarity rule that is implied by these results, and which gives the engineer badly needed assistance in filling in the gap in his knowledge around the speed of sound. At the same time, Eq. (3) gives the theoretician a relatively simple equation with which to study the essential features of transonic flow. Certainly its potentialities have hardly been exploited to date.

Finally, there is one more device for the study of these inherently non-linear flow equations, at least in two-dimensional cases; and that is to transform them to the hodograph plane, i.e., to introduce a change of variables by which the flow velocity components u and v, say, become the independent variables, rather than x and y. The equations then become linear, which is not completely surprising because the essential non-linearity arose from the fact of the density's being a function of the speed, $(u^2+v^2)^{\frac{1}{2}}$. This method of linearization was discovered by Molenbroek[7] in 1890, and was applied to this problem in 1904 by the Russian, Chaplygin,[8] working on the theory of gas jets. It permits the construction of solutions by superposition of elementary solutions—in this case certain hypergeometric functions. The essential difficulty, unfortunately, then resides in the question of satisfying boundary conditions. Naturally, one does not in most cases have any way to satisfy the conditions for flow around a given solid contour in terms of boundary conditions established in the hodograph plane.

Nevertheless, the method has the unique advantage of supplying exact solutions of the equations of steady plane potential flow of a perfect gas. Thus its importance

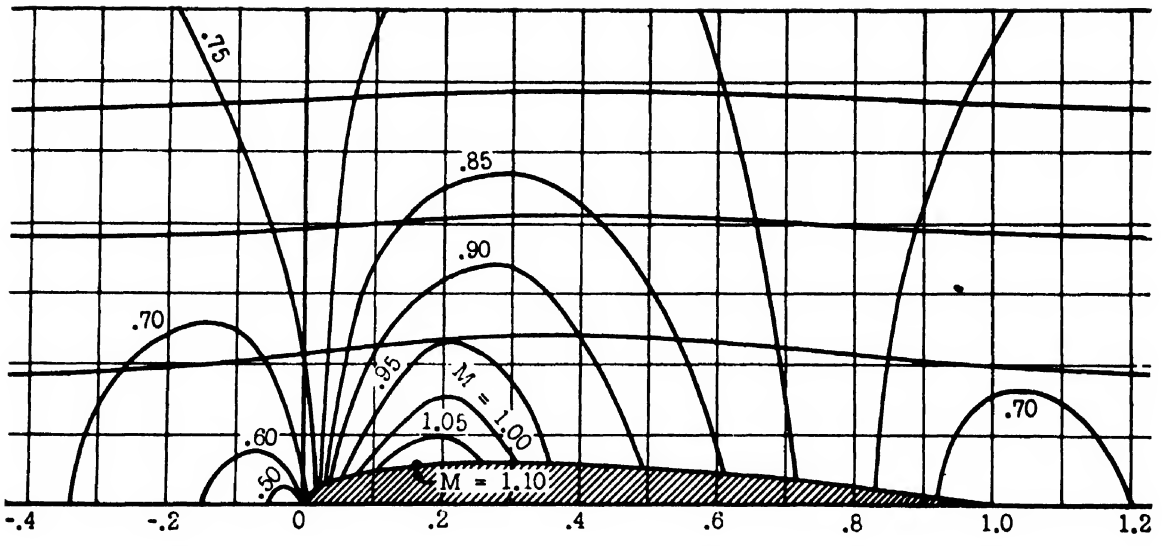

FIG. 4. Transonic potential flow over an airfoil, according to calculations of Emmons (see reference 4). Streamlines and lines of constant Mach number.

in research, and as a test for approximate methods, is great. Being practically unable to satisfy the boundary conditions of given shapes, one naturally tries the next best thing, which is to find a likely solution, either by trial or by relating it to incompressible flow in the proper limiting case, and then to see what sort of physical situation it gives. There are a number of different mathematical techniques for carrying out this sort of calculation, and unfortunately they all seem to be pretty complicated. The hodograph transformation is practically always multiple-sheeted with branch points that cause great difficulties in series expansions. Consequently, in many of these investigations the physics seems to be buried under tremendous amounts of analysis, and there is also an apparently endless controversy, disconcerting to the outsider, among various students of the subject, who fail to find much of value in each other's methods.

2. THEORETICAL MIXED FLOWS

Nevertheless, the hodograph method, in common with all the other, approximate, methods that have been applied to the transonic flow problem, has yielded one result of startling significance to the aeronautical engineer. It produces isentropic, potential flows that involve local acceleration through the velocity of sound, an imbedded region of supersonic flow near a body, and deceleration back to subsonic speeds. This is intriguing because it contrasts so radically with the situation commonly observed in nature—where the transition from supersonic to subsonic flow is accomplished by means of a violent, non-isentropic process, namely, a shock wave.

Apparently the first example of this theoretical phenomenon was provided by Taylor,[1] who found it in a symmetrical nozzle, using the series expansion mentioned above. One of his results is reproduced in Fig. 1. Analogous results were obtained by Görtler[3] (Fig. 2) and Kaplan[2] (Fig. 3), both using the method of expansion in powers of the thickness, and by Emmons[4] in his purely numerical solutions (Fig. 4).

The first exact solution of this type was found by Ringleb,[9] by means of the hodograph transformation. Ringleb started with a very simple solution of the hodograph equations, being, in fact an almost obvious generalization of the incompressible case of flow around a 180° corner. His result is reproduced in Fig. 5. It is not only of interest as the first exact mixed solution, but it presents two other surprising features. The first of these is the great magnitude of the supersonic Mach numbers attained in the flow (about 2.5), and the second is the appearance of singularities, called "limit lines" which seem to invalidate the solution when too great wall curvature is attempted. In other words, any two streamlines such as (a) and (b) in Fig. 5 might form the walls of a channel, and according to the theory, this channel would permit isentropic acceleration to, and deceleration from, supersonic speeds. But streamlines between (c) and (d) cannot be traced beyond the limit line; according to the transformation, in fact, they double back on themselves there and cross other streamlines—in other words, they go over onto a different Riemann sheet.

When Ringleb's paper first appeared, in 1940, there was considerable speculation about the physical meaning of the limit line, and there was a natural tendency to identify them with shock waves. More recently, however, aerodynamicists have taken a more cautious

[9] F. Ringleb, "Exakte Lösungen der Differentialgleichungen einer adiabatischen Gasströmung," Zeits. f. angew. Mat. Mech. 20, 185–198 (1940). Abstract in J. Roy. Aero. Soc. 46, 403–404 (1942).

position on this question—although it remains controversial. In Ringleb's case, for example, the appearance of the limit line at streamline (c) is accompanied by infinite curvature of that streamline. There is considerable doubt as to whether it could ever appear, anywhere in the flow, in the case of flow over a smooth solid body of fixed shape. This question has been studied by Tollmien,[10] Schaefer,[11] Nikolskii and Taganov,[12] and Friedrichs,[13] not all of whom have arrived at the same conclusions. However, it is not the principal concern of this paper, and we shall leave it at this point.

The resemblance of Ringleb's flow pattern to the flow over the top of an airfoil at high subsonic speed inspired Tsien and Kuo[14] to attack problems of this type with the hodograph method; i.e., flow of a parallel, subsonic stream past a cylindrical obstacle. One of their results is shown in Fig. 6. Here we have a symmetrical, nearly elliptic cylinder, in plane potential flow, and the Mach numbers in its imbedded supersonic zone reach a maximum value of 1.24.

It should be clear at this point that perfect-fluid theories, both exact and approximate, predict smooth potential mixed flows, in channels and past obstacles, that involve both acceleration and deceleration through the speed of sound. It is obviously of great practical and scientific importance to explore thoroughly the prospects of achieving this type of flow experimentally. The Tsien-Kuo cylinder clearly produces no drag, in the absence of skin friction, while the shock wave, if one occurred at a Mach number near 1.24, would be of strength sufficient to involve considerable drag, and moreover would probably cause boundary-layer separation and all of the undesirable consequences thereof. There would be great merit in learning how to reproduce this smooth mixed flow in nature.

The absence, to date, of any convincing experimental confirmation of this type of flow, however, is impressive. Invariably, when the local supersonic speeds of a transonic situation are great enough to make the determination reliable, we find that the supersonic region terminates in a shock wave, or in a series of shock waves, rather than in a smooth deceleration through the speed of sound.

3. POSSIBLE EXPLANATIONS

What is the reason for this glaring discrepancy between theory and experiment? Three different plausible explanations have been suggested: (a) that the theory is in error by the neglection of viscosity; (b) that the potential flows exist for only special shapes and flow speeds and do not have neighboring solutions. Hence they cannot be actually produced in experiments; (c) that the potential flows are unstable to small disturbances in the airstream.

In support of the first of these, Professor Liepmann has pointed out[15] that the smooth deceleration can be thought of as the result of effects carried rearward by the family of Mach waves originating farther forward, as sketched in Fig. 7(a), and that a distortion of the contour, as might be caused by a boundary layer, would suffice to cause an envelope of waves, as in Fig. 7(b). Such a discontinuity, of course, marks the breakdown of potential flow, and the pattern must be replaced by one involving a shock. But this would imply that a slightly different body, producing the Mach waves of Fig. 7(a) outside of its boundary layer, would permit smooth

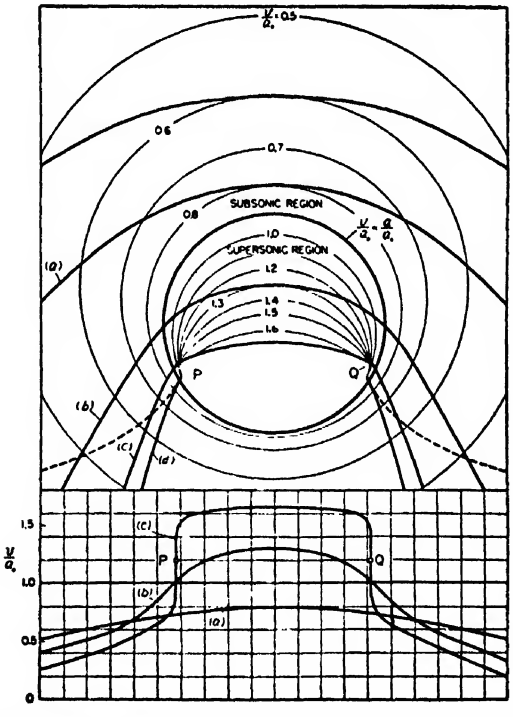

FIG. 5. Transonic flow around an obstacle, according to calculations of Ringleb (see reference 9). Top: streamlines and lines of constant speed. Bottom: velocity distributions along three streamlines.

potential flow. This proposal hardly seems adequate to explain the complete absence of flows of this type in experiments.

Moreover, if Liepmann's explanation is correct, it should be possible to achieve shockless mixed flows experimentally with the aid of boundary-layer removal. It seems important to decide whether or not the inviscid potential flow itself has any peculiarities that would make it impossible.

The second proposal, that the flows are very special ones, with no neighboring flows, is supported by Guderley and Busemann. Their physical argument is illustrated by Fig. 8, which is taken from Busemann's recent paper.[16] Suppose there exists a smooth mixed flow, and that a slight change is made in the body contour as shown. Since the local flow is supersonic, the effects of this alteration, in the new steady-flow pattern, will be confined to an "alley" leading to the sonic curve, from which point it is reflected back to the body, and so forth, as sketched. But according to this process it finally affects the nearly-sonic flow toward the rear, and we know that the pressure, density, and speed increments will be magnified in such a region. Thus a small change of the boundary shape must produce a large change in the flow pattern; i.e., there is no neighboring solution. Substantially the same argument has been put forth by Frankl.[17]

All this is quite analogous to the case of decelerating channel flow. It is easy to draw up a channel for smooth deceleration of supersonic flow, through sonic, to subsonic; in fact, the channel is simply a Laval nozzle in reverse (Fig. 9). But the flow is unreal, because there is

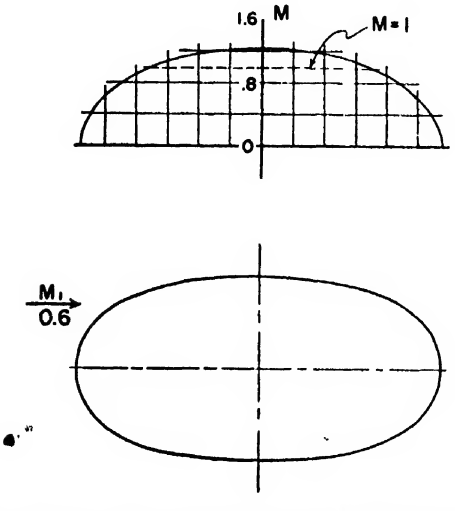

FIG. 6. Mach number distribution along a cylinder in transonic potential flow at a stream Mach number of 0.6, according to calculations of Tsien and Kuo (see reference 14).

[16] A. Busemann, "The drag problem at high subsonic speeds," J. Ae. Sci. 16, 337–344 (1949).

no neighboring solution. A slight change of the contour at A produces violent effects at B. The real flow is the one involving a shock wave.

Thus, Busemann's is certainly a very plausible explanation. It would be indisputable if the perturbation at the sonic curve did not actually affect the whole flow pattern through the subsonic flow, but of course it does. To carry along the channel analogy, the trouble at B (Fig. 9) can be avoided by a small alteration at C or C', or by an alteration upstream, as at D or D', which would cancel the effect at A. Busemann argues that in the case of flow past a body it is unlikely that the effect on the subsonic flow will be just what is required to neutralize the disturbance and prevent the large changes toward the rear. Perhaps it does seem unlikely, but what is unlikely is often true.

Guderley[6] has attempted to give a mathematical theory of this effect, showing that there are eigensolutions that would invariably be brought in by any alteration of the contour, and whose coefficients increase without limit as the sonic line is approached. Unfortunately, Guderley's calculation becomes so complicated, requiring further approximations and assumptions as it progresses, that its conclusions are not convincing. For example, these solutions have infinite amplitudes at both the upstream and downstream sonic points, and since we postulate smooth flow upstream, it is not clear why they should not all be rejected, removing the trouble at the downstream end as well. I suspect that the singularities are not real ones, but have arisen from Guderley's method of approximation, and the form of his results seems to confirm this.

There is also the problem of reconciling the Guderley-Busemann-Frankl theory with the Taylor, Emmons, and Kaplan cases mentioned above. None of these were calculated for a peculiar or special body shape or for any unique combination of body shape and Mach number. It seems preposterous to think that they are some kind of singular solutions, without neighbors. But these are all approximate solutions, and how much can one conclude about existence and uniqueness from investigations of this sort? Again it seems "unlikely" that these calculations would not show some trouble if they were being forced to fit contours not specially suited for this type of flow. For example, one might have thought that Emmons' numerical work would diverge. This point is not conclusive, however, for the effects may be small at the Mach numbers handled, and may not have been noticed. Moreover, returning to our channel analogy, we must admit that there an approximate method (one-dimensional gas dynamics) fails entirely to predict the non-existence of the flow of Fig. 9.

4. THE STABILITY OF MIXED FLOWS

In this situation, my colleague, Professor Kuo,[18] has undertaken to investigate the stability of mixed po-

[18] Y. H. Kuo, "On the stability of two-dimensional smooth transonic flows," paper delivered at the Annual Meeting of the

tential flow by the standard method of tracing the histories of time-dependent small disturbances. To a considerable extent his method follows that of Kantrowitz,[19] who carried out an approximate, but highly illuminating investigation of the stability of decelerating channel flow. Kantrowitz considered a channel flow going from supersonic to subsonic and calculated the behaviors of expansion and compression disturbances coming from downstream. He pointed out that the compression part of either a compression or expansion pulse steepens to form a weak shock (as Riemann showed for a uniform field) and the pulse assumes a characteristic triangular shape. Furthermore, he showed that the expansion pulses are unable to penetrate the supersonic region, and, in fact, are "consumed" by their own shock waves. Compression pulses, on the other hand, which have shock waves at their heads, move into the supersonic flow and pile up there, so that the flow finally undergoes violent changes.

Following Kantrowitz, Kuo considers the effects of upstream-moving disturbances of the compression-pulse type, and assumes that they have undergone the Riemann steepening process and have taken on the characteristic triangular shape. Since the sonic region is most critical, and since disturbances travel slowly in this region, he assumes that the pulses take on the character typical of sonic flow; i.e., their derivatives have the relative magnitudes specified by the Kármán-Guderley transonic similarity theory and stated in Eqs. (4). This leads to an accompanying assumption about the relative size of the time derivatives; it turns out that there is only one possibility here that gives a reasonable result for the non-stationary flow.

These assumptions are sufficient to permit a solution for small disturbances superimposed on a steady potential mixed flow of a parallel stream past a cylinder, at least for the region near either sonic boundary.

Let the velocity potential of the flow be

$$\varphi'(x, y, t)=\Phi(x, y)+\phi(x, y, t), \tag{5}$$

where $\phi(x, y, t)$ denotes the potential of the small disturbance superimposed on the steady transonic flow $\Phi(x, y)$. Then, by virtue of the order-of-magnitude argument for the sonic region, the differential equation for $\phi(x, y, t)$ is reduced to the following approximate one:

$$(\gamma+1)(\Phi_x^{(1)}+\phi_x)\phi_{xx}-a^*\phi_{yy} +2\phi_{xt}+(\gamma+1)\Phi_{xx}^{(1)}\phi_x=0, \tag{6}$$

where $\Phi^{(1)}$ denotes $\Phi-a^*x$. Kuo approximates to $\Phi^{(1)}$ in linear form; i.e.,

$$\Phi^{(1)}=\alpha\xi+\beta\eta, \tag{7}$$

where α and β are constants, while ξ and η denote

FIG. 7. Sketch showing effect of boundary layer on transonic potential flow: (a) without viscosity; (b) with viscosity.

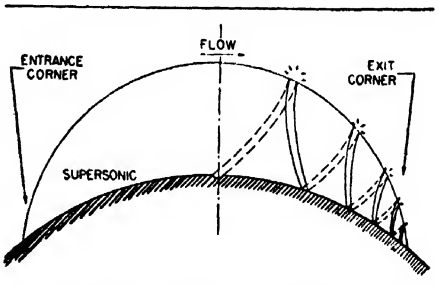

FIG. 8. Sketch showing effect on transonic potential flow of small alteration of boundary shape, according to Busemann (see reference 16).

distances measured parallel and perpendicular to the body contour from the sonic point. The boundary condition at the solid body is, similarly,

$$\phi_\eta=\phi_\xi(m+k\xi), \tag{8}$$

where m is the slope (relative to the free-stream direction) and k the curvature of the body surface at the sonic point.

Kuo finds the solution $\phi(x, y, t)$ in simple functions involving, besides initial conditions, the parameters

$$\left.\begin{aligned}&\nu=(\gamma+1)\alpha\\ \text{and}\qquad&\\ &\sigma=\tfrac{1}{2}(\nu+k/m).\end{aligned}\right\} \tag{9}$$

In the case of one-dimensional flow, his results reduce to those of Kantrowitz.[19]

For convex surfaces, $k<0$. At the accelerating sonic point, $\alpha>0$ and, presumably, $m>0$; this combination makes all the disturbances damp rapidly to zero, which confirms the observed stability of such flow. On the other hand, where $k<0$ and $\alpha<0$ (decelerating steady flow over a convex surface), the damping or growing of triangular pulses is influenced by the sign of m. When the decelerating sonic point occurs in a region of negative slope m, as is the case in Figs. 1–6, the disturbances increase in size in the sonic region, which indicates instability. But the theory brings forth an intriguing new idea: if m were positive here, the flow might again be stable. For example, if the imbedded supersonic area near an airfoil could be made to lie entirely *forward* of the maximum ordinate of the surface (Fig. 10), there would be a great reduction in the rate of growth of pulses as they pass through the sonic area, so that much larger disturbances could be tolerated; this might be termed pseudostability. Moreover, certain combinations of α, β,

Institute of Aero. Sciences, New York, January 24, 1950 (to be published).

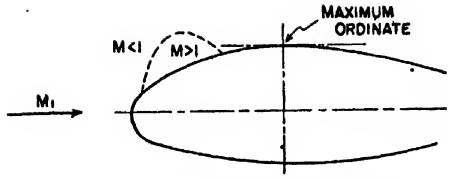

FIG. 10. Sketch showing possible stable transonic potential flow according to Kuo.

and m would result in complete damping of the pulses, i.e., stability.

So far as we know, there are no definitive measurements for flows of this type. Apparently it is possible to find airfoil shapes that have their supersonic regions entirely forward of their maximum ordinates. We are not yet sure that the peculiar combinations of α, β, and m mentioned above, for which the pulses are completely damped out, do occur. As Kuo has pointed out, there is a remarkable coincidence between his theoretical prediction and some recent experimental results of the N.A.C.A.[20] Entirely independently of Kuo's work, Nitzberg and Crandall at Ames Laboratory arrived at the empirical conclusion that the relative location of the sonic area and the "crest" of the airfoil is of significance in predicting the drag-divergence Mach number, M_D. To attribute this result to Kuo's stability effects is a long step, implying as it would that a shockless potential mixed flow exists before drag divergence or at least that the growth of small disturbances calculated by Kuo is the cause of drag divergence. A more conservative explanation would be that, although there are stationary shock waves, rather than potential flow, both below and above M_D, the shock waves do not cause separation of the boundary layer until $M=M_D$. Nevertheless, the coincidence is striking and, as Kuo has stated, seems to justify further research.

[20] G. E. Nitzberg and S. Crandall, "A study of flow changes associated with airfoil section drag rise at supercritical speeds," N.A.C.A. T.N. 1813 (1949).

5. CONCLUSION

In conclusion, it may be stated with assurance, that progress is now being made on this important question of shockless transonic flows. It might be pointed out explicitly that temporal instability and non-existence of neighboring solutions may represent the same phenomenon. One can explain the instability of an Euler column, for example, in either way, and Kantrowitz's results show that this is also true for the decelerating channel. Nevertheless, Guderley's, Frankl's, and Busemann's arguments have not suggested any stable decelerating cases, as Kuo's criterion suggests.

It seems advisable to undertake experimental confirmation of Kuo's results as soon as possible. We are studying this possibility at Cornell, but are realizing that the experimental difficulties may be considerable. One would like to have a really smooth potential flow to begin with, and to watch preselected disturbances travel into it. Unfortunately, there are usually an alarming number of disturbances naturally present, apparently originating in the boundary layer. We should like to suppress these, or to have so stable a flow that a disturbance larger than these would still be damped out. So far, we have not figured out how to accomplish this.

Analysis of Intensities Obtainable Using Pinhole and Slit Collimators in X-Ray Powder Diffraction Techniques

LEROY ALEXANDER
Department of Research in Chemical Physics, Mellon Institute, Pittsburgh, Pennsylvania
(Received February 6, 1950)

Other factors being equal, the integrated intensity of a powder diffraction reflection is a function of the geometry of the source, collimator, and sample. By means of a geometrical and algebraic analysis one can predict the relative intensities to be expected with pinhole or slit collimators of different dimensions. Important gains in intensity can be obtained by replacing pinholes with slits, and the advantage is about the same if the x-ray focal spot is viewed either longitudinally or laterally through slits of sufficient length. These results confirm experimental results reported by other investigators and also re-emphasize the potential value of the "side" windows of x-ray tubes, which are commonly neglected.

SEVERAL investigators[1–3] have recently pointed out the practicability of preparing Debye-Scherrer x-ray diffraction photographs by employing a pair of parallel slits rather than pinholes. The gain in intensity is great, being roughly proportional to the ratio of the slit length to the diameter of the pinholes employed in customary practice (for the case of the pinhole diameter equal to the slit width). The increased intensity is gained at the expense of decreased resolution and a shift in line positions, but both of these effects are very small for moderate slit lengths,[3] whereas the attendant intensity gain is several fold. Consequently such an arrangement is entirely satisfactory for the numerous applications of powder diffraction for which optimum line quality is not a prime consideration, and furthermore it permits a very substantial saving in exposure time and increase of x-ray tube life.

If the focal spot is viewed at some fixed small angle to the target face, say 6° or 7°, and if the two slits, the long dimension (if any) of the projected focal spot, and the sample axis are all parallel, it has been found[1,3] that for slits of sufficient length substantially equal gains in intensity are obtained whether the source is viewed (a) in a direction parallel to its long axis so that it appears foreshortened, the usual orientation when using pinhole techniques, or (b) in a direction normal to its long axis. In the present discussion orientations (a) and (b) will be respectively denoted the longitudinal and lateral arrangements. Thus by a relatively simple modification in camera design the "side" windows of an x-ray tube, commonly neglected by most diffractionists, can be put to good use. For this reason the recommendation has recently been made that x-ray tube manufacturers build four- rather than two-window diffraction tubes.[2]

The relative intensities to be expected with different collimator and source arrangements can be predicted with considerable accuracy by a geometrical and algebraic analysis. The mathematical development will be simplified by making the following initial assumptions: (a) The x-ray focal spot is a rectangle of uniform intensity. (b) The source-to-sample distance, x_3, is kept constant. If it were to be varied, an additional factor $1/x_3^2$ would need to be applied to each intensity equation. (c) The focal spot is viewed at some constant angle, α, with the target face. This requirement must be met since at angles less than about 8 or 10° the energy flux from the focus diminishes appreciably with decreasing angle.[4] (d) The x-ray beam impinges perpendicularly upon the sample, which takes the form of a flat sheet of negligible absorbing power for the x-rays. In actuality the results apply without serious error to a cylindrical Debye-Scherrer sample of low or moderate absorbing power. (e) The apertures S_1 and S_2 are rectangular or square in shape.

Let us set up a three-dimensional rectangular coordinate system with origin at the center of the x-ray tube focus as shown in Fig. 1. It will be noted that the widths of the slits S_1 and S_2 and the projected dimension of the focal spot as governed by the angle of view, α, are measured in the direction Z. The distances separating the source, slits, and sample are measured in the direction X; and the heights of the slits, the height of the area of sample irradiated, and the *non-projected* dimension of the x-ray focus are measured in the direction Y. For reasons that will become apparent as the analysis proceeds, one may consider the effects of the Z dimension as being virtually constant for all experimental

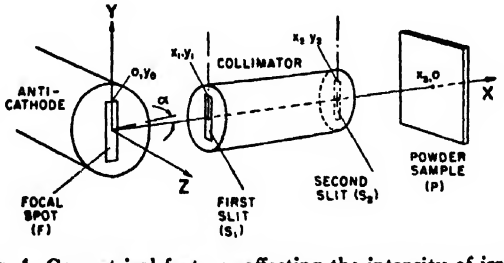

FIG. 1. Geometrical features affecting the intensity of irradiation of a powder diffraction sample. The case portrayed is that in which the focal spot is viewed laterally.

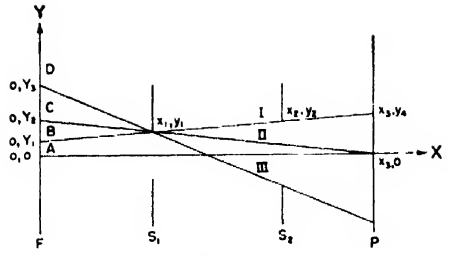

FIG. 2.

cases in which the apertures S_1 and S_2 have the same width (Z dimension) and in which at the same time the aperture width is either roughly equal to or larger than the projected (Z) dimension of the focal spot. These conditions obtain in the usual experimental cases, such as those to be compared in the present communication, and hence we may simplify the mathematical treatment by confining it to the XY plane.

Referring again to Fig. 1, the coordinates of the relevant features of our apparatus are: ends of focus, $(0, y_0)$ and $(0, -y_0)$; ends of slits 1 and 2, (x_1, y_1), $(x_1, -y_1)$ and (x_2, y_2), $(x_2, -y_2)$ respectively; intersection of x-ray beam axis and sample trace, $(x_3, 0)$. Four principal mathematical cases arise, depending upon the relative values of x_1, x_2, x_3, y_1, y_2, and y_0. Referring to Fig. 2, we may characterize these cases as A, B, C, and D according to whether y_0 falls in region A, B, C, or D respectively. Let Y_1, Y_2, and Y_3 be the respective zone boundaries AB, BC, and CD. These zone boundaries are the Y intercepts of the lines I, II, and III, and by consideration of the diagram their equations are seen to be

$$Y_1 = y_1 - \left(\frac{y_2 - y_1}{x_2 - x_1}\right)x_1 = \frac{x_2 y_1 - x_1 y_2}{x_2 - x_1}, \tag{1}$$

$$Y_2 = y_1 + \left(\frac{y_1}{x_3 - x_1}\right)x_1 = \frac{x_3 y_1}{x_3 - x_1}, \tag{2}$$

$$Y_3 = y_1 + \left(\frac{y_1 + y_2}{x_2 - x_1}\right)x_1 = \frac{x_1 y_2 + x_2 y_1}{x_2 - x_1}. \tag{3}$$

The four principal mathematical cases may then be expressed as follows:

Case A. $Y_1 \geq y_0$.
Case B. $Y_2 \geq y_0 \geq Y_1$.
Case C. $Y_3 \geq y_0 \geq Y_2$.
Case D. $y_0 \geq Y_3$.

Further geometrical cases arise when the apertures S_1 and S_2 differ very greatly in length. Thus when $y_1 \ll y_2$, Y_1 becomes negative, and when $y_1 \gg y_2$, y_4 becomes negative (see Fig. 3). However, these unusual arrangements have little practical value, and it is desirable to avoid complicating the present discussion by introducing these additional geometrical cases.

Before carrying out the mathematical analyses it will be useful to write the equations for the intersections of five lines with the line x_3 (see Fig. 3):

$$y_3 = y_0 + (y_1 - y_0)\frac{x_3}{x_1} = y_1 + (y_1 - y_0)\left(\frac{x_3 - x_1}{x_1}\right), \tag{4}$$

$$y_4 = y_1 + (y_2 - y_1)\left(\frac{x_3 - x_1}{x_2 - x_1}\right)$$

$$= y_2 + (y_2 - y_1)\left(\frac{x_3 - x_2}{x_2 - x_1}\right), \tag{5}$$

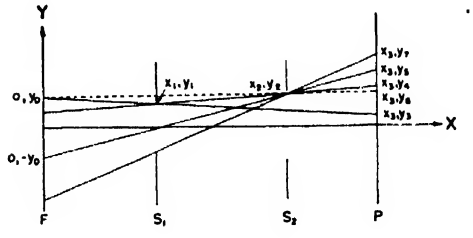

FIG. 3.

$$y_5 = -y_0 + (y_0 + y_2)\frac{x_3}{x_2} = y_2 + (y_0 + y_2)\left(\frac{x_3 - x_2}{x_2}\right), \tag{6}$$

$$y_6 = y_0 - (y_0 - y_2)\frac{x_3}{x_2} = y_2 - (y_0 - y_2)\left(\frac{x_3 - x_2}{x_2}\right), \tag{7}$$

$$y_7 = -y_1 + (y_1 + y_2)\left(\frac{x_3 - x_1}{x_2 - x_1}\right)$$

$$= y_2 + (y_1 + y_2)\left(\frac{x_3 - x_2}{x_2 - x_1}\right). \tag{8}$$

We now proceed to analyze the rather typical case B. Figure 4 shows the geometrical properties of this case. At the right of the sample trace, P, the intensity of illumination of the sample as a function of y is depicted by the hatched contour. The relative integrated intensity of illumination may in general be represented by

$$I = \int_{-\infty}^{+\infty} I_y dy,$$

which becomes because of symmetry

$$I = 2\int_0^{\infty} I_y dy. \tag{9}$$

For the present case the function I_y is different for each of the regions $0 - y_3$, $y_3 - y_4$, and $y_4 - y_5$, so the integral for convenience may be broken up into three terms:

$$I = 2\int_0^{y_3} I_y dy + 2\int_{y_3}^{y_4} I_y' dy + 2\int_{y_4}^{y_5} I_y'' dy.$$

These three integrals are seen by inspection of Fig. 4 to be given respectively by the areas of a rectangle, trapezoid, and triangle, so that the expression for I becomes

$$I=2[y_3I_3+\tfrac{1}{2}(y_4-y_3)(I_3+I_4)+\tfrac{1}{2}(y_5-y_4)I_4].$$

At any point in the zone $-y_3$ to $+y_3$ the entire focal spot can be seen and, hence, the intensity of irradiation is a maximum, I_m. Substituting I_m for I_3 and combining terms, we obtain

$$I=I_m(y_3+y_4)-I_4(y_3-y_5) \quad \text{(case B)} \qquad (10)$$

in which y_3, y_4, and y_5 are given by Eqs. (4), (5), and (6) respectively. Now the intensity I_4 is equal to I_m times the fraction of the focal spot visible at the point x_3, y_4. By comparing Figs. 2 and 4 this is seen to give

$$I_4=I_m\cdot\frac{y_0+Y_1}{2y_0},$$

$$=(1/2)I_m\left[\frac{x_2y_1-x_1y_2}{y_0(x_2-x_1)}+1\right]. \qquad (11)$$

Substitution of Eqs. (4)–(6) and (11) in (10) leads to a somewhat complicated algebraic expression for the integrated intensity of illumination of the sample powder as a function of the dimensions and positions of the collimating apertures and the dimensions of the focal spot. Because of the complexity of the fully substituted Eq. (10) it is more convenient to evaluate it for specific experimental cases by first evaluating y_3, y_4, y_5, and I_4 and then substituting the numerical values in Eq. (10).

It would be tedious and unnecessary to reproduce in full here the complete analyses for cases A, C, and D. Suffice it to say that by a procedure very similar to that described above for case B the appropriate integrated intensity expressions can be derived. The expressions for all four cases are summarized herewith:

Case A.

$$I=2I_m\frac{x_3}{x_2}y_2. \qquad (12)$$

Case B.

$$I=I_m(y_3+y_4)-I_4(y_3-y_5), \qquad (10)$$

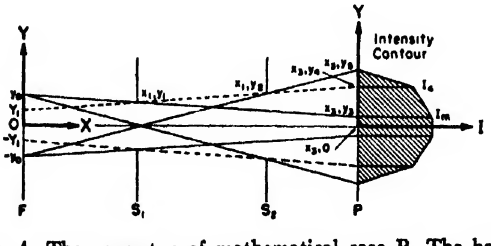

FIG. 4. The geometry of mathematical case B. The hatched contour depicts the intensity of sample irradiation as a function of the coordinate y.

TABLE I. Values of the x and y parameters for four typical experimental situations.

Parameter	Values of the parameters in mm (1)	(2)	(3)	(4)
x_1	60	60	60	60
x_2	100	100	100	100
x_3	150	150	150	150
y_0	0.500	4.000	0.500	4.000
y_1	0.375	0.375	2.750	2.750
y_2	0.375	0.375	2.750	2.750

TABLE II. Quantities computed in the evaluation of the integrated intensities for the four experimental situations of Table I.

Quantity	(1)	(2)	(3)	(4)
Y_1	0.375	0.375	2.750	2.750
Y_2	0.625	0.625	4.580	4.580
Y_3	1.500	1.500	11.000	11.000
Mathematical case	B	D	A	B
y_3	0.187	—	—	0.870
y_4	0.375	—	—	2.75
y_5	0.812	—	—	6.13
I_4	$0.875I_m$	—	—	$0.844I_m$
Calculated intensity in I_m units	1.11	0.26	8.25	8.06
Relative intensity (rectangular apertures)	13.4	3.2	100.0	97.5
Relative intensity (circular pinholes)	10.5	2.5	100.0	97.5

where

$$I_4=(1/2)I_m\left[\frac{x_2y_1-x_1y_2}{y_0(x_2-x_1)}+1\right]. \qquad (13)$$

Case C.

$$I=I_3(y_4-y_3)+I_4(y_3+y_5), \qquad (14)$$

where

$$I_3=I_m\frac{y_1}{y_0}\left(\frac{x_3}{x_3-x_1}\right) \qquad (15)$$

and I_4 is given by Eq. (13).

Case D.

$$I=2I_m\frac{x_3y_1y_2}{y_0(x_2-x_1)}. \qquad (16)$$

Equations (7) and (8), although not explicitly involved in the final intensity formulas, are essential to the derivation of Eqs. (12) and (16), respectively.

We may now return briefly to the observation made earlier that the Z dimensions of the apparatus could justifiably be disregarded in the present analysis. This action can be seen to be completely justified when the apertures S_1 and S_2 have the same width ($2z_1=2z_2$) and when at the same time the projected source dimension, $2z_0$, is equal to or less than $2z_1$, because this is simply mathematical case A applied to the Z dimension, and Eq. (12) shows I to be independent of y_0 (or z_0 in the present application). When z_0 begins to exceed z_1

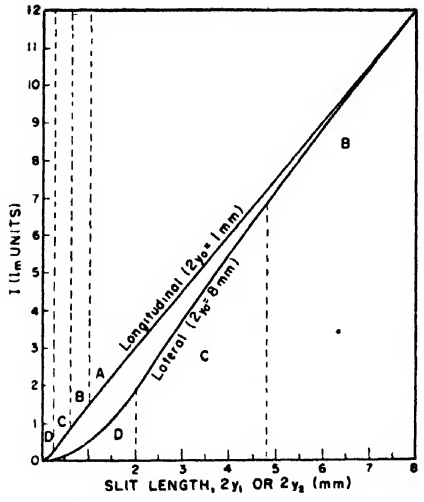

FIG. 5. Variation of integrated intensity, I, with slit length for a pair of identical rectangular slits of length $2y_1=2y_2$. The upper curve is for longitudinal and the lower for lateral view of the focus. Rectangular focal spot 1×8 mm; $\alpha=7°$; $x_1=60$, $x_2=100$, $x_3=150$ mm; slit width 0.75 mm. A, B, C, and D indicate applicable mathematical cases.

we are dealing with case B, but the application of Eq. (10) demonstrates that I diminishes very little until z_0 exceeds about $1.5z_1$.

For purposes of illustration we now apply these mathematical results to typical experimental conditions. Let $x_1=60$, $x_2=100$, and $x_3=150$ mm, and suppose the focal spot is a rectangle 1×8 mm in size. Furthermore, let us suppose that the focus is viewed at such an angle (7° in the present instance) that when observed in the longitudinal direction it appears as a square 1×1 mm in size. When viewed laterally, then, it will have the apparent dimensions 0.12×8 mm. Let us compare the integrated intensities of illumination for four important situations, including viewing the focal spot through: (1) two 0.75 mm pinholes longitudinally (customary arrangement using "end" windows), (2) two 0.75 mm pinholes laterally (using "side" windows), (3) two 0.75×5.5 mm slits longitudinally, (4) two 0.75×5.5 mm slits laterally. The proper values of the six x and y parameters for these four cases are given in Table I.

Table II lists the values of the various quantities which are calculated during the process of determining the integrated intensities for these four experimental situations. First, the quantities Y_1, Y_2, and Y_3 are computed, from which the appropriate mathematical treatment (case A, B, C, or D) is selected for each set of experimental conditions. Experimental cases (1) and (4) are found to fall in mathematical class B, and accordingly the quantities y_3, y_4, y_5, and I_4 are evaluated preliminary to the application of Eq. (10). Experimental cases (2) and (3) are found to fall in mathematical classes D and A respectively, for which no further quantities need be evaluated. Next the integrated intensity in I_m units is calculated using the appropriate equation, (10), (12), (14), or (16). The next row of data gives the relative intensities for the four cases referred to case (3) as 100. In the last row the relative intensities for the square apertures of edges $2y_1$ and $2y_2$ of cases (1) and (2) are converted to the equivalent values for circular apertures of diameters $2y_1$ and $2y_2$ by applying the factor $\pi r^2/(2r)^2=0.78$. The figures in the last row of Table II, then, give a direct comparison of the intensities to be expected when employing a pair of identical pinholes or a pair of identical rectangular slits.

The results given in Table II demonstrate clearly that a pair of pinholes is greatly inferior to a pair of slits of moderate length from the standpoint of irradiation intensity. Furthermore, the gain in intensity is found to be nearly the same whether the source be viewed longitudinally or laterally. These results agree with the experimental findings of Garrod[3] except for the precise extent of the intensity increases, which would hardly be expected to agree more closely because of differences in the respective experimental conditions. The second column of Table II shows a marked loss of intensity on viewing a rectangular focus laterally through a pair of pinholes with diameters much smaller than the length of the focus. This is, of course, the reason for the customary neglect of the "side" windows of the x-ray tube when only pinhole collimators are available.

The intensities provided by rectangular slits of various lengths are portrayed graphically in Fig. 5. The following typical conditions are assumed: $x_1=60$, $x_2=100$, $x_3=150$ mm; identical slits ($y_1=y_2$ and $z_1=z_2$); 1×8 mm rectangular focus viewed at 7°. The slit width ($2z_1$ or $2z_2$) is constant and equal to 0.75 mm. Figure 5 shows that the longitudinal direction of view is much preferable to the lateral for small values of $2y_1$ and $2y_2$, that is, when the slits are so short as to approach a square in shape. As the length of slit increases, the lateral intensity approaches the longitudinal, until when the slit length equals the length of the focus ($2y_1=2y_2=8$ mm in the present instance) the two techniques give equal intensities.

An analysis somewhat similar to the above has been carried out by Bolduan and Bear[5] for the special conditions inherent in low angle diffraction techniques. The results are applied to the design of collimators calculated to give optimum resolution and intensity.

Average Electron Density Measurements by Low Angle X-Ray Scattering*

H. M. Barton, Jr. and R. Brill
Polytechnic Institute of Brooklyn, Brooklyn, New York, and Phillips Petroleum Company, Bartlesville, Oklahoma
(Received March 8, 1950)

According to Guinier the low angle x-ray scattering of particles should disappear when they are immersed in a fluid of equal electron density. This furnishes a way of measuring the electron density of powders, providing a suitable impregnating fluid can be found. Experiments of this type have been carried out with carbon black. A method of calculating the low angle scattering coefficient defined by Warren is given for impregnated samples. Measurements of the total low angle scattering intensity were made using a double crystal spectrometer and Geiger counter. No liquid was found that would give complete matching but approximate matching was obtained with phosphoric acid solution. The data extrapolate to show an electron density of $1.1N \pm 0.1N$ where N = Avogadro's number. This compares with a value of $0.99N$ as calculated from the helium immersion mass density measurement on the same sample.

I. INTRODUCTION

IT has been stated by Guinier[1] that if particles of average electron density† ρ_e are suspended in a medium of electron density ρ_e', they will give low angle scattering as if they had electron density $(\rho_e - \rho_e')$ and were in a vacuum. This, of course, means that if there is no difference in electron density between the particles and their surroundings there will be no low angle scattering. This is analogous to the optical effect that particles immersed in a fluid of the same index do not scatter light.

Kratky, Secora, and Treer[2] investigated this experimentally for cellulose, finding in a qualitative way that the intensity of low angle scattering went to a low value when the particles were immersed in ethyl iodide, and that there was more intensity with fluids having greater or less electron density than the ethyl iodide.

Kratky and Wurster[3] extended the above experiments, measuring quantitatively the effect of different impregnating fluids on the small angle scattering of cellulose. They concluded that the intensity is proportional to the cube of the difference in electron densities. Their measurements were carried out using the photographic method. This procedure is rather complicated and requires many corrections, the magnitude of which may often be many times the measured value.

We used a more direct method, given by Warren.[4] By this method the total intensity scattered in the low angle region is measured by means of a double crystal spectrometer fixed at the maximum intensity angle. Warren defined a coefficient μ_{SA} which describes the reduction in primary beam intensity by a unit mass per unit area due to low angle scattering, in addition to that by the mass absorption; and showed it to be proportional to the integrated energy in low angle scattering. He derived the relation:

$$\mu_{SA} = \mu_m \frac{\ln(I_B/I_A)}{\ln(I_0/I_B)}, \tag{1}$$

where μ_m is the mass absorption coefficient for powders, I_A, I_B, and I_0 are the relative intensities measured with the sample in position A between the crystals, in position B in front of the Geiger counter, and out of the beam, respectively. The particles were in air.

II. SCATTERING COEFFICIENTS FOR IMPREGNATED SAMPLES

For samples impregnated with an ordinary liquid of mass absorption coefficient μ_i, we may set up the equation for the intensity at position A between the crystals

$$I_A = I_0 \exp[-\mu_i m_i - (\mu_p + \mu_{SA}) m_p], \tag{2}$$

where m_i is the mass per unit area of the impregnating liquid in the beam, μ_p is the mass absorption coefficient for powders of the particles, and m_p is the mass per unit area of the particles.

In position B in front of the Geiger counter where the low angle radiation is also registered:

$$I_B = I_0 \exp[-\mu_i m_i - \mu_p m_p], \tag{3}$$

and also we have for the total mass per unit area:

$$m_t = m_i + m_p. \tag{4}$$

Combining these three equations we get

$$\mu_{SA} = \frac{(\mu_p - \mu_i)\ln(I_B/I_A)}{\ln(I_0/I_B) - \mu_i m_t}, \tag{5}$$

which reduces to the Warren equation when μ_i is negligible. In the case where $\mu_p = \mu_i$, Eq. (5) becomes indeterminate, but this indeterminancy may be re-

* This is a condensation of a thesis presented by H. M. Barton in partial fulfillment of the requirements for a Masters degree at

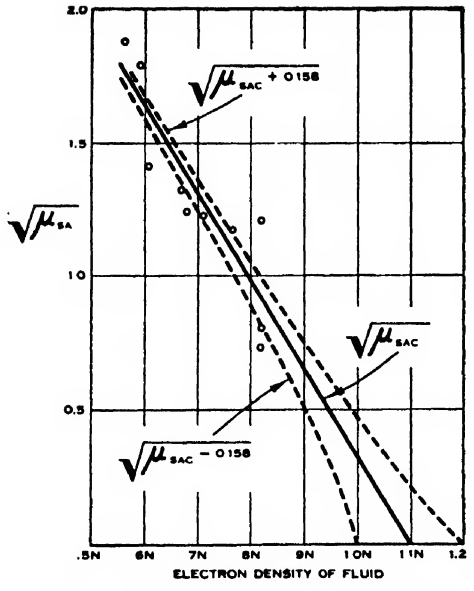

FIG. 1. Average electron density of impregnating fluid *vs.* square root of low angle scattering coefficient. μ_{SAC} is least squares calculation.

moved, giving

$$\lim_{\mu_p \to \mu_i} \mu_{SA} = \frac{\mu_i \ln(I_B/I_A)}{\ln(I_0/I_B) - \mu_i m_i}. \tag{6}$$

This case will seldom be encountered, however.

III. RELATION OF SCATTERING TO RELATIVE ELECTRON DENSITY

The intensity of low angle scattering is generally considered to be proportional to the square of the number of electrons per particle, when the medium may be neglected. If the medium has appreciable electron density and if Guinier's statement holds, then the particles would scatter as if the electron density of the particles were diminished by that of the medium, and the effective number of electrons per particle would be $(\rho_e - \rho_e')V$ where V is the volume of a particle. The low angle scattering is thus seen to be proportional to $(\rho_e - \rho_e')^2$, or

$$\mu_{SA} = b(\rho_e - \rho_e')^2. \tag{7}$$

If this equation holds, then it will not be necessary to actually match the electron densities of the particles and fluid, but only to define the parabola (7) with sufficient accuracy.

IV. EXPERIMENTAL

To test this, a double crystal spectrometer was set up using calcites in the parallel position. The half-width at half-maximum of crystal B was about 19 seconds. Copper $K\alpha_1$ radiation was used, and the resultant radiation was measured with Geiger counter equipment removed from a Norelco x-ray spectrometer.

Experiments were made on impregnated carbon black. The fluids finally used were solutions of phosphoric acid. It was not possible to match the electron density of the carbon black with these solutions, so it was necessary to extrapolate to find the match point. It is difficult to find liquids with high electron densities which do not also have very high absorption. This requires reducing the thickness of the sample, but the sample must be kept thick enough to give sufficient low angle scattering. Some salts such as magnesium nitrate have suitable electron densities and mass absorptions. It proved possible to make pastes with molten salts but on solidifying the salts gave their own low angle scattering. Construction of a hot holder was not undertaken.

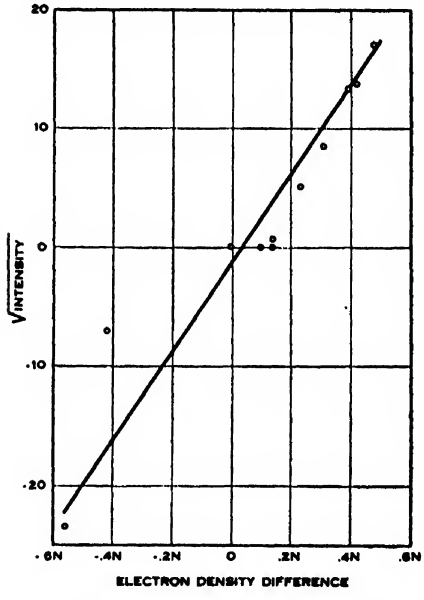

FIG. 2. Replot of data by Kratky and Wurster. Electron density difference between impregnating fluid and calculated electron density difference of hydrocellulose *vs.* square root of low angle scattering intensity. Intensity square roots are plotted as negative values for negative values of electron density difference.

V. RESULTS

Figure 1 shows the data plotted as the square root of μ_{SA} *vs.* the electron density of the fluid. The straight line is that obtained by least squares approximation to Eq. (7). It extrapolates to the axis at an electron density of $1.1N$. The average error expected for a measurement of μ_{SA} is:

$$p = \pm\left(\frac{\Sigma\Delta^2}{i(i-1)}\right)^{\frac{1}{2}}\left[1+\left(\frac{1}{2(i-1)}\right)^{\frac{1}{2}}\right], \tag{8}$$

where Δ is the difference between the least squares value and the experimentally measured value, and i is the number of measurements. For these data this comes out to be 0.158. The dashed curves were obtained by adding and subtracting this amount to the least squares curve and taking the square root. They are very close to

straight lines except near the intercept. The positive error curve does not actually go through the axis, but is shown extrapolated to get a rough idea of the error. These show an electron density for the carbon black of $1.1N \pm 0.1N$, corresponding to an electron density of $0.99N$ as calculated from the mass density determined by helium immersion of 1.98 g/cc.[5]

It would be highly desirable to obtain data closer to the point where the electron densities match. Experimentally this will require higher precision than was obtained in this work. It should be noted that the logarithm of the ratio of I_B to I_A occurs in Eq. (4). When there is little low angle scattering, this ratio is close to unity. Noting that when x is small the $\ln(1+x)$ is approximately x, it is easily seen that when the ratio is 1.01, a 1 percent error in measurement of the ratio will give a 100 percent error in the result. Measurements of intensities near the minimum of the parabola must therefore be made with great precision. Normally the extrapolation technique will give better results.

According to the paper by Kratky and Wurster,[3] the total intensity of small angle scattering should be proportional to $(\rho_e - \rho_e')^2$. Figure 2 shows their data replotted as the square root of the corrected intensities *vs.* $(\rho_e - \rho_e')$. We have the impression that a straight line fits with sufficient accuracy their results thus plotted to show the quadratic relation. Since it is not possible to obtain reasonable results with our data using the cubic assumption, we feel that the second power called for by theory is true.

We are indebted to Professor I. Fankuchen for several helpful discussions during the course of this work.

A Removable Intermediate Lens for Extending the Magnification Range of an Electron Microscope

J. Hillier
RCA Laboratories, Princeton, New Jersey
(Received February 27, 1950)

A removable intermediate lens is described which extends the range of magnification of a conventional instrument to 25:1 without sacrificing the accessibility of the objective and projection lens polepieces. The distortion, sensitivity to changes in accelerating potential and reproducibility of calibration are studied and found to be equal to, or better than in the standard arrangement. The system provides two values of the magnification which are essentially independent of the accelerating potential.

I. INTRODUCTION

In conventional electron microscopes it has been customary to use an objective of fixed magnification in the neighborhood of 100× and single projection lenses of variable magnification with maximum values in the range 200 to 300. In other words the maximum electronic magnification by the entire instrument is usually in the range 20,000 to 30,000 diameters. Values greater than this are possible but have been used only occasionally owing to a number of technical difficulties including in particular, the high bombardment of the specimen necessary to provide sufficient image intensity. While the projection lenses are usually variable, more than a fourfold variation is rarely used owing to the introduction, at the lower values, of excessive image distortion and to an excessive limitation of the field of view. The minimum magnification attainable in the example cited above is in the range 5000 to 7500 diameters. However, these values are not sufficiently low for many uses of the electron microscope. For survey purposes or for correlation with the light microscope, magnifications in the range 500 to 1500 are desirable. It has been well known by those familiar with electron optics that the range of magnification and the field of view can be extended by the use of multiple projection lenses. Hillier[1] and Prebus[2] used double projection lenses each of which was weaker than a single conventional lens but together gave both a wide range of magnification (including values higher than those attainable with a single lens) and an increased field of view. This system did not find favor at the time because the lenses were not easily accessible and for some parts of the range excessive distortions were encountered. Marton suggested that lower magnifications might be included in the range by interposing a weak and variable lens between the objective and projector of a conventional instrument. More recently le Poole[3] has built an instrument in which he combined these two ideas introducing two lenses between the objective and projector. By properly activating one or two of these three projection lenses he is able to achieve any magnification he desires between zero and a maximum in the range 50,000 to 100,000 diameters. The adjustment can be made so that there is minimum distortion and satisfactory field of view at all magnifications.

In the design of electron microscopes easily accessible

polepieces have been considered of prime importance. This arises through the necessity of keeping the polepieces scrupulously clean. It has had the further advantage that a wide range of magnification could be obtained by the easy substitution of different lens combinations. For most work this has been found to be quite satisfactory. However, the convenience of a multiple lens system which enables the operator to survey his specimen at low magnification without breaking the vacuum, is not one to be overlooked.

In order to obtain the convenience of multiple lens operation without sacrificing polepiece accessibility in the electron microscope, a removable intermediate lens was designed which provides a range of magnification of 25:1 without changing polepieces. This new lens also reduces the distortion in the system, requires only a slight change in the electrical circuit of the RCA Model EMU, and provides the range of magnification in ten reproducible steps. The lens described was designed specifically for the standard RCA Model EMU in use in this laboratory.

II. DESCRIPTION OF REMOVABLE INTERMEDIATE LENS

Figures 1 and 2 are photographs of the complete unit. It is simply a lens spool consisting of two Armco iron end plates (one of which carries the central tube) threaded into a brass spacer which also acts as the lens-gap. The vacuum seal is achieved in the usual way by soft-soldering the threaded joints. The outer faces of the end plates are provided with projections which are machined respectively identical to the top and bottom ends of the intermediate chamber casting which it replaces in the instrument. The spool is surrounded by the usual sheath of Armco iron to complete the magnetic circuit. The spool is wound with insulated wire and must have a minimum resistance of 400 ohms. In our experimental model 9000 turns were wound on the coil which then had a resistance of 450 ohms. Connections to the coil were brought out into a shielded cable long enough to reach from the intermediate image position to the magnification control on the panel.

III. THEORY AND PERFORMANCE

The projection lens power supply in the Model EMU consists of a constant current regulator supplying 150 ma to the lens circuit and several regulator tube filaments. Variations in magnification are obtained by reducing the current in the projection lens; this being accomplished by a system of shunting resistors on a ten position step switch. (See Fig. 3) Table I gives the values

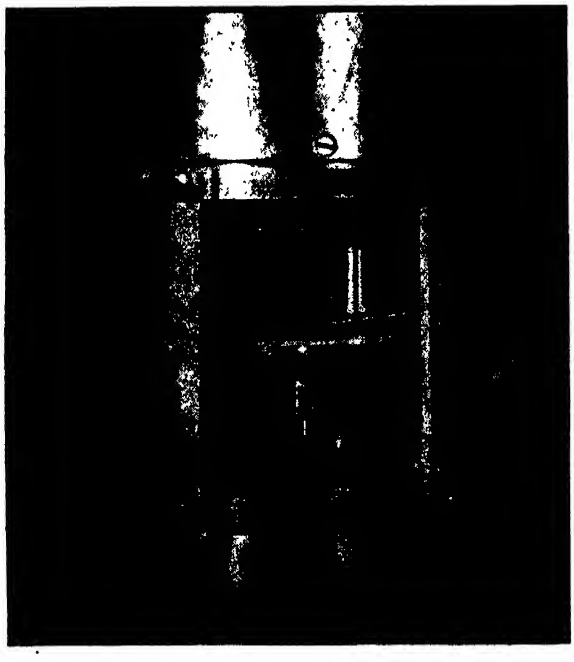

FIG. 1. A photograph showing the intermediate lens in position.

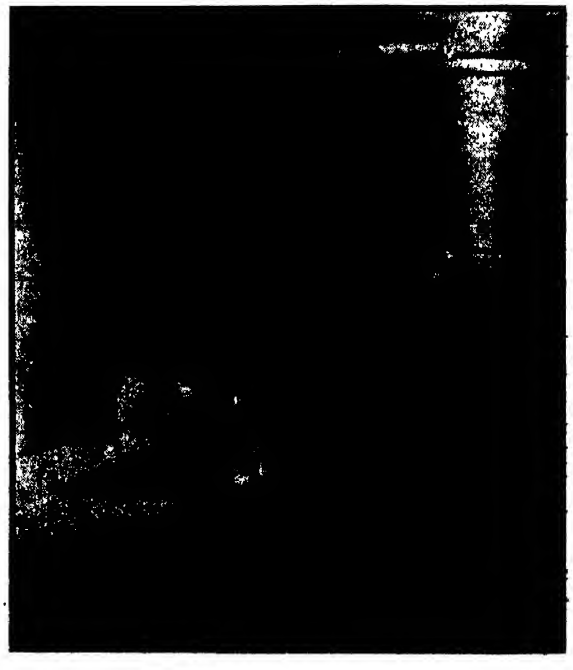

FIG. 2. A photograph showing the intermediate lens removed from the instrument.

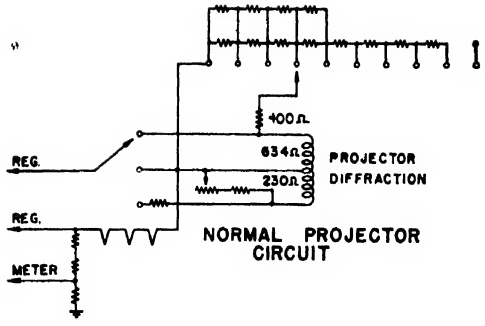

FIG. 3. A schematic diagram showing the circuit for the projection lens in the standard RCA Model EMU electron microscope.

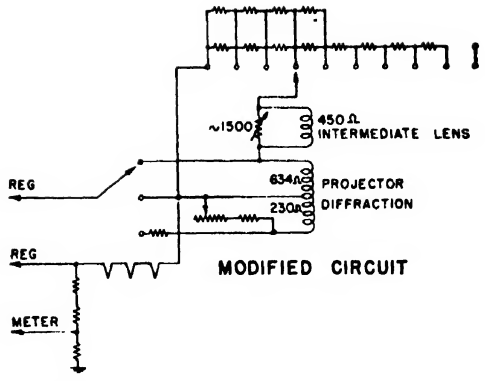

FIG. 4. A schematic diagram showing the circuit for the projection lens as modified for the insertion of the intermediate lens.

of the shunt resistor and the approximate magnifications achieved in the instrument using the standard short spacer in the projection lens polepieces.

The modified circuit used with the removable lens is shown in Fig. 4. The 400-ohm resistor in the arm circuit of the shunt system is replaced by the coil winding and another shunt resistor of rather higher value. The actual value of this second shunt resistor is set experimentally to attain the lowest magnification possible consistent with a full field of view and minimum distortion. In our model this value was 1500 ohms giving a minimum magnification of 990.

The performance of this system can be derived from the following simple theory. Figure 5 is a simplified diagram of the optical system including the intermediate lens. The following notation and values are used: $u_1 = -0.24$ cm, specimen to objective distance (fixed); v_1, image position for objective (cm); $u_2 = v_1 - d_1$, object position for intermediate lens (cm); $d_1 = 12.7$ cm, separation of objective and intermediate lens (fixed); $d_2 = v_2 = 11.4$ cm, image position for intermediate lens (fixed); f_1, focal length of objective (cm); f_2, focal length of intermediate lens (cm); f_3, focal length of projection lens (cm); m_3, magnification of projection lens having values given in Table I; m, magnification of objective and intermediate lenses combined; $M = mm_3$, total instrumental magnification.

At a given projection lens setting the magnification of the objective and intermediate lenses combined will determine the change in the total magnification as compared to the standard arrangement since the circuit change has virtually not affected the current flowing through the projection lens. Thus, to determine the total magnification for each step, it is necessary only to calculate the magnification of the objective-intermediate lens system and multiply it by the known value of the magnification of the projection lens at the same step. Thus

$$m = v_1 v_2 / u_1 u_2 = v_1 d_2 / u(v_1 - d_1) \qquad (1)$$

but

$$1/f_2 = 1/v_2 - 1/u_2 = 1/d_2 - 1/(v_1 - d_1) \qquad (2)$$

and

$$v_1 = \frac{f_2(d_1 + d_2) - d_1 d_2}{f_2 - d_2}. \qquad (3)$$

Substituting in expression (1) gives

$$m = \frac{d_1 + d_2}{u_1} \cdot \frac{d_1 d_2}{f_2 u_1} \qquad (4)$$

which on substituting numerical values gives

$$m = 100 - (600/f_2) \text{ (very nearly)}. \qquad (5)$$

From the expression (5) it is apparent that the focal length of the intermediate lens is the controlling factor as far as the magnification m is concerned. Furthermore, as the power $(1/f_2)$ of the intermediate lens increases, the over-all magnification first decreases to zero then increases to the limit of the lens. Since the power of the lens increases with increasing current, in the circuit described, it will have maximum power for Step 1 on the magnification control. Since the lowest magnification is desired at this step and the current is known, the design of the coil can be established. The maximum intermediate lens power that will be required is such that $m = 0$, that is, $f_2 = 6$ cm. Substituting numerical values in the equation for the focal length: $f_2 = (KVD_2)/(n_2 i_2)^2$ where K = instrumental constant (approximately 50); $V = 50{,}000$ volts; $D_2 = 1.27$ cm; n_2 = number of turns; i_2 = current in amp., shows that the coil should have 715 amp. turns. Since the current to be expected is 0.093 amp. approximately 8000 turns are required. By using No. 30 wire, such a coil will have a resistance of approximately 400 ohms. The maximum power consumption is 3.45 watts.

From the above data it is now possible to calculate the total magnification to be expected from the system. In these calculations, the projection lens polepiece with the short spacer is used. Furthermore, the calculations apply to the model of the intermediate lens built and installed with a 1500 ohm shunt resistor. The results of these calculations are collected in Table II. The calculated

and measured values of M are plotted on Fig. 6. It can be seen that the agreement is quite good in spite of the numerous assumptions and approximations inherent in the calculations.

Magnifications below 900 are not satisfactory because of excessive barrel distortion (see Fig. 7). Actually, at a magnification of 900 a single opening of the 200-mesh screen commonly used as a specimen support just covers the 2×2 in. image field. Thus, no increase in field is achieved until more than one opening is imaged. This requires magnifications below 500 which are beyond the range of the present system. They can be achieved however, by using the intermediate lens in combination with other projection lens polepiece arrangements. In every case the maximum magnification given by a given projection lens polepiece remains unchanged and the minimum is 1/25 (approximately) of the maximum. The image field in each case is that of the specific projection polepiece arrangement.

A point which should be mentioned in connection with the use of this lens is that the variation in focus with change in magnification is no longer negligible. This is particularly true at the lower values of magnification. The dependence of f_1 on f_2 is given by the expression:

$$\frac{1}{f_1}=\frac{f_2-d_2}{f_2(d_1+d_2)-d_1d_2}\frac{1}{u_1}. \tag{6}$$

The substitution of numerical values shows that longer objective focal lengths are required for the lower magnifications. The increase for the entire range amounts to 7.1 percent most of which occurs in the lowest three steps. This corresponds to a reduction in objective current of approximately 3½ percent.

One other aspect of the optics of this system remains to be discussed, namely the distortion. Since for the range of values of f_2 considered the intermediate lens is always producing a real image of a virtual object, its spherical aberration results in a barrel distortion which becomes most apparent for those values of f_2 that cause the magnification m of the objective intermediate-lens system to approach zero. The projection lens, on the other hand, is always producing a real image of a real object and hence, as is well known, produces pincushion distortion. This is also more apparent at the lowest magnifications. Thus the distortion in the intermediate image is always opposite to that produced by the projector and tends to neutralize it.[4,5] It did not appear worth while to calculate the distortion since it was easier to measure it. Figure 7 shows the measured distortion at each magnification step. The distortion is expressed as a percentage increase in magnification, measured in the radial direction, at a point 2.5 cm from the center of the final image. It will be seen that for all practical purposes the system does not have excessive distortion. For comparison the distortion present in the final image produced by the standard projector lens with short spacer is plotted on the same figure.

IV. SOME PRACTICAL ASPECTS OF THE REMOVABLE INTERMEDIATE LENS

It is apparent from Fig. 6 that the relative rate of change of the total magnification M is very high for the lowest steps on the magnification control. For this reason, no attempt was made to design the intermediate lens for a specified minimum magnification. Instead, as already indicated, sufficient ampere-turns and resistance

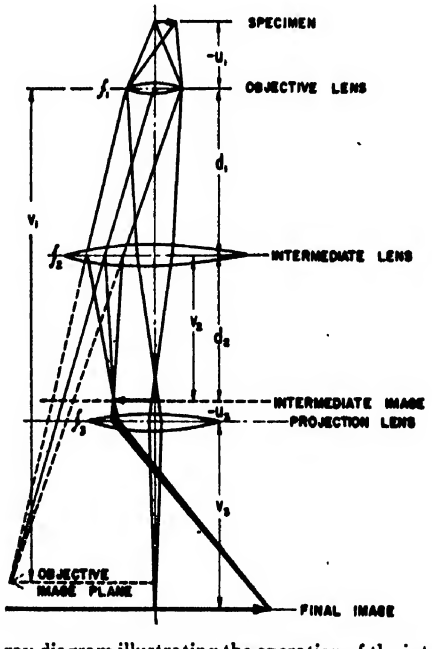

FIG. 5. A ray diagram illustrating the operation of the intermediate lens and the notation used in the text.

[4] J. Hillier, J. App. Phys. 17, 411–419 (1946).
[5] J. Hillier, U. S. Patent 2,418,349.

were built into the coil to permit adjustment by external shunts. The theory shows, and has been verified, that the magnifications obtained for settings above Step 2 were relatively insensitive to the value of this external shunt. In our work the shunt was adjusted so that one opening of 200-mesh screen was seen in its entirety on the final screen at Step 1 on the control. At this adjustment the high barrel distortion of the intermediate lens made itself apparent by a "folding" into the center of the image of screen openings *outside* the field being examined. This difficulty was eliminated by placing an aperture (0.150–0.200 in. diameter) in the intermediate lens.

The high rate of change of the magnification at the lower settings makes the system very sensitive to hysteresis effects in either the intermediate or projection

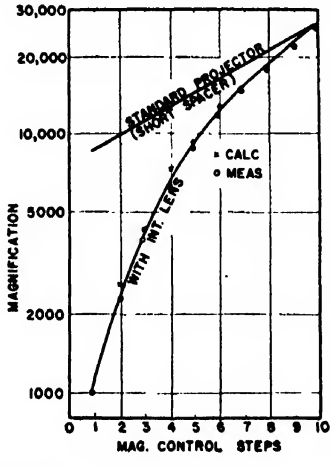

FIG. 6. A plot of the magnification against control position for the standard projector and for the standard projector in conjunction with the intermediate lens.

lenses. This was anticipated and particular care was taken in the choice of the iron used in the intermediate lens. When tested, however, it was found that the value of the lowest magnification was quite sensitive to the history of the lens. The extreme values encountered were 1110 and 990. The lower value was obtained by switching the projection lens circuit off and on several times. The higher value was obtained by leaving the circuit activated and turning the magnification control from Step 1 to Step 10 and back again several times. This manipulation showed that the effect was due to some retentivity in the iron of the projection lens since the two manipulations produce identical changes in the current flowing in the intermediate lens while they produce opposite changes in the current flowing in the projection lens.

In view of this situation, about which nothing could be done, some tests were made to check the reproducibility of the magnification at the lowest value. Four exposures were made of one field with the magnification at Step 1. Between the exposures the entire instrument

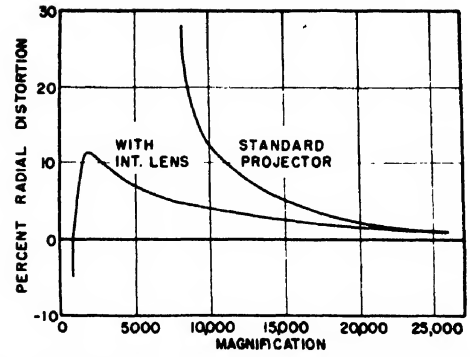

FIG. 7. A plot of percent radial distortion against magnification for the standard projector and for the standard projector in conjunction with the intermediate lens. The distortion is expressed as the percentage increase in magnification (measured in the radial direction) between the center and a point 2.5 cm from the center of the final image field.

was turned off and on and all the controls were changed in a random way. The image was then re-established and focused and the projection lens switch was turned off and on three or four times before making the exposure. The images obtained were then measured carefully. The results obtained are tabulated in Table III. It can be seen that the magnification had a mean value of 994 with a mean square deviation of 1.2 percent. Thus, while the system is sensitive to hysteresis effects, standardizing the magnetic history of the lens makes it possible to obtain very reproducible magnifications.

Since f_2 is proportional to the accelerating potential and the magnification given by Eq. (5) is a difference which approaches zero for the lowest step of the magnification control, it is apparent that the lowest magnifications are more sensitive to voltage changes than with the single projector. To check this, the percentage change in magnification which occurs when the accelerating potential was reduced from 50,000 volts to 45,000 volts was calculated for each step. The results are shown in Figs. 8 and 9; the former being a plot of the magnifications, the latter a plot of the percentage change in magnification. These calculations pointed out another important advantage of this system, namely that for Steps 4 and 5 (magnifications of 7140 and 9000) the *magnification of the system is essentially independent of*

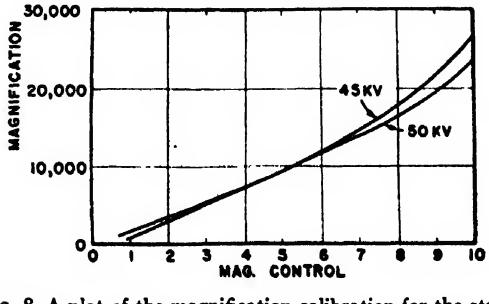

FIG. 8. A plot of the magnification calibration for the standard projector in conjunction with the intermediate lens for accelerating potentials of 45 kv and 50 kv.

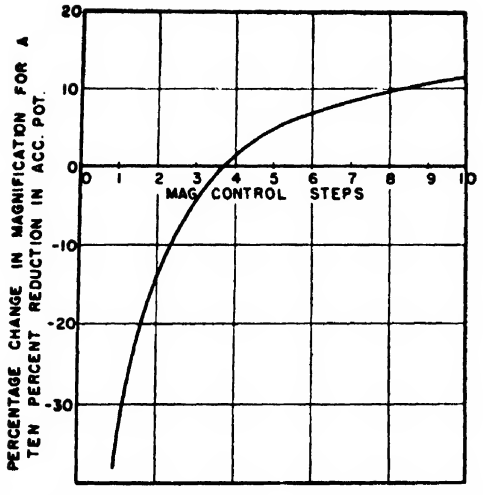

FIG. 9. A plot showing the percentage increase in magnification caused by a 10 percent reduction in accelerating potential.

the value of the accelerating potential. The potential change used in this example was 10 percent, which is many times greater than would be expected in normal use of the microscope, yet the change in magnification was only 1.5 percent for Step 5. Thus, if the specimen is placed accurately in the same position (within 0.001 in.) and the magnetic history of the intermediate and projection lens system is reproduced, the magnification calibration will remain accurate to within approximately 2 percent *for all time.* At all steps with the exception of Step 1, the dependence of the magnification on the accelerating potential (and hence on the state of the standard batteries) is the same or less than with a single projector.

The factors discussed in the preceding paragraph with regard to the dependence of magnification on the accelerating potential, also apply to changes in electron velocity caused by the absorption of energy in thick specimens. Thus, at Taps 4 and 5, chromatic change in magnification is minimized. This feature is particularly useful in the electron microscopy of sections of tissue. With uniformly thick 0.2-micron sections, the chromatic change in magnification has constituted a serious limitation of the field of view obtainable at the low magnifications used. To make the best use of the intermediate lens in the study of tissue sections, it is desirable to use a projection lens arrangement which gives a magnification of 700 to 1000 at Taps 4 and 5. The intermediate lens then becomes ideal for the examination of tissue sections.

A final point with regard to the practical use of the intermediate lens is the possibility of obtaining much lower magnifications for visual survey purposes by simply reducing the objective current. In experimental tests with thin specimens the defocusing could not be detected visually down to magnifications of 200 and was not serious to 100×. This does not apply to thick specimens such as tissue sections where the scattering greatly reduces the depth of field.

V. CONCLUSION AND SUMMARY

A removable intermediate lens has been described which extends the range of magnification in the direction of lower values without sacrificing the accessibility of the objective and projection lens pole pieces. Magnifications covering the range 900 to 24,000 are achieved without breaking the vacuum of the instrument. A complete field of view is obtained at all values and the distortion is in general less than with a conventional projector. The system provides one or two values of the magnification for which chromatic change in magnification is largely eliminated, thus providing the possibility of making an absolute and permanent magnification calibration.

While hysteresis effects in the existing projection lens cause the lowest values of the magnification to be sensitive to the magnetic history of the lens, it is shown that accurately reproducible magnifications can be obtained if the magnetic history is normalized.

The Wall-Quenching of Laminar Propane Flames as a Function of Pressure, Temperature, and Air-Fuel Ratio

RAYMOND FRIEDMAN AND W. C. JOHNSTON
Westinghouse Research Laboratories, East Pittsburgh, Pennsylvania
(Received February 13, 1950)

The quenching distance between plane parallel plates has been measured for propane-air flames at eight pressures ranging from 0.0832 to 2.77 atmos., and air-propane ratios ranging from 11 to 24. Other tests have been made at atmospheric pressure in which (a) the temperature of the quenching plates has been varied from 80° to 715°F, (b) the temperatures both of the inlet gas and the quenching plates have been varied from 80° to 545°F, and (c) a series of six different solid surfaces was tested. The minimum quenching distance is found to occur at an air-propane ratio between 13.5 and 14.0, and is proportional to the minus 0.91 power of pressure. Lean mixtures are found to be slightly less pressure-sensitive. When both the inlet gas and plates are heated, the minimum quenching distance is found to be proportional to the minus 0.5 power of absolute temperature. The quenching effect appears to be independent of the nature of the surface.

INTRODUCTION

THE quenching effect of relatively cold solid surfaces upon pre-mixed laminar gas flames has been explored by several workers, including Holm,[1] Lewis, von Elbe *et al.*,[2–4] Friedman,[5] and Forsyth and Garside.[6] The aim of this investigation is to extend the data for the propane-air system, with particular emphasis on the pressure effect. Quantitative measurements of the effect of surface temperature and of inlet gas temperature are also made for the first time, and a search for catalytic surface effects is described.

The importance of the quenching effect in Bunsen flame flash-back has been brought out by Lewis and von Elbe. The possibility exists that quenching plays a role in blow-off from a flame-holder, although this has not been conclusively demonstrated. Williams, Hottel, and Scurlock[7] found that heating of the flame-holder extends the stability limits considerably, which suggests that quenching by the cold anchor is of some importance. Particularly at low pressures, where the quenching distance is large, one might expect that incomplete combustion near cold burner walls is associated with quenching. Further, it appears reasonable that rich and lean inflammability limits and the low pressure limit of inflammability are governed by quenching effects. To illustrate this, the minimum pressure at which gasoline vapor-air may be ignited in a 2-in. tube is reported by Jones and Spolan[8] as 0.046 atmos. The extrapolated results of this investigation show the minimum quenching distance of propane-air at 0.046 atmos. to be 1.2 in. for plane-parallel walls, and this would be about 35 percent greater in a tube (or 1.6 in.), according to Fig. 6 of reference 3. This 1.6-in. quenching diameter for propane may be compared with the 2-in. tube in which gasoline ceases to propagate flame at this pressure, and it is seen that quenching must be important in burning near the low pressure limit. At atmospheric pressure also, the rich and lean limits as determined by upward propagation in tubes appear to depend upon quenching; data obtained by White[9] for five fuels (H_2, CO, CH_4, C_2H_4, C_2H_2) and air in 1-, 2-, and 3-in. tubes show a progressive broadening of both limits in each case with increasing tube size. The broadening of these limits may be thought of as extensions of the limbs of the familiar U-shaped curve of quenching distance against air-fuel ratio.

This investigation was undertaken, therefore, because of the general importance of the quenching phenomenon in combustion. Measurements were made by measuring the minimum spacing between plane-parallel plates through which flash-back can occur with a given fuel-air ratio, pressure, ambient temperature, and wall temperature. Propane was chosen as the fuel because of availability in pure form, ease in metering, and the

similarity between propane and higher saturated hydrocarbons with regard to burning velocity,[10] minimum ignition energy,[3] flame temperature, and low temperature oxidation characteristics.[11]

EXPERIMENTAL TECHNIQUE

The procedure for determining the quenching distance consists in producing a flame stabilized on a rectangular port whose length-to-width ratio is always greater than 3.6. When the flow to the burner is quickly reduced to zero the flame will either be quenched by the plates or will flash back through the slit, depending on the air-fuel ratio of the mixture and the ambient conditions. The critical mixture is determined by testing a series of mixtures until a composition is found that separates a region of flash-back from a region of quenching. In general, there is a rich as well as a lean critical mixture corresponding to any particular set of conditions.

Variable-Pressure Flow Apparatus

The apparatus for measuring the quenching distance at various pressures is shown schematically in Fig. 1. A mixture of air and propane of controlled composition and pressure is supplied to the combustion chamber by a flow system. A thermocouple connected to a microammeter indicates the occurrence of flash-back, which can also be observed through a Pyrex window. The flow is reduced to zero by the action of the solenoid valves, surge chamber, and throttling valve. It was found that the sudden movement of the plunger in the solenoid valve was sufficient to disturb the flame, so that a surge chamber and throttling valve were necessary to smooth the flow during this period. The throttling valve was set to reduce the flow to zero in about 0.1 to 0.3 sec., although this setting was not found to be critical, and the data were reproducible over a fairly wide range of valve settings.

The vertical approach section to the burner is four inches in diameter and contains glass beads held in position by 60-mesh copper screens. The jaws of the slit are $\frac{3}{16}$-in. copper plates with water-cooling tubes attached. Slit widths are adjusted by thickness gauges.

The propane* used for these tests is reported to be 99.0 percent pure. The air is supplied at 80 p.s.i. g and contains 0.33 percent by weight water vapor. The effect of this concentration of water vapor upon the data appears to be negligible since the atmospheric curve of Fig. 2 agrees with previous work done with dry air.

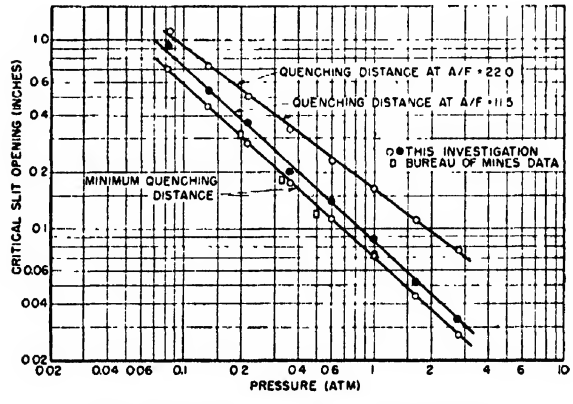

FIG. 3. The dependence of propane-air flame quenching on pressure.

The flow meters were calibrated against a Sargent wet-test meter.

Variable-Temperature Flow Apparatus

The variable-temperature apparatus consists of identical air and propane flow systems. In each system the gas from a tank is reduced by a regulator and supplied to a critical-flow orifice.[12] The temperature and pressure at the orifice determine the density and hence the mass flow of gas. The pre-mixed gases are supplied to the burner through a hand-operated valve which is used for reducing the flow when testing. The burner consists of parallel copper plates with independent means for electrical heating of the plates and the gas. Tests showed that the results are independent of the plate thickness over the range from $\frac{1}{16}$ to $\frac{3}{16}$ in., as long as the inlet gases and the plates are at the same tempera-

ture. Thermocouples are embedded in the plates for measuring the temperature of the quenching surface. Results indicate that the temperature gradient in the copper is negligible, being about 1°F per $\frac{1}{8}$ in. near the quenching surface when the flame is burning and the plates are water-cooled.

Factors Limiting Extent of Data

It is of interest to discuss the factors limiting the range of testing at the highest and lowest pressures and at the richest and leanest compositions. On the rich side, when air-propane ratios were below about 11, moving ridges appeared in the flame surface, often in a herringbone pattern. On further enrichment of the mixture, the flame would resolve itself into several individual cellular flames, each convex toward the unburned gas. Similar examples of polyhedral and cellular flames have been described in the literature.[13,14] When attempts were made to quench these flames, erratic results were obtained. Since these rich mixtures are characterized by very low burning velocities, it appears that sufficient time is available for surrounding gases to mix with the combustible gas beneath the flame surface.

On the lean side, it became progressively more difficult to ignite and stabilize the flames, the tendency for blow-off being very pronounced. At the lowest pressure the primary difficulty was ignition; it was found necessary to ignite each mixture at about 0.13 atmos. and then gradually reduce the pressure to 0.0832 atmos. for testing. This pressure represents substantially the lowest that can be obtained with the available pumping equipment. At the highest pressure, 2.77 atmos., and slit openings of 0.030 in. and less, testing was difficult because of excessive moisture condensation from the flame upon the plates.

RESULTS

Precision and Accuracy

The data showing the effect of pressure upon quenching appear in Fig. 2. There are 118 points, each representing a group of bracketing tests; 78 percent of these points are within one percent of the curves, and 97 percent are within three percent of the curves. No points have been discarded. The points were not obtained in any regular sequence. Thus, the precision, or

reproducibility, of the test procedure is seen to be satisfactory.

An indication of accuracy was obtained by determining the quenching curve at 1 atmos. and 75°F both with the variable-pressure and the variable-temperature apparatus, these two flow systems having been independently calibrated. Also the burner geometry and method of flow reduction to produce flash-back were somewhat different in the two cases. Upon comparing the two curves at a given slit opening, the air-propane ratios never differed by more than two percent. The minimum slit openings differed by 5.5 percent.

The Bureau of Mines investigators[4] report data for minimum spacing of flanged electrodes for ignition in a static system with a spark of minimum energy. Their data for propane-air between 0.2 and 1 atmos. agree very well with the results of this investigation, as shown in Fig. 3.

Effect of Pressure and Composition

In Table I and Fig. 2, data are presented showing critical slit openings for quenching of propane-air flames from 0.0832 to 2.77 atmos., at 75°F ambient temperature. At each pressure, a U-shaped curve is obtained with the minimum at a mass air-propane ratio near 14 at the lower and 13.5 at the higher pressures. The stoichiometric air-propane ratio is 15.65. The minima are plotted against pressure in Fig. 3, a log-log plot, and a straight line is obtained, from the slope of which it follows that the minimum quenching distance is proportional to the minus 0.91 power of the pressure. It may be noticed in Fig. 2 that the pressure effect upon quenching is slightly smaller for the leaner mixtures. Upon plotting in Fig. 3 the quenching distance for an air-propane ratio of 22.0 against pressure, a straight line is again obtained, of reduced slope. The quenching distance is proportional to the minus 0.76 power in this case. For a mixture on the rich side of the minimum (air-propane ratio of 11.5), the minus 0.91 power is still valid.

The Bureau of Mines spark-quenching data for propane-air are seen to be consistent with these results both in magnitude and in pressure variation. Further, the Bureau of Mines spark-quenching data for methane-air between 0.1 and 1 atmos. reveal a minus 0.88 power pressure dependence when the minima are plotted in this fashion.

Effect of Temperature and Composition

In the first series of temperature tests at atmospheric pressure, the quenching plates were electrically heated to various temperatures while the inlet gas was maintained at 80°F. Results are shown in Fig. 4. It is seen that the quenching effect is diminished by increasing the plate temperature, as would be expected. In tests of this type, a certain unavoidable heating of the gas occurs as it flows through the slit. Rough measurements showed that the gas was heated to about 180°F when the plates were at 540°F. Because of this effect, the data of Fig. 4 are only semiquantitative.

Other tests were made at atmospheric pressure in which both the gas and the plates were heated to the same temperature, with results shown in Fig. 5 and Table II. The quenching effect is seen to become regularly less as the temperature is increased. For rich and stoichiometric flames, the quenching distance varies with about the

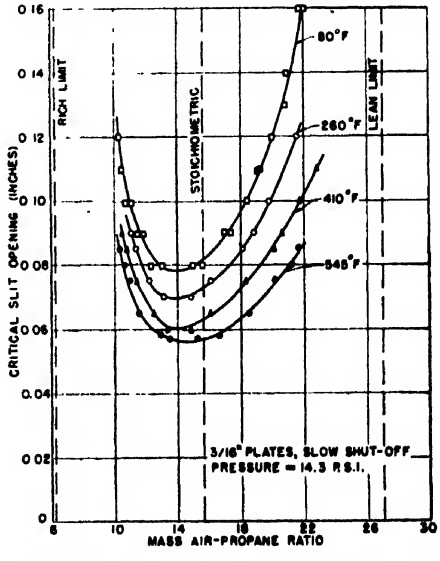

FIG. 5. Quenching of propane-air flames with various inlet temperatures (gas and plates at same temperature).

minus 0.5 power of absolute temperature, while for lean flames the negative exponent increases, being 0.85 at an air-propane ratio of 21.0.

Effect of Surface Coatings

A series of surface coatings on copper was investigated, with the gas and $\frac{3}{16}$-in. plates at 410°F. No measurable differences in quenching behavior were observed for either lean or rich mixtures, for any of the following types of surfaces: nickel, platinum, bright gold, roughened gold, potassium chloride, and water glass. This result indicates that neither the catalytic power of the surface nor its absorptivity for radiation significantly affects the quenching phenomenon.

Electromagnetic Field of the Conical Horn*

MARVIN G. SCHORR** AND FRED J. BECK, JR.
Yale University, New Haven, Connecticut
(Received January 20, 1950)

Maxwell's equations are solved for a perfectly conducting conical wave guide and the propagation coefficients of this guide are discussed. The field at the mouth of a finite conical horn is estimated and the radiation therefrom is calculated in integral form. These integrals are solved in series form for horns of small flare angle and moderate length and the results compared with experiment.

INTRODUCTION

THE use of electromagnetic horns for both matching purposes and enhanced radiation directivity in high frequency antennae was suggested by Southworth[1] and Barrow[2] in 1936. Since that time many observers have verified these properties and several attempts have been made to attain a satisfactory agreement between theory and experiment. The early workers calculated radiation phenomena from the scalar Kirchhoff-Huygens principle, but it was soon recognized that this formalism was inadequate, the major defect being in the assumption of continuity of the fields at the aperture from which the radiation ensues. Two rigorously correct methods are available for computing radiation from horn structures. They are the vector diffraction theory of Stratton and Chu,[3] and the assumed field technique recently restated by Schelkunoff.[4] A recent paper by Woonton, Hay, and Vogan[5] gives a good discussion of some of these matters.

The great majority of the existent theoretical work has been done for propagation in and radiation from uniform wave guide and sectoral horns. Buchholz[6] gave a rather complete analysis of electromagnetic fields in conical wave guide and also commented on a method of exciting such a guide. However he treated only the special case of azimuthally symmetric guided waves. Excellent experimental work is available in the literature on both conical[7] and pyramidal horns[8] and it is the purpose of this paper to show that the rigorous assumed-field technique, when applied to the conical horn, yields good agreement with experiment over a range of cone angles for which the radiation integrals may be satisfactorily evaluated.

FIELDS IN CONICAL WAVE GUIDE

Let us first consider the permissible electromagnetic fields inside a perfectly conducting conical wave guide of semi-infinite extent, filled with a dielectric of permeability μ and permitivity ϵ, ϵ being complex if the dielectric is lossy. The choice of a spherical (r, θ, ϕ) coordinate system is clearly indicated, and if the apex of the cone coincides with the origin of coordinates and the polar axis is the longitudinal axis of symmetry of the cone, then conical surfaces will coincide with surfaces of constant colatitude and the flare angle of the cone will be measured by the colatitude of its surface. The flare angle, so defined and henceforth used, is then one-half the total angle subtended by the cone. The cone is assumed excited near the apex in such a manner that the fields propagate positively radially outward; also the azimuthal reference axis is chosen so that a single trigonometric function describes the azimuthal variations of the fields. The permissible fields are well known and are given by:

Transverse-Electric Waves

$$
\begin{aligned}
E_r &= 0 \\
E_\theta &= Bj\omega\mu \cos m\phi h_n^{(2)}(kr) P_n^m(x) \\
E_\phi &= -Bj\omega\mu \sin\theta \sin m\phi h_n^{(2)}(kr) P_n^{m\prime}(x) \\
H_r &= B[n(n+1)/r] \sin m\phi h_n^{(2)}(kr) P_n^m(x) \\
H_\theta &= -B \sin\theta \sin m\phi [(1/r) h_n^{(2)}(kr) \\
&\qquad + k h_n^{(2)\prime}(kr)] P_n^{m\prime}(x) \\
H_\phi &= B[m/\sin\theta] \cos m\phi [(1/r) h_n^{(2)}(kr) \\
&\qquad + k h_n^{(2)\prime}(kr)] P_n^m(x);
\end{aligned}
\tag{1}
$$

Transverse-Magnetic Waves

$$
\begin{aligned}
E_r &= B[n(n+1)/r]\sin m\phi h_n^{(2)}(kr)P_n^m(x)\\
E_\theta &= -B\sin\theta\sin m\phi[(1/r)h_n^{(2)}(kr)\\
&\qquad +kh_n^{(2)\prime}(kr)]P_n^{m\prime}(x)\\
E_\phi &= B[m/\sin\theta]\cos m\phi[(1/r)h_n^{(2)}(kr)\\
&\qquad +kh_n^{(2)\prime}(kr)]P_n^m(x)\\
H_r &= 0\\
H_\theta &= B(j\omega\epsilon m/\sin\theta)\cos m\phi h_n^{(2)}(kr)P_n^m(x)\\
H_\phi &= Bj\omega\epsilon\sin\theta\sin m\phi h_n^{(2)}(kr)P_n^{m\prime}(x),
\end{aligned}
\tag{2}
$$

where the primed function always denotes the derivative with respect to the argument, and the wave number $k=2\pi/\lambda$, λ being the free space wave-length and $\omega^2=\mu\epsilon$. The $h_n^{(2)}(kr)$ and $P_n^m(x)$ are the spherical Hankel function of the second kind and associated Legendre function of the first kind respectively, and $x=\cos\theta$. The spherical Hankel function of the first kind does not appear since it represents a wave traveling in the negative radial direction, contrary to hypothesis; the associated Legendre function of the second kind also does not appear since it has a singularity on the polar axis which is contained in the region considered. The spherical Hankel function of the second kind has a singularity at the origin but this is of no consequence since, as will be seen later, the neighborhood of the origin is very highly attenuating so that no energy ever reaches it. The single-valuedness of the solutions in azimuth requires that m be an integer which we may take as positive. The colatitude boundary condition, namely $E_r=E_\phi=H_\theta=0$ at $\theta=\theta_0$, requires for TE waves,

$$[-\sin\theta P_n^{m\prime}(\cos\theta)]_{\theta=\theta_0}=0, \tag{3}$$

and for TM waves,

$$P_n^m(\cos\theta_0)=P_n^m(x_0)=0. \tag{4}$$

Hence n must be a root of the multibranched transcendental Eqs. (3) or (4) considered as functions of the order n of the associated Legendre function. In general n will be non-integral and a function of the flare angle θ_0 of the cone; we may consider only the positive roots. For small integral values of n, $0<n\leqq 10$, excellent tables of associated Legendre functions are available for determining the zeros of Eqs. (3) and (4)[9] and reasonably accurate interpolation to non-integral orders is possible. For large orders the zeros may be determined from the asymptotic expansions of these functions.

The solutions of Eqs. (1) and (2) then form a doubly infinite set corresponding to all positive integral m and all positive n giving zeros of Eqs (3) and (4). Those modes actually present in the guide will of course be determined by the source of excitation.

It is convenient in discussing conical wave guide to adopt the cylindrical wave guide terminology since if we allow a given cross section of the cone to remain constant and let the flare angle approach zero, then in the limit the cone goes over into a hollow cylinder. The permissible modes in conical guide are hence designated TE_{mp} or TM_{mp} having m field variations in one azimuthal circuit and p field variations from the polar axis to the cone wall. The designation of propagation constants for conical guide does not, however, follow in the usual sense. In conical wave guide the fields are not periodic functions of the propagation coordinate r and propagation constant loses much of its intuitive meaning. However, in lieu of a better definition, a complex propagation coefficient is defined for conical wave guide, in the manner used by Barrow and Chu for sectoral horns,[10] by

$$\gamma(Q,r)=-1/Q(\partial Q/\partial r)=-(\partial/\partial r)(\log Q), \tag{5}$$

where Q is any field component. In general γ will be a function of r and will be different for various field components. This definition, it may be observed, reduces directly to the usual definition of the propagation constant if Q is simple harmonic in r, and γ is then a true constant. For regions in which γ is not too rapid a function of radius useful information is still obtained.

In an entirely similar manner we may define a pseudo guide wave-length $\lambda_g(Q,r)=2\pi/Im\gamma$, and a pseudo phase velocity $v_p(Q,r)=\omega/Im\gamma$. From Eq. (1) for TE waves and the asymptotic expansions of the spherical Hankel function for large and small argument

$$
h_n^{(2)}(kr)=\begin{cases}\left(\frac{\pi}{4}\right)^{\frac{1}{2}}\dfrac{1}{(n+\frac{1}{2})!}\left(\dfrac{kr}{2}\right)^n\\ \qquad +j\left(\dfrac{\pi}{4}\right)^{\frac{1}{2}}(n-\frac{1}{2})!\left(\dfrac{2}{kr}\right)^{n+1}, & kr\ll 1\\ \dfrac{1}{kr}\exp\left[-j\left(kr-\dfrac{n+1}{2}\pi\right)\right], & kr\gg 1\end{cases}
\tag{6}
$$

where $(n+\frac{1}{2})!$ has been written for the gamma function $\Gamma(n+\frac{3}{2})$, we may obtain the parameters of Table I which gives the propagation coefficient, the pseudo guide wave-length, and the pseudo phase velocity for the E_θ and H_ϕ components. Following Barrow and Chu we designate $kr\gg 1$ as a transmission region and that for which $kr\ll 1$ an attenuation region. In the transmission region the waves behave asymptotically as spherical waves in a free medium while in the attenuation region the behavior is similar to that in a uniform cross section guide near the cut-off wave-length.

These results can be expected to have physical validity only if the propagation coefficient γ is not too severe a function of r, or in other words, if the radial space variation is almost periodic. In the region near the apex where this condition is not true two anomalies arise. First, the phase of $\gamma(H_\phi)$ in the attenuation region is negative, which in uniform guide indicates a wave traveling in the negative radial direction, contrary to

[9] Math. Tables Project, Columbia University Press, New York (1945).

[10] W. L. Barrow and L. J. Chu, Proc. I.R.E. 27, 51 (1939).

hypothesis. Second, the group velocity v_g, if computed from the usual relation $v_g = d\omega/d(I_m\gamma)$ turns out to be of the same form as the phase velocity and the product of group and phase velocities is not c^2, as is required for a dispersionless medium. These anomalies can be ascribed to the severe aperiodicity of the Hankel functions in the region near the apex. It should be emphasized that the physical significance of the propagation coefficients here developed should not be exaggerated; however the implications of the results are of value in understanding the phenomena occurring.

Additional light on the properties of conical wave guide may be obtained from the behavior of the Poynting vector and power flow in the guide. It is not difficult to show that the angular components of the Poynting vector S are always pure imaginaries whereas the radial component is in general complex. In the attenuating region the radial component is largely imaginary along with the angular components. These latter decrease as $1/r^3$ at large distances and soon reach a negligible value compared with the radial component which decreases only as $1/r^2$.

From Eqs. (1) and (2), and the asymptotic expansions of the Hankel functions, Eq. (6), it is readily observed that in the transmission region all transverse field components decrease with reciprocal radius while the radial components decrease as reciprocal radius squared. As the wave progresses down the guide it therefore becomes more nearly a TEM wave matched to free medium, as may be seen from the wave impedance. For TE and TM waves, respectively, the wave impedance is given asymptotically by

$$kr \gg 1, \quad \begin{cases} Z_E = (\mu/\epsilon)^{\frac{1}{2}} \\ Z_H = (\mu/\epsilon)^{\frac{1}{2}} \end{cases}$$

$$kr \ll 1, \quad \begin{cases} Z_E = (\mu/\epsilon)^{\frac{1}{2}} \left[\dfrac{\pi(2n+1)}{n(n-\frac{1}{2})!(n+\frac{1}{2})!} \times \left(\dfrac{kr}{2}\right)^{2n+2} + j\dfrac{4}{nkr} \right] \\ Z_H = (\mu/\epsilon)^{\frac{1}{2}} \left[\dfrac{\pi(2n+1)}{(n-\frac{1}{2})!(n+\frac{1}{2})!} \times \left(\dfrac{kr}{2}\right)^{2n} - j\dfrac{n}{kr} \right]. \end{cases} \quad (8)$$

In regions near the apex the wave impedances are largely reactive, inductive for TE and capacitive for TM waves. As the wave moves into the transmission region the reactive part decreases, the resistive part increases and approaches asymptotically the characteristic impedance $(\mu/\epsilon)^{\frac{1}{2}}$ of the free medium.

RADIATION FROM A CONICAL HORN

Let us consider a cylindrical wave guide feeding a concentric conical wave guide. We will assume the cylindrical guide is excited in its lowest mode, TE_{11}, as is usually the case. At the junction of the uniform guide with the cone there is a discontinuity in the slope of the conducting boundary and higher order modes are required to satisfy the boundary conditions, the fundamental mode being partially reflected and partially transmitted. In the cylindrical guide the higher order modes will be rapidly attenuated but the behavior in the conical guide depends on whether the waves are introduced in the attenuating or transmitting regions of the cone. Certainly the cone will be transmitting for the fundamental mode on purely physical grounds since the diameter of the cone cross section is always greater than that of the uniform guide. The higher order modes, however, may be in an attenuating region and we have seen that such modes have an attenuation coefficient linearly proportional to the mode order, n, of the wave. The distance that a given order mode travels in an attenuating region may be calculated in a strictly qualitative manner, if it is assumed that in conical guide any order wave is in an attenuating region until the cross-sectional diameter of the cone approximates the diameter of a cylindrical guide just permitting propagation of that order wave in the uniform guide. If the diameter of the uniform guide operating in its lowest mode is D_0, and if the diameter corresponding to the nth mode is D_n, then the distance of travel of the nth mode wave in an attenuating region of the conical guide of flare angle θ_0 may be taken as

$$d = (D_n - D_0)/(2\sin\theta_0).$$

Small flare angles result in long journeys through attenuating regions. Also small flare angles result in smaller discontinuities at the cylinder-cone junction and, hence, require less higher mode energy to satisfy the boundary conditions. These factors both markedly discriminate against higher order modes.

In the conical guide, then, there will be present TE and/or TM waves composed principally of a fundamental and contaminated with higher order modes whose magnitudes depend on the flare angle and length of the guide. As the wave propagates in the positive radial direction, Eqs. (1), (2), and (6) show that, asymptotically, the radial components decrease only as reciprocal radius. Hence, some distance down the conical guide the wave will be almost transverse electromagnetic with only a small radial component. As this occurs, the wave impedance approaches that of a wave in free medium. Cutting off the conical guide at this distance should not materially alter the fields anywhere inside the cone since it is essentially matched into free space; very little energy will be reflected from the mouth. The small radial component still present is just sufficient to close the loops of the field lines of the TEM wave in free medium. The open ended cone thus becomes a source of radiation.

The calculation of the radiation characteristics of such a source involves two approximations at the outset:

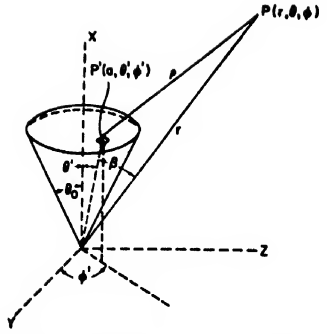

FIG. 1. Coordinate system for radiation calculations.

(1) the field at the mouth of the horn is assumed to be that which would exist at that cross section if the horn extended to infinity; and (2) there is assumed to be no field leakage around the rim of the mouth to the exterior surface of the horn. These matters have been discussed at length by others and will here be assumed valid provided the cone flare angle is not too great and its length is not too short.

The assumed field technique of Love,[11] MacDonald,[12] and later Schelkunoff[4] leads to the following expressions for the electric and magnetic intensities.

$$\begin{aligned} E&=k^2A+\nabla\nabla\cdot A-j\omega\mu\nabla\times F,\\ H&=k^2F+\nabla\nabla\cdot F+j\omega\epsilon\nabla\times A, \end{aligned} \tag{9}$$

where the vector potentials A and F are given by

$$\begin{aligned} F&=-\frac{1}{j\omega\mu}\int_{S'}\frac{[n\times E']ds'}{4\pi\rho},\\ A&=\frac{1}{j\omega\epsilon}\int_{S'}\frac{[n\times H']ds'}{4\pi\rho}. \end{aligned} \tag{10}$$

and E and H are the fields at any point in space distant ρ from a surface element ds' on which a field E' and H' exist, n being the unit vector normal to the surface and brackets indicating retardation in the Lorentz sense. The TE field at the mouth of the horn, S', is given by Eq. (1), and Fig. 1 shows the coordinate system used. Note that primed coordinates refer to the cone mouth while unprimed coordinates refer to the field point $P(r, \theta, \phi)$. Since the integrands are vector quantities the change in direction of the unit spherical vectors must be considered. This is most readily accomplished by expressing all vectors in rectangular coordinates. Noting that for the distant field

$$\rho\doteq r-a\cos\beta,$$

and

$$\cos\beta=\cos\theta\cos\theta'+\sin\theta\sin\theta'\cos(\phi-\phi');$$

and defining B_E and B_H by

$$B_E=B\frac{a^2}{4\pi r}e^{-jkr}h_n^{(2)}(ka)$$

$$B_H=B\frac{a^2}{j\omega\epsilon 4\pi r}e^{-jkr}\left[\frac{1}{a}-h_n^{(2)}(ka)+kh_n^{(2)\prime}(ka)\right],$$

so that $B_H/B_E=-Z_H$ at the spherical cap $r=a$; then the rectangular components of F and A are given by:

$$\begin{aligned} F_x&=-B_E\int_0^{\theta_0}\int_0^{2\pi}e^{jka\cos\beta}\sin m\phi'\\ &\qquad\times\sin^3\theta' P_n^{m\prime}(x')d\theta'd\phi',\\ F_y&=B_E\int_0^{\theta_0}\int_0^{2\pi}e^{jka\cos\beta}\{mP_n^m(x')\cos m\phi'\sin\phi'\\ &\quad+P_n^{m\prime}(x')\sin m\phi'\cos\phi'\sin^2\theta'\cos\theta'\}d\theta'd\phi',\\ F_z&=-B_E\int_0^{\theta_0}\int_0^{2\pi}e^{jka\cos\beta}\{mP_n^m(x')\cos m\phi'\cos\phi'\\ &\quad-P_n^{m\prime}(x')\sin m\phi'\sin\phi'\sin^2\theta'\cos\theta'\}d\theta'd\phi',\\ A_x&=B_H\int_0^{\theta_0}\int_0^{2\pi}e^{jka\cos\beta}mP_n^m(x')\\ &\qquad\times\cos m\phi'\sin\theta'd\theta'd\phi',\\ A_y&=-B_H\int_0^{\theta_0}\int_0^{2\pi}e^{jka\cos\beta}\\ &\quad\times\{mP_n^m(x')\cos m\phi'\cos\phi'\cos\theta'\\ &\quad-P_n^{m\prime}(x')\sin m\phi'\sin\phi'\sin^2\theta'\}d\theta'd\phi',\\ A_z&=-B_H\int_0^{\theta_0}\int_0^{2\pi}e^{jka\cos\beta}\\ &\quad\times\{mP_n^m(x')\cos m\phi'\sin\phi'\cos\theta'\\ &\quad+P_n^{m\prime}(x')\sin m\phi'\cos\phi'\sin^2\theta'\}d\theta'd\phi'. \end{aligned} \tag{11}$$

The azimuthal integrations are over an orthogonal interval and present no difficulty, but the colatitude integrations are not over an orthogonal range and the evaluation of these integrals does not seem possible, analytically, in their present form. For small flare angles approximations may be made which permit the evaluation of the integrals in a sufficiently converging series.

The horn is assumed excited in the dominant TE mode used by Southworth and King in an experimental study of the radiation patterns of conical horns with which the calculated patterns are compared. We take

$$\begin{aligned} \cos\beta&\doteq\cos\theta+\sin\theta\sin\theta'\cos(\phi-\phi')\\ P_n^1(\cos\theta')&\doteq\sin(\alpha\theta')P_n^1(\cos\theta_0)\\ P_n^{1\prime}(\cos\theta')&\doteq-\frac{\alpha\cos(\alpha\theta')}{\sin\theta'}P_n^1(\cos\theta_0), \end{aligned} \tag{12}$$

where $\alpha=\pi/2\theta_0$. The Legendre function approximation may be checked against tabulated values for integral n and is very good except for a small range where θ' is nearly equal to θ_0. The approximation in $\cos\beta$ involves neglect of the variation of $\cos\theta'$ over the aperture of

TABLE I. Propagation coefficients in conical wave guide.

		E_θ component	H_ϕ component
$kr \gg 1$	γ	$1/r+jk$	$1/r+jk$
	λ_g	λ	λ
	v_p	c	c
$kr \ll 1$	γ	$\frac{n+1}{r}+jk\frac{\pi}{2}\frac{2n+1}{(n-\frac{1}{2})!(n+\frac{1}{2})!}\left(\frac{kr}{2}\right)^{2n}$	$\frac{n+2}{r}-jk\frac{\pi}{2}\frac{(2n+1)(n+1)}{n(n-\frac{1}{2})!(n+\frac{1}{2})!}\left(\frac{kr}{2}\right)^{2n}$
	λ_g	$\lambda\cdot\frac{2}{\pi}\frac{(n-\frac{1}{2})!(n+\frac{1}{2})!}{2n+1}\left(\frac{2}{kr}\right)^{2n}$	$\lambda\cdot\frac{2}{\pi}\frac{n(n-\frac{1}{2})!(n+\frac{1}{2})!}{(2n+1)(n+1)}\left(\frac{2}{kr}\right)^{2n}$
	v_p	$c\cdot\frac{2}{\pi}\frac{(n-\frac{1}{2})!(n+\frac{1}{2})!}{2n+1}\left(\frac{2}{kr}\right)^{2n}$	$c\cdot\frac{2}{\pi}\frac{n(n-\frac{1}{2})!(n+\frac{1}{2})!}{(2n+1)(n+1)}\left(\frac{2}{kr}\right)^{2n}$

the horn. The phase factor may now be written as

$$e^{jka\cos\beta}=e^{jka\cos\theta}\cdot e^{j\frac{1}{2}ka\sin\theta\sin(\theta'+\phi-\phi')}\cdot e^{j\frac{1}{2}ka\sin\theta\sin(\theta'-\phi+\phi')},$$

and the last two factors expanded in a Fourier-Bessel series of the form

$$e^{jx\sin y}=\sum_{p=-\infty}^{\infty}J_p(\gamma)e^{jpy}.$$

Setting

$$\gamma=\tfrac{1}{2}ka\sin\theta,$$

$$e^{jka\cos\beta}=e^{jka\cos\theta}\sum_{p=-\infty}^{\infty}\sum_{s=-\infty}^{\infty}J_p(\gamma)J_s(\gamma)\cdot e^{j[(p+s)\theta'+(p-s)\phi-(p-s)\phi']}. \tag{13}$$

The neglect of the variation of $\cos\theta'$ over the mouth is thus seen to be a first order approximation in that terms of the second order and higher are neglected. It should be noted that the extent of the approximation is a function of the length, ka, of the horn and, for long horns, the neglected portion of the phase factor may have a considerable effect on the integrals, even though θ' varies over only a small range. The approximation is best for short horns and for co-latitudes far removed from the polar axis.

In the expansion, Eq. (13), the azimuthal coordinate ϕ' appears only in the trigometric form $e^{-j(p-s)\phi'}$ and this expansion when inserted in Eq. (11) is multiplied by other trigonometric functions of ϕ' and integrated over the orthogonal interval $(0, 2\pi)$. This will cause the vanishing of all terms of the double sum, Eq. (13), except those for which a definite constant relation exists between the indices p and s, and the double sum is reduced to a single sum over the index p. The vector potentials then become, from Eq. (11) with $m=1$,

$$F_x=-j\pi/2B_E P_n^1(x_0)e^{j(ka\cos\theta+\phi)}\times\sum_{p=-\infty}^{\infty}J_p(\gamma)J_{p-1}(\gamma)f_x(p,\theta_0),$$

$$F_y=-j\pi/2B_E P_n^1(x_0)e^{j(ka\cos\theta+2\phi)}\times\sum_{p=-\infty}^{\infty}J_p(\gamma)J_{p-2}(\gamma)f_y(p,\theta_0),$$

$$F_z=-\pi B_E P_n^1(x_0)e^{jka\cos\theta}\sum_{p=-\infty}^{\infty}\{\langle J_p(\gamma)\rangle_M^2 f_z(p,\theta_0)+1/2e^{j2\phi}J_p(\gamma)J_{p-2}(\gamma)f_y(p,\theta_0)\},$$

$$A_x=\pi B_H P_n^1(x_0)e^{j(ka\cos\theta+\phi)}\times\sum_{p=-\infty}^{\infty}J_p(\gamma)J_{p-1}(\gamma)a_x(p,\theta_0),$$

$$A_y=-\pi B_H P_n^1(x_0)e^{jka\cos\theta}\sum_{p=-\infty}^{\infty}\{\langle J_p(\gamma)\rangle_M^2 a_y(p,\theta_0)+1/2e^{j2\phi}J_p(\gamma)J_{p-2}(\gamma)a_z(p,\theta_0)\},$$

$$A_z=j\pi/2B_H P_n^1(x_0)e^{j(ka\cos\theta+2\phi)}\times\sum_{p=-\infty}^{\infty}J_p(\gamma)J_{p-2}(\gamma)a_x(p,\theta_0); \tag{14}$$

where the "f" and "a" functions are defined by

$$f_x(p,\theta_0)=(\alpha/2)\{g_1(2p+1,\theta_0)-2g_1(2p-1,\theta_0)+g_1(2p-3,\theta_0)\},$$

$$f_y(p,\theta_0)=-j(\alpha/4)\{g_1(2p,\theta_0)+g_2(2p-2,\theta_0)-g_1(2p-4,\theta_0)\},$$

$$f_z(p,\theta_0)=j(\alpha/4)\{g_1(2p+2,\theta_0)-g_2(2p,\theta_0)-g_1(2p-2,\theta_0)\},$$

$$a_x(p,\theta_0)=(\alpha/8)\{g_2(2p,\theta_0)-g_2(2p-2,\theta_0)\},$$

$$a_y(p,\theta_0)=-j(\alpha/2)\times\{\tfrac{1}{4}[g_2(2p+1,\theta_0)+g_2(2p-3,\theta_0)]-[g_1(2p+1,\theta_0)-g_1(2p-3,\theta_0)]\},$$

$$a_z(p,\theta_0)=-j(\alpha/2)\times\{\tfrac{1}{4}[g_2(2p-1,\theta_0)+g_2(2p-3,\theta_0)]+[g_1(2p-1,\theta_0)-g_1(2p-3,\theta_0)]\}, \tag{15}$$

and the "g" functions are given by

$$g_1(K,\theta_0)=\frac{\alpha e^{jK\theta_0}-jK}{K^2-\alpha^2}$$

$$g_2(K,\theta_0)=-\frac{4}{\alpha}\frac{Ke^{jK\theta_0}-j\alpha}{K^2-\alpha^2}. \tag{16}$$

The "g" functions and hence "f" and "a" converge as reciprocal summation index provided $|K|$ is greater

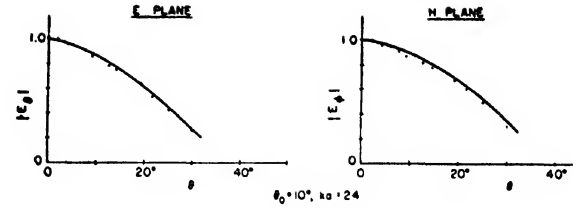

FIG. 2. Radiation pattern for conical horn of 10° flare angle. Solid curve is experimental and dotted points are calculated.

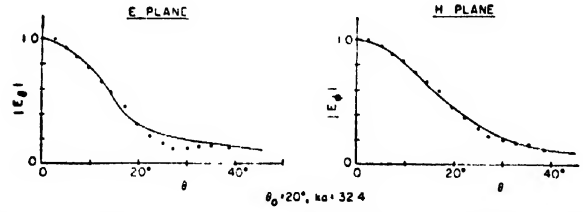

FIG. 3. Radiation pattern for conical horn of 20° flare angle. Solid curve is experimental and dotted points are calculated.

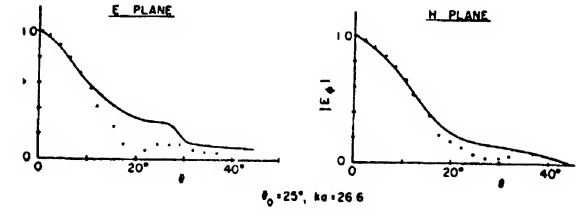

FIG. 4. Radiation pattern for conical horn of 25° flare angle. Solid curve is experimental and dotted points are calculated.

than α. The product of the two Bessel functions converges rapidly once the order p is greater than the argument γ. Hence the summations of Eq. (14) converge rapidly and, in general, only about γ terms must be included in the sum. These summations are over all integral values of p, positive and negative; however, the symmetry properties of the summands permits expression of the series as sums over only the positive integral indices. The only non-vanishing summations are those for which the total summand is an even function of the index of summation.

The vector potentials vary with radius as e^{-ikr}/r and thus if one ignores those radiation field components which vary faster than reciprocal radius, then Eq. (9) reduces to

$$E=k^2\frac{e^{-ikr}}{r}\{\theta_1[(\mu/\epsilon)^{\frac{1}{2}}F_\phi+A_\theta]-\phi_1[(\mu/\epsilon)^{\frac{1}{2}}F_\theta-A_\phi]\},$$

$$H=k^2\frac{e^{-ikr}}{r}\{\theta_1[F_\theta-(\epsilon/\mu)^{\frac{1}{2}}A_\phi]+\phi_1[F_\phi+(\epsilon/\mu)^{\frac{1}{2}}A_\theta]\},$$

where F and A are now the angular parts of the vector potentials, the radial parts being included in the e^{-ikr}/r factor. A receiving dipole oriented parallel to the E plane will then measure electric intensity patterns pro-

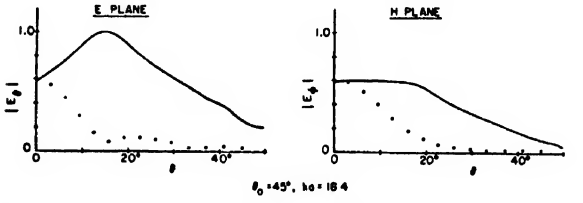

FIG. 6. Radiation pattern for conical horn of 45° flare angle. Solid curve is experimental and dotted points are calculated.

portional to

$$E_{\theta E}\propto F_z-A_x\sin\theta+A_y\cos\theta$$
$$E_{\phi H}\propto -F_x\sin\theta+F_z\cos\theta+A_y$$

in the $E(\phi=0)$ and $H(\phi=\pi/2)$ planes, respectively.

The "g," "f," and "a" functions have been tabulated for various flare angles up to 45 degrees. If γ is restricted to values less than eight, then ten terms of the series are adequate. The field point colatitude at which numerical information is obtained is $\theta=\arcsin 2\gamma/ka$ and will be a function of the length of the horn. In general, it is found that longer horns give sharper radiation patterns and the increased resolution and decreased maximum field angle is not undesirable. However, no information on the small scale radiation at large polar angles is predicted. The greatest contribution to the radiation arises from the F_z and A_y components; F_x and A_x are negligible in all horns up to about 30 degrees flare angle.

Radiation patterns were calculated for horn flare angles from 10 to 45 degrees and horn lengths, ka, from 18.4 to 32.4. Horn parameters were chosen to agree with those used by Southworth and King[7] in an experimental study of conical horns fed by cylindrical guide at 15.3 cm free space wave-length. The flare angles used by them are total flare angles and hence double the flare angle θ_0 used here; the lengths of their horns were determined from the diameter of the aperture D and the excitation wave-length λ by

$$ka=(\pi D)/(\lambda\sin\theta_0).$$

The resulting patterns are shown in Figs. 2 to 6 in which the magnitude of the electric field is plotted as a function of the field point polar angle in the E and H planes. The solid curves are replots of Southworth and King's Fig. 10,[7] while the dotted points are normalized values calculated by the assumed field method. Ampli-

tude patterns are given here so as to compare directly with the experimental patterns. Only one-half the pattern is shown, since the theory is completely symmetrical, with respect to co-latitude, about the polar axis. There is little difference in the experimental curves between symmetrical halves but, where such differences exist, the average of the two halves was used to draw the solid curves.

The agreement between theory and experiment is seen to be good in the E plane for the 10° and 20° horns, poor at 25° and 30°, and very poor for the 45° horn. In the H plane the agreement is excellent for 10° and 20° horns, fair for 25° and 30°, and very bad for the 45° horn. The complete failure of the theory for the 45° horn is perhaps not surprising in the light of the small angle approximation made. Certainly it is not sound to neglect the variation of $\cos\theta'$ when the flare angle is as large as $\pi/4$. The possibility existed that the large discrepancy in the case of this 45° horn might be due to a considerable third harmonic excitation at the mouth because of the large discontinuities at the feed junction and the relative shortness of this horn. However, a qualitative calculation of the third harmonic contribution was unable to account for this behavior. The theory, in its present form, seems unable to yield a radiation pattern whose maximum amplitude is anywhere but on the polar axis, whereas experiment shows that it is quite possible to obtain maximum radiation in other directions. This effect has also been observed by Chu and Barrow[13] in the sectoral horn even after great care had been taken to eliminate all higher order modes. This peaking off the polar axis seems definitely to be a characteristic of large flare angle horns with which the present small angle theory is unable to cope.

Another anomaly in the theory is its prediction of varying horn length, at constant flare angle, on the pattern. The horn length, ka, enters only through γ, the argument of the Bessel functions, and hence the only effect of a change in ka is to alter the field point polar angle at which the calculation yields numerical results. An increase in length will sharpen the whole pattern, but no change should occur in the relative amplitudes of the side lobes and other structure. This prediction is not wholly confirmed by experiment in that, while the directivity tends to increase with length, lobes become more prevalent. This discrepancy again arises from the phase factor approximation where, it will be recalled, the neglect of the variation of $\cos\theta'$ can be justified only for small flare angles and moderate horn lengths. From the figures it is seen that the E plane directivity, i.e., that polar angle at which the amplitude falls to .707 of its maximum amplitude, is always somewhat greater than that in the H plane, the relation being approximately $E_{\theta E}=E_{\phi H}\cos\theta$. However, the H plane pattern is usually much smoother, with less side lobe, and falls to zero somewhat faster.

In conclusion it is perhaps worth while to point out that for pyramidal horns the same field Eqs. (1) and (2) apply provided only that the associated Legendre function of the first kind $P_n^m(x)$ is replaced wherever it occurs by

$$L_n^m(x)=aP_n^m(x)+bQ_n^m(x).$$

The radial part of these conical horn solutions apply directly to the pyramidal case and hence the various propagation factors computed for conical wave guide follow identically for pyramidal guide.

On the Diffraction of a Radar Wave by a Conducting Wedge*

R. B. WATSON AND C. W. HORTON
Defense Research Laboratory, The University of Texas, Austin, Texas
(Received February 14, 1950)

Diffraction patterns of radar waves have been measured about the edge of a perfectly conducting wedge. Theoretical patterns have been calculated using an asymptotic solution suggested by Pauli. Good agreement is observed between experimental and calculated patterns. The thin wedge tested showed much similarity in diffracting properties to a suitable semi-infinite conducting screen. The results may have application to diffraction effects about wedge-shaped wings on high speed aircraft and missiles.

A SOLUTION to the problem of the diffraction of electromagnetic waves by a perfectly conducting wedge was obtained by Sommerfeld[1] and extended by MacDonald[2] and Carslaw.[3] More recently, an asymptotic solution was developed by Pauli[4] which allows for relatively easy calculation of this diffraction. It was pointed out in an earlier article[5] (*I*) on the diffraction of radar waves by a semi infinite conducting screen that optical measurements showed deviations from the theory due to the nature of the screen material and screen geometry. Wolfssohn[6] suggests that these optical results might agree better with theoretical calculations for a wedge, thereby accounting for the thickness of the diffracting material and the shape of the sharpened diffracting edge.

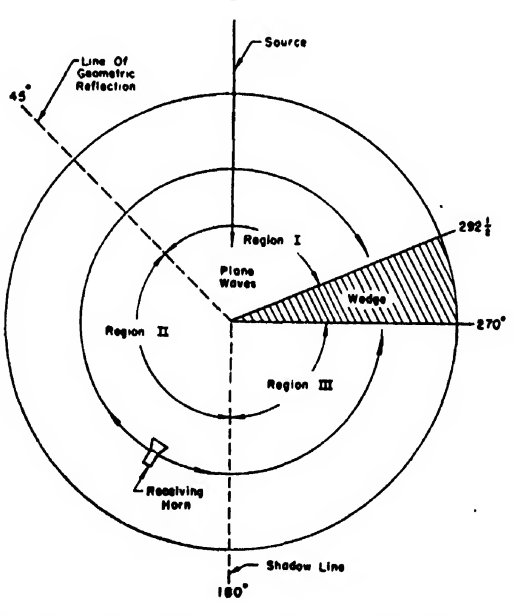

FIG. 1. Geometry of experimental arrangement.

The use of radar waves and metallic screens for obtaining diffraction measurements was justified fully in (*I*). The experimental arrangements described in (*I*) were used for the measurements on the wedge. The semi-infinite screen used in the earlier work was replaced by a hollow 22½° wedge made of two sheets of copper, each 30 in. × 60 in. × $\frac{1}{16}$ in. thick. These sheets were supported in the general manner described in (*I*) except for the use of dural channel members placed between the support members for the two sheets in such a way as to form the rigid 22½° wedge structure with the two ends of the sheets brought together to form a straight edge.

Observations of the incidental diffraction about the upper and lower edges of the wedge, the free ends of the two sheets, and various supporting members were made by taking measurements with the receiving horn at 15 in. and 30 in. radii and at two positions along the diffracting edge: at the midpoint and at the upper edge of the screen. The patterns taken at 30 in. radius showed considerable incidental diffraction effects from other parts than the major diffracting edge, in agreement with measurements in (*I*); thus, data are presented for the 15 in. radius only.

Figure 1 shows the geometrical arrangement of the diffracting wedge with respect to the source and receiver. The source was a sufficient distance from the wedge that the incident waves were effectively plane. The receiving horn was rotated in a circle about the diffracting edge and was thus oriented to face the edge of the wedge at all times and to give maximum sensitivity for waves diffracted from this edge.

Figure 2 shows a polar plot of the received signal when the incident wave was polarized with the electric vector parallel to the diffracting edge. Figure 2 also includes a theoretical plot for the same condition. The wave field was resolved for calculation into plane and cylindrical waves, representing the incident and reflected waves, and the diffracted wave respectively, for the regions I, II, and III. (See Fig. 1.) For these regions, the diffracted wave was calculated by means of the approximate formula given in Eq. (13) of Pauli's paper.[4] In the regions near the shadow line and the line

of geometric reflection, the more accurate asymptotic series given as Eq. (35) in Pauli's paper was used.

Figure 3 gives a similar plot of the received signal when the incident wave was polarized with the electric vector perpendicular to the diffracting edge. Figure 3 further shows the computed pattern for this condition.

The agreement observed between theoretical and experimental patterns thus obtained again verifies the process of resolving the wave field into component fields. There appears a slight difference in the values for the two theoretical values for the angles removed 10° to 15° from the critical boundary lines. This difference arises because of the use of the two different types of approximate formulas in the various regions.

For comparison with optical results, the ratio of the amplitudes of the patterns for the electric vector parallel and perpendicular to the edge of the wedge has been plotted in Fig. 4 as a function of angle, for the shadow region only. The experimental curve agrees quite well with the theoretical curve in the region from 0° to 40°. Diffraction effects from other edges of the wedge and various surrounding objects become increasingly evident for larger angles. In line with Wolfssohn's suggestion that data taken for the wedge may fit optical data better than data taken for a semi-infinite screen, the optical data have been replotted here. There appears to be no significantly greater or less agreement than was observed in (I) for a semi-infinite screen.

The incident wave makes an angle of $-22\frac{1}{2}°$ with the normal to the forward sheet of the wedge. It is, therefore, of some interest to compare experimental measurements for the $22\frac{1}{2}°$ wedge with measurements made for a semi-infinite screen at an angle of incidence of $-22\frac{1}{2}°$. Such data are available in (I). An intercomparison shows only slight differences in detail. Similar agreement is obtained between experimental

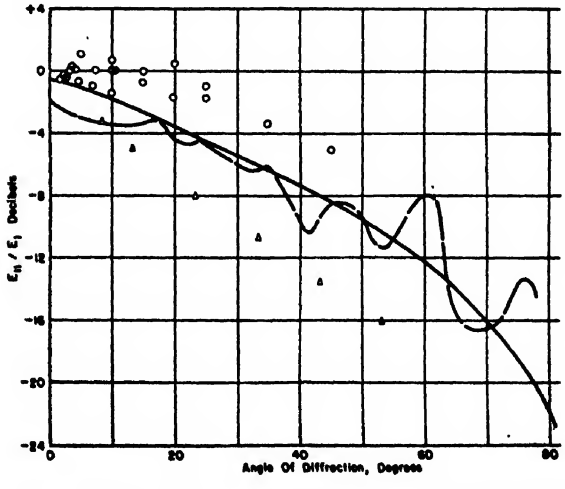

FIG. 4. Ratio of pattern amplitudes for electric vector parallel and perpendicular to diffracting edge. —— theory - - - experiment. Optical data: O Maey, Δ Jentzsch.

patterns for a quarter-infinite plane for an angle of incidence of $-22\frac{1}{2}°$ with the normal to the plane and patterns taken about the top edge of the $22\frac{1}{2}°$ wedge.

It is concluded that the diffraction caused by a thin wedge is not far different from the diffraction caused by the front surface of this wedge alone. Thus for such thin wedges, the rear sheet comprising the rear surface of the wedge is shown to be effectively shadowed by the front surface, and hence produces only small variations in the diffraction. These results may be of use in assessing diffraction about wedge-shaped wings on high speed aircraft and missiles.

Microscopic Observation of the Solidification of Small Metal Droplets

D. Turnbull and R. E. Cech
Research Laboratory, General Electric Company, Schenectady, New York
(Received March 6, 1950)

The solidification behavior of small metal (10 to 100 micron diameter) droplets has been observed on a high temperature microscope stage. An abrupt change in surface appearance and in the case of high melting metals a sudden brightening ("blick") accompanies solidification. The solidification temperatures observed for a collection of droplets may be widely distributed, but a significant, usually the major, fraction of the droplets supercool some maximum amount $(\Delta T_-)_{max}$ that is reproducible and characteristic of the metal. For many metals $(\Delta T_-)_{max} \approx 0.18$ times the absolute melting temperature. $(\Delta T_-)_{max}$ is not much changed by wide variations in the cooling rate and droplet size. The growth rate of metal crystals is very great so that the solidification rate of the droplets is controlled by the nucleation frequency.

INTRODUCTION

In another article[1] it was pointed out that if a metal specimen is broken up into a large number of isolated parts catalysts for crystal nucleation may be localized in a small fraction of the particles. Thus, in most of the particles crystal nucleation must take place homogeneously. In that investigation the solidification behavior of entire aggregates of particles was followed. An alternative procedure that is often advantageous is to remove a small number of particles from an aggregate and observe their solidification behavior microscopically. This is done by placing them in a stage recently designed by one of us[2] for microscopic observation at elevated temperatures. If only a small fraction of the particles contain nucleation catalysts there is a high probability that most of the ones selected for microscopic observation will be free of them. This principle has guided the present investigation.

A distinct advantage of the microscopic method of observation is its adaptability to the study of metals which melt at very high temperatures as well as medium and low melting point metals. Thus, it becomes possible by the use of one experimental technique to compare the solidification behavior of many metals.

For a long time[3] it has been known that small particles of liquid gold supercool significantly before solidification. A sudden brightening or "blick" occasioned by the liberation of the heat of fusion (recalescence) is known to accompany the solidification of the supercooled particle. This phenomenon is observed in the assaying of gold.

Mendenhall and Ingersoll[4] have observed this phenomenon in a number of other high melting metals including platinum, palladium, silicon, rhodium and iridium.

In their experiments metal particles 50 to 100 microns in diameter were supported on a Nernst glower in air or a CO_2 atmosphere, the solidification being observed microscopically. Particles of the same metal often solidified at widely different temperatures but the amount of supercooling, ΔT_-, was considerable and appeared to be roughly proportional to the melting point of the metal. However, the actual numbers for the maximum ΔT_- were given for only two of the metals, platinum and rhodium—370°C for both. These results of Mendenhall and Ingersoll were incidental to an investigation of another topic and their significance does not seem to have been realized.

In the current investigation the supercooling of many metals has been observed directly and the phenomenon studied in detail.

EXPERIMENTAL

In addition to its ease of adaptation to observation of metals having wide variety in melting temperature the microscopic method has the further advantage that particles isolated from one another on the hot stage do not require a film on their surface to prevent coalescence. It has been pointed out that[1] any crystalline protective film on the surface of a metal particle is undesirable in these experiments since it may catalyze crystal nucleation. On the other hand there are certain definite disadvantages of the method that must be recognized.

[1] D. Turnbull (to be published).
[2] R. E. Cech (to be published).
[3] A. D. Van Riemsdyk, Ann. Chim. Phys. 20, 66 (1880).
[4] C. E. Mendenhall and L. R. Ingersoll, Phil. Mag. 15, 205 (1908).

In producing aggregates of particles or in transferring them to the stage it is possible for nucleation catalysts to be picked up. Also, the particles, though free of crystalline films, must be supported on the stage and the possibility exists that the supporting surface or certain areas of it might catalyze crystal nucleation. In order to minimize this possibility, flakes of freshly blown quartz or pyrex glass were used as the supporting surface. These glass flakes, being amorphous, would not be likely to catalyze crystal nucleation. Another disadvantage of the microscopic method is that vibrations probably are more likely to promote solidification of small particles on a rigid supporting surface than particles in the interior of an aggregate. Sometimes these vibrations can be minimized by floating the particle in a suitable liquid flux.

MATERIALS

The source, purity, form, and method of preparation of particles are summarized in Table I. When the metal was supplied in the form of rod or wire small particles were made either by crushing with a mortar and pestle if brittle or by chipping with a sharp fragment of pyrex if ductile. Nickel particles and one sample of copper particles were formed from wire (fabricated from form listed in Table I) by means of a metallizing spray gun and the particles collected on a clean surface. These particles and those of other metals particularly susceptible to oxidation probably contained considerably more oxide than would be inferred from the purity listed. These metals were always given an *in situ* treatment with pure hydrogen in order to remove oxygen prior to observations of solidification. Different lots of some metals were obtained from two or three independent sources and the source designation used in the presentation of results is indicated in the table.

MICROSCOPE STAGE

Full details in the design of the microscope stage used in this investigation will be published in another paper.[2] A rough sketch is given in Fig. 1. The sample to be investigated was supported on a $\frac{1}{4}$-in. wide and 10 mil thick strip of molybdenum or platinum that was heated electrically.

Temperature was controlled by the amount of current passing through the ribbon heater and was varied by means of a variac transformer operated from a constant voltage source. By maintaining a constant power input into the heater it was possible to keep the temperature constant to $\pm 5°$ for long periods of time. The maximum temperature attainable was limited by the melting point of the heater metal. The stage is vacuum tight and its atmosphere (hydrogen, helium, or vacuum) is controlled by the indicated gas inlet. Temperature was calculated from the e.m.f. developed in an 0.005-in. diameter thermocouple welded to the underside of the heater. This e.m.f. was measured with a General Electric thermocouple potentiometer. The thermocouple was calibrated to read the temperature of the particles by accepting the known melting point of the metal as the standard. Deviation from the nominal temperature determined from standard calibration charts was usually +2 percent at the melting point. Solidification temperatures were corrected by assuming the deviation to be a linear function of temperature. A chromel-alumel thermocouple was used for temperatures below 1200°C and a platinum-platinum 10 percent rhodium thermocouple for temperatures greater than this. A new thermocouple was used for each specimen placed in the stage in order to prevent cumulative contamination from evaporation and condensation of the metals investigated. The error in the measured supercooling due to uncertainties in thermocouple and potentiometer calibrations and potentiometer readings is estimated to be ± 5 percent at most.

PROCEDURE

Figure 2 shows the two types of experimental arrangements that proved most satisfactory. In (a) the heater has two bends or stirrups that were introduced to

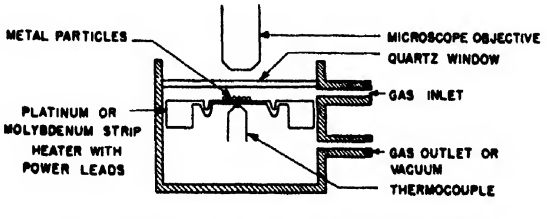

FIG. 1. Microscope stage with flat strip heater.

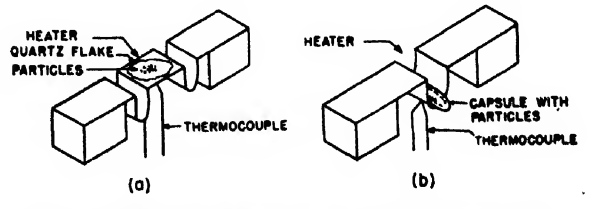

FIG. 2. Experimental arrangements used in investigation.

increase the effective length so that the temperature of the center horizontal section would be more uniform. This section supported a quartz flake on which a number of metal particles were placed for observation. In (b) a few metal particles were placed in the quartz capsule $\frac{1}{32}$-in. diameter by $\frac{1}{4}$-in. long which in turn was placed inside the single stirrup. A much larger number of particles could be observed at one time in arrangement (a) than in (b) in which the number was limited to 3–5. On the other hand, in (b) the temperature was very uniform along the length of the capsule and the calibration of the thermocouple more closely approximated that of the standard calibration charts. Also, (b) was much more satisfactory than (a) for observing volatile melts since in the latter arrangement the quartz window became fogged due to condensation of metal vapors on it. A new heater was used for each metal investigated in order to prevent contamination of the particles from condensation of metals accumulated in the heater during previous experiments.

An atmosphere of pure hydrogen, helium, or argon was maintained in the stage (excepting in the few instances that it was evacuated) during observations. Tank hydrogen was purified by passing it over a train consisting of a sulfuric acid bubbling tower and ascarite predryer, a copper chip furnace deoxidizer and a final dryer having dryerite and a liquid air trap. Tank helium or argon was forced through a purification train of two calcium chip furnaces in series operated at 550°C and 350°C.

In some of the experiments with metals melting at high temperatures Pyrex glass powder was mixed initially with the particles to provide a liquid coating during the solidification observations. It was thought that a liquid flux would cushion the particles against vibration and carry away or react with accidental crystal nucleation catalysts that might be present on the particle. However, it was demonstrated that the presence of a flux is not essential to the behavior to be described.

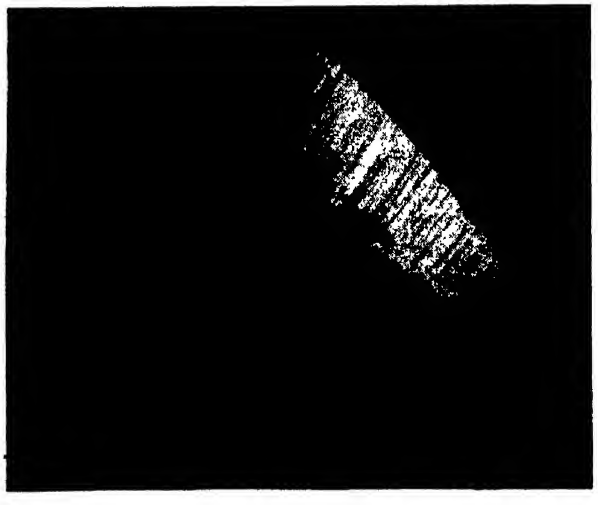

FIG. 3. Gold particles chipped from ingot. 25°C. 75×.

Melting and solidification of metals having melting points below 1000°C were inferred from the abrupt change of the surface condition of the particles that accompanied the processes. Upon initial melting, the particle lost its irregular shape and became spherical. Oblique illumination caused a bright spot or ribbon of light to be reflected from its mirror-like surface. When solidification occurred the rapid crystal growth in the particle caused a disruption of the smooth surface to one apparently having many sharp ridges and protrusions. These surface changes are illustrated in photomicrographs showing gold particles originally chipped from the ingot (Fig. 3), melted (Fig. 4), and solidified (Fig. 5). Melting and solidification temperatures were determined by association with the corresponding surface changes.

Solidification of metals having melting points greater than 1000°C was detected by the blick accompanying it. The initial melting of the particle permitted a thermocouple calibration as the particle became spherical. A further calibration was obtained by finding the maximum thermocouple e.m.f. that could be reached such that the particle did not blick upon cooling from the corresponding temperature. This e.m.f., which agreed within experimental error with that accompanying the initial shape change, was assumed to be that characteristic of the thermodynamic melting temperature. It was necessary to use filters for visual observations above 1100°C.

The melting and solidification temperatures of copper, gold, and germanium were measured by both the surface change and blick and the comparative results of the two methods are in complete agreement. Also, the maximum supercooling of bismuth particles (90°C) measured by observation of the surface changes is in close agreement with the value (90°C) determined dilatometrically by Turnbull.[1] In view of these facts there can be little doubt that the observed surface changes are caused by melting and solidification and that the blick observed in high temperature experiments is caused by solidification.

Particle diameters of the metals observed ranged from 10 to 100 microns excepting that some germanium particles were 400 microns in diameter. With the highest magnification that could be used, 240 diameters, it was not possible to detect the solidification temperature of particles smaller than 10 to 15 microns with certainty.

To determine the solidification temperature, the particles on the stage were cooled by decreasing the current through the strip heater. At intervals the cooling was interrupted and the thermocouple potentiometer exactly balanced and the e.m.f. recorded. The solidification temperature was taken to be that corresponding to the lowest exactly measured e.m.f. at which the particle was still liquid. Of the order of five minutes time usually elapsed in cooling from the melting point to the solidifi-

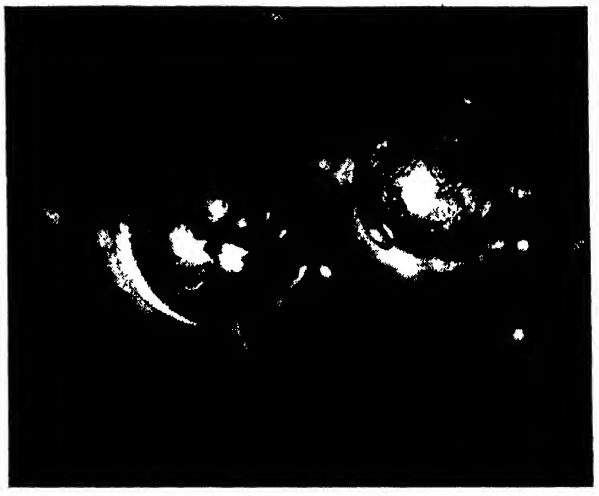

FIG. 5. Gold particles after solidification. 830°C. 75×.

cation temperature; most of this period was spent with the particles close to the solidification temperature. This cooling rate is rapid compared to that used in the dilatometric experiments but very small in relation to the maximum rate attainable (200°/sec.) with the apparatus. The temperatures of melting and solidification were checked several times for each particle or group of particles observed.

RESULTS

In general, the solidification temperatures of pure metal particles observed in a group ranged between the melting temperature, T_0, and some minimum temperature, $T_{\min}$. The results could be represented in terms of a number distribution curve relative to solidification temperatures or degrees of supercooling ΔT_-, where $(\Delta T_-)_{\max}=(T_0-T_{\min})$.

Depending upon the metal and circumstances (e.g., surface films) the number distribution of solidification temperatures sometimes had a maximum at $\Delta T_-\rightarrow 0$ (this is not certain for metals studied by the blick procedure since a blick cannot be certainly detected for $\Delta T_-<25$), or at $\Delta T_-\rightarrow(\Delta T_-)_{\max}$ or at some intermediate value of ΔT_-, and occasionally was fairly uniform so that no maximum was apparent.

It is an important fact that the solidification temperatures of a particular particle were not randomly distributed between $\Delta T_-=0$ and $(\Delta T_-)=(\Delta T_-)_{\max}$ throughout successive melting-solidification cycles but remained fixed for at least several and usually all such cycles. Occasionally the solidification temperature, after remaining nearly constant for several cycles, did shift abruptly to some other value and remained there in a series of succeeding cycles. This behavior is analogous to that of the one g continuous gallium samples described in a preceding paper.[1]

As noted before the sizes of the particles observed generally were between 10 and 100 microns. From a statistical standpoint the solidification temperature of smaller particles tended to be less than that of larger ones. However, it is significant that the solidification behavior of particular particles often deviated consistently from this generalization. Thus, 10-micron particles were occasionally observed to solidify at the melting temperature while 50-micron particles solidified at $\Delta T_-\approx(\Delta T_-)_{\max}$ throughout several melting-solidification cycles.

It appears reasonable to attribute the great differences in the solidification behavior of individual particles to the influence of minute quantities of accidental impurity particles. It is quite probable that colloidal particles suspended in the atmosphere and capable of serving as crystal nucleation catalysts become lodged in the quartz surface or on the surface of the metal particles during the assembly and operation of the microscope stage. (The experiments of Vonnegut[5] and Schaefer[6] have demonstrated that the concentration of colloidal material that can be effective in promoting the formation of snow is fantastically small.) Further, the abrupt change sometimes observed in the solidification behavior of particular particles can be attributed to the capture or dislodgement of a minute amount of impurity. *A priori* these impurities could either promote or inhibit solidification. However, there is much justification for the belief that such impurities promote crystal nucleation. This evidence has been summarized elsewhere[7] and will be discussed more fully in a following paper.[8] For the present purpose it will be assumed that minute impurities catalyze solidification. It follows that the only solidification temperature that could be characteristic of uncatalyzed solidification is $(\Delta T_-)_{\max}$. For this reason only the maximum supercooling $(\Delta T_-)_{\max}$

[a] Corresponds to maximum supercooling that could be reached such that crystallization did not occur on re-heating.

that could be reproduced under various conditions will be listed in the results.

The results are summarized in Table II. Values of $(\Delta T_-)_{max}$ determined in different atmospheres or in vacuum agreed within experimental error. The $(\Delta T_-)_{max}$ listed is the average value. Absolute melting temperatures of the metals listed in column 3 are from Kelley's[9] compilation.

FRACTION OF PARTICLES SUPERCOOLING MAXIMUM AMOUNT

In general the major fraction of metal particles melting at temperatures more than 950°C (Ge through Pd) did not solidify until supercooled to or nearly to $(\Delta T_-)_{max}$. Particles of source (*A*) gold constituted an interesting exception to this behavior. Without any Pyrex flux none of the particles were observed to supercool more than about 40°C. In the presence of the flux the supercooling was larger and a significant fraction supercooled to $(\Delta T_-)_{max}$. On the other hand the major fraction of gold particles chipped off gold wire (source *B*) supercooled to $(\Delta T_-)_{max}$ either with or without flux. The difference in the behavior of these two samples appears to confirm the principle set forth in an earlier publication[1] that crystal nucleation catalysts are more likely to be absent in metal particles freshly formed by breaking up a massive piece of metal than in particles formed "separately" or that have been permitted to accumulate catalytic dust on their surfaces for long periods. Another factor that might account for the difference is that the particles of source *A* gold actually observed were coalesced from several of the original particles which by themselves were too small for their solidification to be detected by the microscopic method. Thus, in effect more surface having the possibility of holding catalytic dust went into source *A* particles than into source *B* particles.

The distribution of particles of low melting metals with respect to solidification temperature had some interesting aspects and will be considered separately.

EFFECT OF ATMOSPHERE

Whenever a high melting metal having an oxide stable at the melting point was studied pure hydrogen was passed over the heated particles for some time and the melting and solidification temperatures were observed concurrently. After this the stage was flushed with pure helium and solidification observations were made in this atmosphere. When results were obtained for both atmospheres those for helium have been put in the table for the reasons that (1) hydrogen is significantly soluble in some of the metals and (2) e.m.f.'s of the platinum platinum-rhodium couple are not reproducible when the junction is in a hydrogen atmosphere. However, the maximum supercooling in the two atmospheres did not differ by as much as the uncertainty of the measurements.

It is significant that the supercooling of copper par-

[9] K. K. Kelley, Bureau of Mines, Bulletin No. 393 (1936).

ticles fabricated with a metallizing spray gun increased by about 100° after having been treated in hydrogen at 1000–1100°C for about 15 min. This may indicate that Cu_2O that formed in the fabrication process catalyzes the formation of copper crystals. Further evidence in favor of this view is that copper particles chipped from the original rod that supercooled the maximum amount in hydrogen or helium did not supercool significantly when the atmosphere was changed to air at low pressure.

The solidification of iron particles that had been hydrogen treated, evacuated, and sealed off in a quartz capsule also took place at the same temperature as in a helium atmosphere.

ALUMINUM

As received, the aluminum particles had a rod-like form that persisted in the liquid state due to the rigidity of the oxide skin. When placed on a quartz leaf with no flux practically all of these particles supercooled 48±2°C. The solidification range was so narrow that there was some temptation to assert that aluminum crystals nucleate spontaneously at $\Delta T_{-}=48$. However, in order to test the possibility that solidification was catalyzed by the oxide film, observations were made on solidification in a molten sodium hydroxide "flux." Under these conditions the particles spheroidized but a surface film (possibly sodium aluminate) remained. However, after heating 200° in excess of T_0, the particles supercooled 120° to 130°. This result appears to demonstrate that aluminum oxide does in fact catalyze the nucleation of aluminum crystals possibly by the mechanism suggested by C. S. Smith.[10] Of course there is no assurance that the film remaining in molten sodium hydroxide does not also catalyze solidification.

LEAD

Particles of lead placed on a Pyrex leaf in a hydrogen atmosphere solidified at temperatures ranging from the melting point to 60–65° below it at which only a minor fraction crystallized. As already noted, however, the behavior of particular particles was constant throughout successive melting-solidification cycles. When sodium hydroxide was used as a flux the fraction of particles solidifying at lower temperatures was greatly increased and a maximum supercooling of 69° was observed. On the other hand, in a flux consisting of a nitrate-nitrite mixture (56 percent KNO_3 and 44 percent $NaNO_3$) practically all the particles solidified at only 20–30° supercooling. A yellow film presumed to be lead oxide was present on the surface of the particles in the latter experiments. Thus, it seems likely that either lead oxide (PbO) or lead suboxide (Pb_2O) is a very effective catalyst for the crystallization of lead. Also it is interesting that the major fraction of source *A* particles supercooled to or nearly to $(\Delta T_{-})_{max}$ with no flux when the stage was evacuated to a pressure of 0.01 mm of mercury.

The maximum supercooling obtained in these experiments is about the same order as the supercooling of the major portion of lead in dilatometric and thermal experiments described in a preceding paper but is more than 10° less than the maximum measured in dilatometric experiments. Also, excepting when a sodium hydroxide flux was used, the fraction of source *B* particles that supercooled to 55–65° was much smaller in the microscopic experiments than in the thermal and dilatometric ones. These results perhaps may be accounted for by the fact that the particles observed in the microscopic experiments were considerably larger on the average than those used in the dilatometric and thermal experiments and so had more opportunity to contain or pick up nucleation catalysts.

BISMUTH

Although a major fraction of source *A* oxide coated bismuth particles supercooled 90° in dilatometric experiments only a minor fraction (presumed not to be oxide coated) supercooled the maximum of 90° on the microscope stage. However, it is significant that more than one-half of the particles made by breaking up source *B* bismuth rod in a mortar and pestle did not solidify unless supercooled about 90°. This difference in behavior of source *A* and *B* particles observed microscopically cannot be accounted for on the basis of different particle sizes for the *B* particles were significantly larger than the *A*. On the other hand, it seems probable that the difference in behavior of *A* particles in the dilatometric and microscopic experiments can be accounted for by the fact that many of the *A* particles observed on the stage had formed by coalescence of several small particles. As a result of this process, the proportion of particles containing nucleation catalysts was larger.

It is also significant that the temperature of solidification of bismuth particles that supercooled the maximum amount was not a function of the maximum temperature reached in the range of liquid stability when this was 10 to 100° greater than the melting point. This fact coupled with the lack of thermal history dependence in the dilatometric experiments proves that the thermal history effect observed in the solidification of large continuous bismuth samples is not an intrinsic property of bismuth and must be due to some extraneous effect.

The most important result of these experiments on bismuth is that the same maximum supercooling, 90°C, was obtained by two independent methods and with bismuth particles from two sources.

CRYSTAL GROWTH RATES

With the exception of selenium all of the droplets that had supercooled considerably solidified in a time too short to estimate, even to an order of magnitude,

[10] C. S. Smith, J. of Metals 1, 204 (1949).

after a nucleus had formed. From these observations it can only be maintained that the linear growth rates were greater than 1 mm/sec. It seems likely that crystals with relatively more complex structures such as bismuth and germanium would grow into their melts much more slowly than cubic crystals but this could not be proved or disproved by these experiments.

The extremely short period of growth relative to the total time required for solidification of a particle proves that "nucleation" is the rate-determining step in the reaction. Here the term nucleation is used in the broad sense as referring to a period of very slow growth of small crystals relative to large for whatever reason.

In no case excepting selenium was it possible to form a "glass" from the metal particles by quenching directly from the melt. Liquid selenium particles cooled to room temperature without crystallization. However, the glass particles so obtained crystallized upon reheating to temperatures 100°C or greater.* By cooling rapidly to some given temperature below the melting point and reheating, it was established that selenium nuclei were formed when the supercooling was greater than 25–30°C.

KINETICS OF ISOTHERMAL SOLIDIFICATION

Up until now it has been tacitly assumed that it is possible to assign "solidification temperatures" to particular particles. Since solidification is a rate process some justification of this assumption is necessary. As has been pointed out already, qualitative observations of Turnbull[1] have indicated that the temperature coefficient of the solidification rate of small metal particles is so very great that the rate changes by several orders of magnitudes within a narrow temperature range. Thus, solidification will be observed to take place only within this narrow range for widely different rates of cooling from the melting temperature.

This was confirmed by some observations on gold and copper particles. Liquid gold particles were on several occasions held at temperatures 180 to 190° below their melting point for one to three hour periods without solidification. They did not then solidify until cooled 230° below the melting point that corresponds to $(\Delta T_-)_{max}$ reported in Table II. Similar results were obtained with copper particles chipped from the rod.

DISCUSSION

The basic phenomena involved in the solidification of small metal particles now seem clear. In general, particles 100 microns or less in size can be supercooled to an extent far in excess of that ever attained on large continuous samples. Only for iron has a ΔT_- been reported[11] for a large continuous sample that is of the same order of magnitude (258°) as $(\Delta T_-)_{max}$ (295°) measured for small particles. For other metals having cubic crystal structures it has rarely been possible to supercool large continuous samples of the liquid more than 5–10°.

In an aggregate of metal particles the solidification behavior of individuals is quite specific and persistent but a significant fraction supercools some maximum amount $(\Delta T_-)_{max}$ that is reproducible and characteristic of the particular metal. The ratio of $(\Delta T_-)_{max}$ to the absolute melting temperature T_0 is 0.18 ± 0.02 (see Table II) for the metals studied having cubic crystal structures excepting lead and aluminum. (In making this calculation for iron and manganese, it was assumed that the crystal modification in equilibrium with the liquid at atmospheric pressure was nucleated although solidification in both instances takes place in a temperature range where a different crystalline modification is stable.) The lowest temperature of solidification of small particles is varied only a small extent with widely different rates of cooling from the melt and with changes in the particle volumes amounting to factors of 10^3.

The interpretation of these phenomena is to be given in a succeeding paper by one of us.[8]

ACKNOWLEDGMENT

The authors are pleased to acknowledge the assistance of Mrs. Joyce Rowland on many of the experiments herein reported. They also thank Drs. Leroy Apker and W. C. Dunlap for supplying samples of some of the metals.

* This agrees with prior observations of Apker and Dickey (private communication) on the crystallization of amorphous selenium films.

Mass Spectrometric Study of Solids I. Preliminary Study of Sublimation Characteristics of Oxide Cathode Materials*

R. H. PLUMLEE AND L. P. SMITH
RCA Laboratories, Princeton, New Jersey
(Received March 6, 1950)

Mass spectrometric techniques have been utilized to study sublimation characteristics of materials used in electron tubes. Exploratory experiments and methods are described. Preliminary results concerning general processes induced by heat and by electron bombardment are discussed. Photographs are shown of mass spectrometer traces which demonstrate the effects described. Phenomena noted include (1) the inefficiency of electron bombardment for producing material transport from solids, (2) the thermal evaporation of alkali metal atoms and ions from bare nickel alloys, but no such evaporation from oxide cathodes formed on the same materials, (3) the complex thermal evaporation of oxide cathode constituents, (4) absence of positive ion evaporation from oxide cathodes, (5) the confirmation of mechanisms for negative ion formation in vacuum systems, and (6) the liberation of molecular oxygen from oxide cathodes which increases with electron emission drawn.

I. INTRODUCTION

ALTHOUGH considerable effort has been expended in the past on studies of structure-sensitive phenomena, the interpretation of the measurements produced has been inherently handicapped, for the most part, by a very deficient knowledge of the chemical constituents present in the materials studied. When the property under study, such as an electron emission process, is closely related to the functioning of the solid-vacuum interface as well as to the functioning of the interior of the solid and the solid-solid interfaces, the composition variable becomes quite complicated. The composition of surfaces is not only uncontrollable within the desired limits (because of diffusion exchanges with the interior of the solid, and because of absorption of foreign materials from the vacuum system), but it is also undeterminable by any currently known analytical technique. Surface analyses, ultimately of mono-molecular layers, made concomitantly with measurements of electronic properties, and without appreciably damaging the surface itself, would of course greatly facilitate interpretation of the measurements.

In developing an approach to the problem of surface analysis, mass spectrometric techniques are being applied to the study of materials of interest to the electronics industry. The results of these exploratory experiments described here are of interest in themselves, and, in addition, demonstrate the potentialities of a method applicable to a considerable number of problems in surface chemistry.

II. EXPERIMENTAL

The experiments were performed with a Nier-type spectrometer.[1] The tube was metal and glass with copper-gasket vacuum seals. The entire tube and liquid air trap were oven-baked at 450°C. A mercury diffusion pump was used. The spectrum was scanned by changing the ion energy. Recording was done by a carbon-paper printing mechanism from an obsolete facsimile receiver. The longest spectrum shown in succeeding figures represents less than five minutes of recording time. The ion accelerating potential was scanned linearly with time from high to low and vice versa at several fixed magnetic field values to cover the mass scale. The mass scale is thus inversely linear with ion energy, and the scales of some spectra are mirror images of others. The gaps in the strong peaks (e.g., Fig. 2A) are due to the recording arrangement whereby no printing was done during the scanning of a signal larger than the full ordinate scale (about 15 times the ordinate increment shown). Some of the experiments were recorded with an electron multiplier as detector. Most of the experiments were recorded with a conventional electrometer tube d.c. amplifier arrangement as detector. The ordinate increment shown for these traces represented usually an ion current of about 10^{-13} ampere. This has been translated into the estimated pressure sensitivity equivalent.

This sensitivity estimate was made from the measurement of the CO (mass 28) peak height and the associated ionization-gauge pressure reading during periods when the mass 28 peak constituted about 75 percent or more of the residual spectrum peak height. This estimate is necessarily rough because, besides uncertainties in the pressure measurement, it implies the same ionization cross section for all neutral particles. For many common gases, measured ionization efficiencies vary by less than a factor of ten[2] from that of CO. Although the ionization efficiencies of most of the species with which we are concerned have not been determined, this assumption of equal ionization cross sections is probably sufficiently accurate for present purposes. The necessity for maintaining the best possible vacuum discouraged the use of standard gases admitted for calibration purposes only. With solid samples being evaporated into the ionizing region, the sensitivity and optimum adjustment varied steadily so that frequent checks on the sensitivity were

* Presented in part at the meeting of the American Physical Society at Stanford University, December 30, 1949.

essential. Using this calibrating method, fair agreement was found between the measured vapor pressure of nickel and literature values. For materials evaporated from the samples by the various methods employed, the measured pressures or vapor densities were also translated, by simple kinetic theory equations, into transport rates and into approximate times required for removal of mono-molecular layers.

The ion source most used was the double filament structure shown schematically in Fig. 1. It is essentially the usual gas analysis source with an added upper section for bombarding a heated sample. A similar design was used previously by Dart.[3] Bombardment may be done with positive ions (Kunsman source[4]) or with electrons. We have thus far used only electron bombardment. The sample bombarding region is separated from the ionizing region (analyzer) by a tungsten mesh. The structure therefore allows neutral particles evaporated from the sample to be analyzed in the usual gas analysis fashion, and charged particles from the sample region to be restrained, by suitable potentials, from entering the spectrometer analyzer; on the other hand, if so desired, charged particles from the sample may be accelerated through the spectrometer along with ions from the analyzing beam region, in which case two peaks for the same mass may appear. These peaks will be displaced from each other on the spectrum record by a distance corresponding to the potential difference between the two points of origin. Electron emission from

the sample may be drawn to the surrounding box without traversing the mesh and without contributing to ionization in the analyzer region.

Both directly heated and indirectly heated samples were used, but mainly the latter. The sample was ordinarily in the form of a rectangular box (about $\frac{1}{2}$ in. long $\times\frac{1}{8}$ in. high $\times\frac{1}{8}$ in. wide) welded from a 0.002-in. sheet of the metal (or cathode base material) under study. A thermocouple junction of 0.0005 in. diameter Pt and Pt-Ir wires was welded to the sample, usually to the outside surface, centrally on the flat facing the spectrometer slit area. Oxide cathodes were made by spraying a carbonate mixture in a nitrocellulose-solvent vehicle over the box flat to be bombarded (the flat facing spectrometer slits). The sample was generally processed in the spectrometer. Processing was varied from experiment to experiment, but usually consisted of a brief operation, preliminary to bake-out, to check instrument performance, then a 450°C bake-out of several hours' duration with carbonate breakdown, the total pressure never rising above 10^{-3} mm Hg. After the carbonate breakdown, the liquid air was removed from the trap which was then torched empty of condensate, the liquid air was then replaced around the trap, and the bake-out continued for another hour or so. The residual pressure after bake-out was about 10^{-7} mm Hg with both source filaments operating and with the sample heated by its own heater to about 450°C. The source filaments were tantalum, coated on the emitting areas with tungsten powder and then thoria powder. They proved quite suitable for operations at pressures less than 10^{-5} mm Hg when no hydrogen was added to the residual gas of the system.

Figures 2A, 2B, 2C show typical binder decomposition spectra from an oxide cathode sample heated to 450°C before the bake-out. These materials, carbon-hydrogen-oxygen fragments of cellulose acetate and cellulose nitrate, were found to settle on all moderately cool elements of the ion tube and were not completely removed by the 450°C bake-out. They gradually distilled out of the ion source structure but could always be stirred up by moderately warming other portions of the ion tube.

Figure 3 shows the main residual spectrum at the end of the bake-out. The chief constituent of the residual gas was always CO. All residual peaks could be enhanced at any stage of operations by increasing the sample temperature, particularly in the case of oxide cathodes, indicating that an oxide cathode is never completely outgassed.

III. GENERAL ELECTRON BOMBARDMENT EFFECTS

Some cathode poisoning phenomena, well known to tube makers, have been attributed to dissociation or ionization of materials, adsorbed on grids or anodes, by electrons with energies from about 6 volts up to 25

volts.[5–7] A study of oxide decomposition using cathode poisoning as a method of detection was reported by Jacobs.[8] The technique of cleaning surfaces by electron bombardment has also been utilized.[9] Other experiments demonstrating material transport due to electron bombardment have also been described.[10] Dempster once employed electron bombardment of salts to generate ions for mass spectrometer studies.[11] Dart[3] found a small evaporation of Zn (and ZnO) from ZnO produced by electron bombardment.

It was expected, therefore, that electron bombardment might be the appropriate means of indiscriminantly stripping surface layers off solids for mass spectrum analysis; however, our electron bombardment studies of Ni, ZnO, Mo, Cu, and (BaSrCa) O surfaces have thus far found no general material transport effect that could definitely be separated from the purely thermal effect of the bombardment. No detectable evaporation of any sort was found to be produced by bombardment of these surfaces at low temperatures; however, at temperatures sufficiently high to produce a detectable thermal evaporation spectrum, addition of the bombardment, with the measured shell temperature fixed, enhanced the evaporation of non-metallic coatings only by slight amounts (less than a factor of ten, depending upon the bombardment). Electron bombardment energies up to 1400 ev and current densities up to 6 ma/cm² were used.

In no instance was an effect found which would indicate that surface layers of the bulk material of a solid are uniformly stripped away, at temperatures well below the sublimation point, by electron bombardment.

IV. SPECIFIC ELECTRON BOMBARDMENT EFFECTS

Although there may be numerous specific reactions between solids and low energy electrons, only one such was definitely established and one other probably established by these experiments. These are, respectively, the ejection of O^+ ions from (tank) hydrogen-fired molybdenum, and the ejection of Cl^+ ions from (tank) hydrogen-fired copper. The experimental arrangement by which the Cl^+ ions were obtained did not preclude the generation of these ions by negative ions (e.g., Cl^-) arising from the oxide cathode emission used for bombarding the copper. The ions were definitely formed at the metal surface and not in the gas phase.

Several times, indications were seen of O^+, OH^+, F^+, and Cl^+ liberation by bombardment of other metal surfaces, but the quantities were too small and transient for study. Circumstances suggest that they were all derived from adsorbed materials. Whether these materials were ionized on the surface before desorption, or ionized in the space adjacent to the surface was not operationally determinable.

The O^+ ions produced from the Mo surface had several unique properties, however, by which they differed from other ions in the spectrum. Figure 4 is a typical spectrum from that experiment. The ion source was the structure referred to earlier (Fig. 1) with the potentials $A_2-S=3$ v, $Q-A_2=0$ v, $S-P=10$ v, $P-B=2$ v, $A_1-B=1$ v, thereby transmitting positive ions from the sample region (superscript S peaks) as well as ions from the analyzer region (peaks without superscript S) to give a double spectrum. The displacement between peaks of the same mass should thus be expected to be

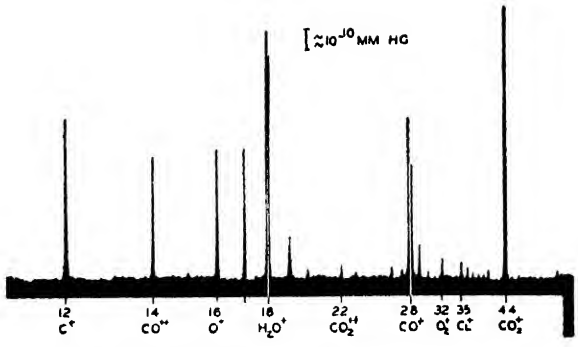

FIG. 3. Main portion of the residual spectrum after bake-out (and carbonate breakdown); sample temperature 450°C.

about 11 volts [the sum of $(S-P)$ and $\frac{1}{2}(P-B)$] corresponding to the potential difference in the two points of origin. Measurement of this displacement gives reasonable agreement for masses 18, 19, 23, 28, and 39, but not for the mass 16 peaks, for which the displacement is somewhat larger. Operation with a reversal of the $S-P$ field suppressed all the S peaks, less than 2 volts being required to suppress 18^s, 23^s, 28^s, 39^s, but about 11 volts being required to suppress 16^s completely. The excess kinetic energy of the O^+ ions (16^s peak) is the first property unique to those ions.

The second property of the 16^s peak not common to other S peaks was its decay under bombardment. The decay was roughly 50 percent in two minutes under bombardment of 0.9 ma per cm² with 300-v electrons and was independent of temperature. After an interlude of no bombardment, the peak could again be obtained at the original height upon resumption of bombardment. Even bombardment with 1000-v electrons provided a period of partial recovery from bombardment with 300-v electrons.

The third property of the 16^s peak was its temperature dependence. It could be obtained at temperatures above 300°C, and increased with temperature. It disappeared, when operations were suspended overnight, and could be obtained again only after a brief heating of the sample to about 900°C, a circumstance which suggests reaction of the Mo with residual gas of the vacuum system, or perhaps diffusion of some material from within the metal to give the surface coating required. The 16^s peak was produced with electrons of energy ranging from 40 volts to 1400, the highest used, with a broad maximum around 140 v. Below 140 v, the efficiency dropped gradually to extinction at 40 v. Since the remaining peaks (excepting the alkali metal peaks 23, 23^s, 39, 39^s, 41^s) showed almost no temperature dependence, they were concluded to be characteristic of the residual gas of the system. Sodium and potassium evaporated thermally from the sample as both atoms and ions. Upon application of bombardment, the increase in the 23^s and 39^s peaks due to electron impact ionization of metal atoms evaporating was small and the ratio of, for example, the regular 23 peak to this increase was not far from the ratios of $18/18^s$ or $28/28^s$ peaks. This established the relative transmission efficiencies for ions produced from the sublimate by the two beams. The $16/16^s$ ratio showed no relationship to this transmission ratio. Thus the 16^s ions must have originated at the surface and not in the vapor phase ionization of neutral particles evaporated from the surface. The excess kinetic energy indicates a dissociation from some excited state produced by bombardment of the surface layer.

V. THERMAL EVAPORATION FROM METALS

Studies of thermal evaporation from several† bare metals (cathode nickel alloys, and one molybdenum sample) showed, at moderate temperatures, copious evolution of alkali metal ions, and, at higher temperatures, evolution of alkali metal atoms as well as ions. At the higher temperatures, nickel alloys produced the expected evaporation of nickel atoms, and a rather profuse spectrum of carbon-hydrogen compounds which obscured the evaporation of minor constituents such as Mg, Mn, Ti, and Si. Molybdenum showed less carbon-hydrogen compounds. All samples had previously been fired in hydrogen.

The alkali metal evaporation was detected roughly as follows from nickel alloys: K^+ above 500°C, Na^+ above 600°C, K^0 and Na^0 above 850°C, the evaporation of all four species increasing with temperature, and the ratio of atoms to ions rising sharply with temperature. It may be significant that oxide cathodes made from the same nickel alloys showed no traces of alkali metal evaporation either as atoms or ions, at temperatures as high as 1100°C.

Referring again to Fig. 4, the 23^s, 39^s, and 41^s peaks are due to $^{23}Na^+$, $^{39}K^+$, and $^{41}K^+$ evaporation. These peaks appeared with both electron beams turned off, and showed temperature dependencies different from those of the regular 23, 39, and 41 peaks obtained with a retarding field ($P-S=5$ v) to prevent ions from the sample region entering the analyzer, and with only the ionizing electron beam turned on. On the other hand, the peaks for masses 12, 16, 17, 18, 18^s, 19, 19^s, 28, 28^s, and 44 were almost independent of sample temperature, and were thus identified as characteristic of the residual gas of the vacuum system. The total pressure of the system was less than 10^{-7} mm Hg according to ionization gauge readings.

VI. THERMAL EVAPORATION OF NEUTRAL PARTICLES FROM OXIDE CATHODES

The thermal evaporation spectrum from oxide cathodes depended very much on previous thermal history of the samples. In the early stages of the heat treatment (after carbonate breakdown and a "hot shot" at 1100°C to simulate activation) the evaporation from (BaSrCa) O cathodes was largely that of barium compounds, some

† A comparable thermal study of Cu was not made.

Ba atoms, and less Sr. The barium compounds evaporating were identified as BaO, and $BaCl_2$ (Fig. 5). (See Section XI.) The early evaporation, detected at temperatures as low as 600°C decayed at roughly 1 percent per minute and could be maintained at the minimum detectable level (about 10^{-10} mm Hg pressure in the ion source region) only by steadily increasing the sample temperature. During several hours of this procedure, the barium chloride evaporation rate declined to values small compared with the BaO evaporation. However, even though samples were held at temperatures around 800°C, for as long as 15 hours, the barium chloride could subsequently be made to register at sample temperatures of 1000°C to 1100°C. It is noted that the barium isotopes contribute fine structure to the peaks, and also that the Ba^+ peaks consist of contributions from ionization of both Ba and Ba compounds in the analyzer. It is also to be remembered that the evaporation is entirely uncharged, the ions being formed in the analyzer and not at the sample.

Prolonged operations with sample temperatures at 950°C±100°C developed, after several hours, a much slower decay rate for the Ba, BaO evaporation, of the order of a few percent per hour. The Ba^+/BaO^+ ratio was never larger than about 2/1 and declined slowly throughout. The ratio was definitely lower for the one platinum based cathode examined (Fig. 6) than for any of the nickel based cathodes formed from alloys containing medium or low quantities of reducing agents. The lowest ratio Ba^+/BaO^+ observed was about 0.4. The minimum peak ratio, Ba^+/BaO^+, is to be derived of course when no Ba evaporates, and is determined by the relative probabilities of the various decomposition processes with which ions are formed by the electron beam of the analyzer. Figure 7 shows even an appreciable Ba^{++} peak resulting from these processes.

The fact that some of the spectra shown were taken with the samples under bombardment is of no significance since the bombardment seemed merely to be an additional source of heat applied to the coating. Potentials were applied so that vapor-phase ions from the bombarding beam were not transmitted through the analyzer. In all cases, the absolute peak heights depended upon the past thermal history of the sample.

In general, the cathodes on nickel bases showed, in addition to the larger Ba/BaO ratio in the evaporation, appreciable Sr evaporation which was often nearly as large as the Ba evaporation (Fig. 7). At higher temperatures, a small Ca evaporation was detected also. The Sr evaporation decayed much less rapidly than the Ba and BaO evaporation.

Only traces of SrO evaporation were found, even at 1100°C, the highest temperature used. At this temperature, the literature[12] value of the vapor pressure of pure SrO is about 10^{-9} mm Hg, about ten times the minimum detectable by the instrument in some experiments. Considering the fact that high temperature effects were examined only toward the end of the experiments when the sensitivity may have diminished because of nonconducting coatings evaporated upon slit edges, the discrepancy between the literature value and the observed evaporation is not excessive. All samples were triple oxides, so that depletion loss of the more volatile BaO and SrO from outer layers of the coating would eventually leave an outer layer consisting very largely of CaO. At any stage, the vapor pressure of each constituent would be approximately equal to the product of its mole fraction and the vapor pressure of the pure material.

The cathodes examined were not what would be considered "well-formed," good emitters. This may have been due to contamination from the ion tube, or to improper activation. Emission values were usually about 25 ma d.c. per square centimeter for a cathode at 800°C.

VII. POSITIVE ION EMISSION FROM OXIDE CATHODES

No positive ion emission was found from oxide cathodes at temperatures as high as 1100°C. The instrument was capable of detecting positive ion evaporation smaller than 10^{-10} amp. per cm^2. This does not conflict, of course, with literature references to positive ion emission from (BaSrCa)O coatings on tungsten at much higher temperatures.

VIII. THE NEGATIVE ION SPECTRUM

Examination of the negative ion spectrum agreed in general with the observations summarized by Sloane and Watt,[13] namely, that three principal mechanisms may be responsible for negative ion formation in partially evacuated systems, (1) thermal evaporation from surfaces, (2) conversion‡ of positive ions striking a surface to negative ions, which subsequently escape, often carrying part of the kinetic energy of the positive

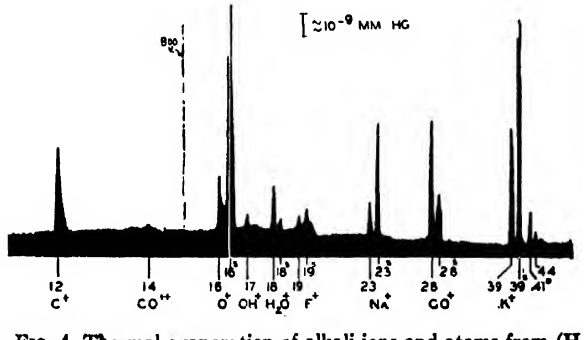

FIG. 4. Thermal evaporation of alkali ions and atoms from (H_2 fired) molybdenum at 1100°C, and ejection of O^+ ions by electron bombardment (4 ma/cm^2, 300 v) of molybdenum surface.

[13] R. H. Sloane and C. S. Watt, Proc. Phys. Soc. (London) **61**, 217 (1948).

‡ F. L. Arnot, Proc. Roy. Soc. (London) **158A**, 137 (1937) gives yield values, N_-/N_+, for this process ranging from 10^{-3} to 10^{-5} with 180-v positive ions.

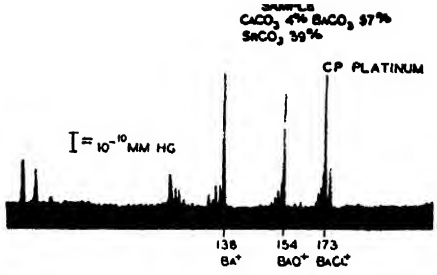

FIG. 5. Oxide cathode initial thermal evaporation at 800°C, all peak heights slightly exaggerated because of electron bombardment (4 ma/cm², 300 v).

ions, and (3) positive ion impact causing the dislodging of absorbed materials¶ as negative ions, which may also carry away some of the kinetic energy of the positive ions. These latter two processes were not distinguishable in the experiments here reported.

The operation demonstrated by Fig. 8 was performed with the source structure of Fig. 1, but with both electron beams turned off. Accordingly, with all source potentials negative with respect to ground and the ion collector, and with $P-S=100$ v, $B-P=2$ v, negative ions and electrons from the sample were accelerated through the spectrometer. In the spectrum, the displacement between peaks of the same mass number was found to be the voltage difference between the mesh P and sample S, and the non-superscript S peaks followed the potential of P. Therefore, these peaks were concluded to originate at the mesh while the S peaks were concluded to originate at the sample. With the field between S and P reversed so electrons and negative ions could not enter the analyzer region, no peaks were obtained. With $P-S=5$ v so electrons and negative ions were drawn from the sample to the mesh with low energy, then through the analyzer with high energy (several hundred volts), the non-superscript (mesh) peaks were again produced. This suggests that they were independent of the bombardment of the mesh by electrons or negative ions. Use of a magnet to deflect electrons (but not ions appreciably), so that the electrons did not accompany the ions through the analyzer, cut out all except the Cl^- ions. The interpretation is then that the large current of electrons in transit through the analyzer ionizes the residual gas to form positive ions which then follow the reverse path of the electrons striking slit edges, the mesh P, and finally the sample. On these surfaces, the incident positive ions generate the negative ions which are affected by the presence, in the source region, of the auxiliary magnetic field.

The largest negative ion peaks were those of the chlorine isotopes (Fig. 8) which were both temperature

¶ R. H. Sloane and R. Press, Proc. Roy. Soc. (London) 168A, 284 (1938). Their results, given for CO^-, Hg^+, CO^+, Hg^{++}, indicate current density yield ratios, N_-/N_+, for this process larger than 10^{-5}, the uncertainty arising from the measurement of the positive ion current. An unknown degree of surface coverage by adsorbed CO is also involved in this yield factor so the yield per impact per CO site is indeterminable.

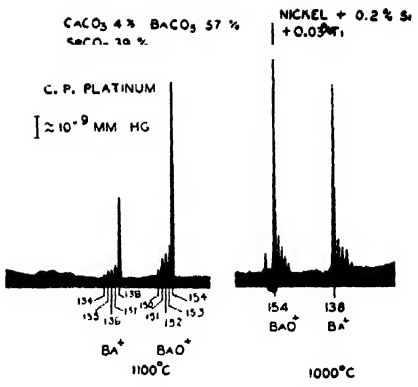

FIG. 6. Comparison of oxide cathode evaporation from platinum and nickel bases.

and pressure dependent, and were concluded to be largely of the thermal evaporation variety. They were found evaporated from an oxide cathode at temperatures as low as 600°C. The Cl^- peaks were much more sensitive to torching of the ion tube at various points than were the Cl^+ peaks formed in the usual operation of the analyzer. This observation suggests that the cathode collects neutral chlorine compounds or atoms and ejects the chlorine as negative ions. It also implies some storage mechanism whereby the Cl^- ejection need not be dependent upon the instantaneous vapor phase concentration of chlorine compounds as is the Cl^+ measured, but rather upon the concentration of chlorine accumulated in the cathode.

Masses 26^- and 14^- (Fig. 8, the superscript s peaks) were also generated at the cathode surface, but probably by one of the positive ion mechanisms, since there was little temperature dependence.

Mass 14^- was generated also, along with 12^-, at the unheated mesh partitioning the sample region from the analyzer section of the ion source (Fig. 1), by positive ion bombardment.

Trace quantities of still other negative ion masses were also found, such masses as 42, 68, 75, 130, but they were too small and erratic in appearance for study. They were apparently generated by a positive ion bombardment mechanism.

There was no visible correlation between the negative ion spectrum obtained as above and the usual residual gas spectrum (compare Fig. 3) obtainable a few minutes previously or subsequently (the change-over time from negative ion search to positive ion search was one to two minutes). In view of the variety of species inhabiting the vacuum system, any attempt to identify the composition of ions less obvious than C^-, $^{35}Cl^-$, $^{37}Cl^-$, seemed entirely speculative.

IX. EMISSION EFFECTS

Only one definite effect of electron emission from an oxide cathode was found reflected in the mass spectrum. This was an increase in the molecular oxygen peak

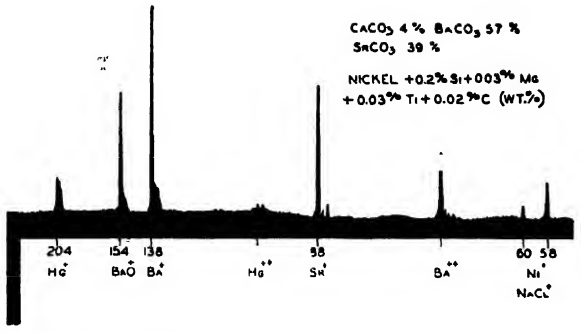

FIG. 7. Oxide cathode evaporation spectrum showing appreciable Sr evaporation at 1000°C.

(mass 32, Figs. 9, 10) as a function of emission drawn from the sample. The emission was drawn to the box surrounding the sample so it did not traverse the mesh P and contribute to the ionization in the analyzer. The bombarding filament was of course turned off during the experiment.

The total gas pressure was less than 10^{-5} mm Hg of which the O_2 partial pressure was probably never more than 1 percent. Examination of the negative ion spectrum showed no evolution of O^- or O_2^-. The evidence thus supports the conclusion that the oxygen left the cathode surface as O_2 molecules. The ratio, N_{O_2}/N_e, of oxygen molecules to electrons evaporated from the sample was estimated at about 10^{-5}.

X. CATHODE BREAKDOWN

The most significant fact of the breakdown was that it was never completed—each of the usual components (Fig. 11) seems to be evolved at a dwindling rate throughout the cathode life. The CO evolution, after the bulk of the decomposition was completed, was the most intense and by far the slowest to decay. The CO_2 and H_2O evolution usually assumed relatively small rates after several hours of sample operation at one particular temperature, only to be renewed at higher, slowly decaying, levels when sample operation was carried to a higher temperature. For nickel alloys and oxide coated samples, CO pressures less than an estimated 10^{-7} mm were never observed; for the Mo sample the CO pressure was about tenfold lower.

XI. DISCUSSION OF RESULTS

A. Electron Bombardment Experiments

The bombardment experiments indicate first that, if there is a general vaporization or dissociation characteristically produced by electron bombardment of solids, it is too small at low temperatures for detection by ordinary mass spectrometric methods. If, as has been proposed,[8] bombardment transport is dependent upon high temperatures to permit escape of excited fragments before de-excitation by other means, it may not be separable from ordinary thermally activated reactions and evaporations occurring at the same temperatures. All cases of simple vaporization or dissociation induced by electron bombardment must be carefully examined to be certain that they are not derived thermally from the temperature rise of the surface. Very few experiments reported in the literature demonstrating mass transfer induced by electron impact are above suspicion in this respect.

The second aspect of the electron bombardment experiments is the evidence that surface layers may undergo specific reactions. These may be expected to vary in efficiency from values approaching those of impact processes in free molecules down to zero, depending upon the particular nature of the layer under bombardment. Various properties of both the surface material and substrate, in addition to simple bond energies, may be critical.

Since these experiments are exploratory in nature and inherently lacking in precision, only a semiquantitative estimate of the results can be presented. The minimum detectable yield ratio, N_0/N_e, of neutral particles removed to bombarding electrons incident at the target, was about 10^{-6}. The minimum detectable yield ratio for positive ions ejected by electron bombardment was $N_+/N_e \cong 10^{-8}$ (because no subsequent ionization step was necessary).

In the case of O^+ ejection from the Mo surface, the 50 percent decay time (e.g., 2 minutes under 1 ma/cm², 300-ev bombardment) was temperature independent, but the peak height increased with temperature. The current density yield ratio, N_{O^+}/N_e, was about 10^{-6} at 1100°C and 10^{-8} at 300°C for 300-v electrons. Because of the constant decay time, it was concluded that the yield variation reflected a temperature dependence of the oxygen supply rather than a temperature dependence of the removal cross section. Assuming that the removable oxygen was adsorbed on the Mo surface, either as atoms or in some molecular form, one O atom at most per Mo site, and that half the supply of O sites was removed in 2 minutes of bombardment (the recovery time was about 5 minutes) and assuming a (100) Mo plane surface, 3.14A unit cell length,[14] the bombard-

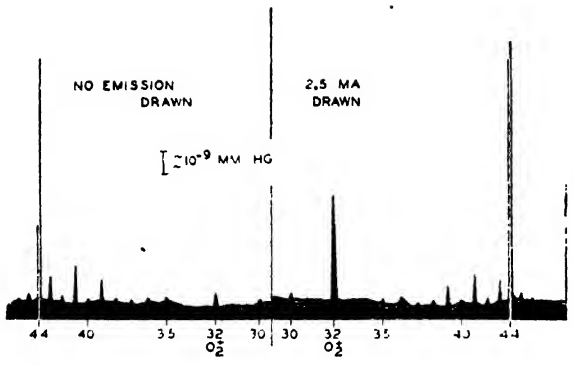

FIG. 9. Gas spectrum in the presence of oxide cathode sample showing increase in O_2^+ peak height with electron emission drawn from sample.

ment required for removing the adsorbed layer corresponded to about 10^3 electron impacts per surface atom site. Over-all yields of 10^{-6} and 10^{-8} thus corresponded to O site concentrations of one per 10^3 and 10^5 Mo sites, respectively.

Scant observations of the Cl^+ removal from Cu by bombardment with emission from an oxide cathode gave a single estimate of $N_{Cl^+}/N_e \cong 10^{-7}$. No decay was observed. If the Cl^+ resulted from conversion of Cl^- ions in the incident beam, the yield must have been near unity. This latter mechanism is considered rather unlikely in view of the fact that the Cl^+ ions were formed with essentially zero energy at the copper surface for bombarding beam energies up to several hundred volts. Had they been related to incident Cl^- ions in the beam, they would probably have carried away some of the kinetic energy of the incident ions.

It should perhaps be emphasized again that although yields as low as one neutral for 10^6 bombarding electrons or one ion for 10^8 electrons could have been detected, no such erosion of the bulk material of targets [e.g., Ni atoms from nickel sheet or Ba from (BaSrCa)O] was found, and the only removal observed was that of ions, formed from foreign materials adsorbed in some fashion on the target surface. Compared with reported positive ion (150 ev energy) sputtering yields[15] near 10^{-1} (one atom to ten ions) general electron sputtering yields are definitely trivial.

An application of these yield figures to the questions of target erosion and cathode poisoning is of interest. For the practical condition of electron emission (300 ma d.c./cm²) being drawn from a cathode to produce a general anode erosion yield of 10^{-6} (which could have been detected experimentally but which was not found), a maximum transport of 2×10^{12} neutral particles per second per cm² would be achieved.|| If this were all deposited on the cathode, one atom site in about 350 would be covered in one second, assuming a smooth (100) BaO plane of 5.50A[14] unit cell length for the cathode surface. In 1000 hours of cathode life, the anode erosion (e.g., copper) would amount to about 10^{-4} inch maximum. Thus anode erosion by this process would be insignificant, and sudden poisoning by the anode material would be unlikely.

Cathode poisoning of the low voltage variety[5–8] is usually associated with the drawing of electron emission to previously unbombarded tube elements and has been attributed to desorption, dissociation, or ionization of materials adsorbed on the target. Often beam energies too low to produce ionization are effective. The poisoning is usually observed to proceed to completion in less than one minute. A transport probably adequate for poisoning, about 0.1 monolayer cathode coverage per second, could be produced by the 10^{-3} efficiency observed for O^+ removal from Mo with space-charge-limited emission (30 ma/cm², 10 v, 0.5 mm spacing) drawn to a well-covered anode. This efficiency, computed as an effective collision cross section, is about 1 percent of peak values found for ionization of simple gases, hence higher values could occur. However, the gross removal efficiency at the critical anode potential may be indefinitely smaller than the peak value, because, depending upon cathode sensitivity to the poisoning agent, thermal energy distributions may determine the apparent threshold.

For pulsed emission operations (e.g., 30 amp./cm², 1 percent duty) the transport per second, aside from thermal effects, would be the same as for the 300 ma/cm² d.c. case; and for a 10^{-6} yield, in a single 100-micro-

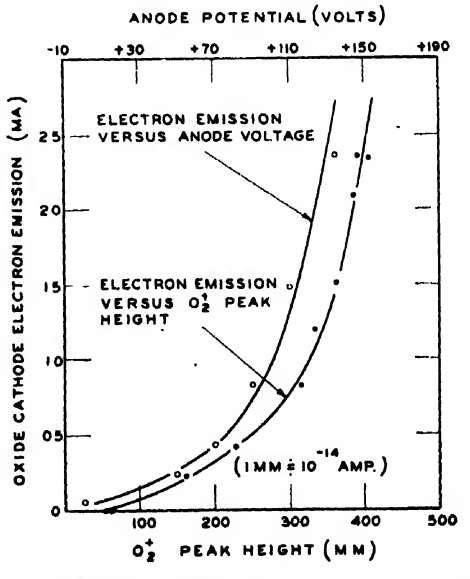

FIG. 10. Plot of electron emission drawn from oxide cathode (about 0.1 cm² coating area) *versus* O_2^+ peak height.

[15] K. H. Kingdon and Irving Langmuir, Phys. Rev. 22, 148 (1923).

|| For comparison, the intervening gas space maintained at a pressure of 10^{-6} mm Hg would contribute about 10^{14} incident gas particles per second per cm² of cathode, and would yield also about 10^{13} positive ions per second per mm of electron beam path (assuming 100-v electrons and a gas having the molecular weight and ionization cross section of CO). There would be only about 10^{10} molecules per cm³ of gas space.

second pulse, 1 percent of the d.c. transport for one second could accrue, 3×10^{-5} monolayer maximum. As indicated previously, about the same transport of positive ions might be derived from the gas space. Deactivation in a single 100 microsecond pulse as a result of reactions initiated by electron transit would thus hardly seem feasible. Higher yield electron bombardment processes, such as the ejection of adsorbed materials from well-covered anodes would appear essential to produce emission decay in this interval.

B. Evaporation Experiments

The evaporation of alkali metal impurity ions from other metals has been widely studied.[16] The re-evaporation of alkali metals as atoms and ions from heated filaments on which they had previously been deposited is also well known.[17] From these data it would be expected that, where impurity alkali ions are found evaporating from heated surfaces, atoms might be observed evaporating also. This has been reported[18] for Kunsman sources; however, we have found no reference reporting that impurity alkali atoms were detected evaporating from metals. The alkali metal atoms may conceivably have quite an important role in the reactions postulated to occur in oxide cathodes, since it was found that neither the alkali ions nor atoms evaporate from (BaSrCa)O coatings on metals which, when bare, gave a large evolution of alkali ions and atoms.

The evaporation of neutral entities from oxide cathodes was somewhat complicated. As anticipated from the accepted picture of the evaporation, the more volatile barium compounds were lost quite rapidly in the initial heat treatment and then much more slowly at a gradually diminishing rate. This agrees with the suggestion of Claassen and Veenemans[12] that the outer layers of individual crystals of (BaSrCa)O are quickly depleted of BaO and the rate shortly becomes limited by the diffusion rate.

The evidence of $BaCl_2$ evaporation from cathodes is based on the identification of peak groups (Fig. 5) as isotopic $BaCl^+$ (isotopic in both Ba and Cl). This identification is made with some hesitation in that no trace of $BaCl_2^+$ was found in the spectrum. These peaks were originally identified as BaO_2^+, $Ba(OH)_2^+$ from

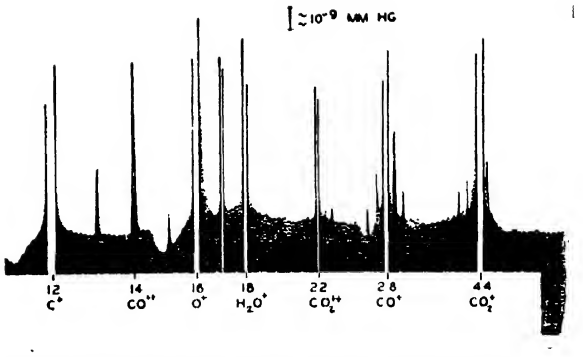

FIG. 11. Main portion of oxide cathode breakdown spectrum.

BaO_2 and $Ba(OH)_2$, respectively. Duplication of the result on several successive samples, together with the constancy of the isotopic (chlorine) ratios and better fit on the mass scale calibration favors the $BaCl^+$ identification. A $BaCl_2$ evaporation was reported by Hamaker, Bruining, and Aten.[6]

The Ba evaporation was expected, on the basis of the "free barium" picture and the mechanism of continuous core reduction of BaO, to be the most prominent feature of the cathode evaporation spectrum. The fact that it was always approximately equal to the BaO evaporation suggests it is not independent of the BaO evaporation, hence that it is perhaps limited by the rate of BaO reduction which in turn is limited by the rate of BaO diffusion to the reducing agent (and not by diffusion of reducing agent to the BaO). The presence of Sr in the sublimate, without SrO, argues against the possibility that the bulk of the Ba was oxidized by the residual gas as fast as it was generated and that the Ba^+ in the spectrum was all derived from ionization of BaO. The evaporation phenomena suggest that a considerable amount of information concerning the reaction mechanism could possibly be derived from a thorough study of evaporation rates and ratios and their decay characteristics.

XII. ACKNOWLEDGMENTS

Valuable assistance was derived from the suggestions of other members of the Physical Research Group, particularly Dr. D. O. North. Acknowledgment is made also of important contributions to the instrumentation by Dr. A. T. Forrester, Mr. W. B. Whalley, and Mr. J. F. Williamson, Jr., former members of the Laboratories staff. The recording system was designed by Dr. R. E Shrader.

The Static Electrification of Dust Particles on Dispersion into a Cloud

W. B. KUNKEL*
University of California, Berkeley, California
(Received February 17, 1950)

An extensive study of the charge and size distribution of particles from 0.5 to 30 microns radius in dust clouds of diverse exemplary types dispersed in air under a variety of conditions ranging from blowing with minimum of turbulence to conditions of violent and maximum impact with various types of surfaces was made using adaptations of the Hopper and Laby modification of the oil drop experiment. It was observed that all dusts, including homogeneous dusts with no impacts on solid surfaces, were charged. In homogeneous systems the charges of opposite sign were equal, no *net* charge resulting, the number of particles of similar size with opposite charges being about the same. The magnitude of charges increased somewhat less rapidly than the surface of the particle. There was no correlation between size and sign of charge. There is strong evidence that charging occurs on separation of the contacts between particles in the dispersion of the cloud. Humidity did not affect the charging. Studies of heterogeneous systems making contact with solid walls of different composition from the powder gave consistent asymmetry of charge of varying degrees depending on the proportion of particles striking the surfaces relative to those just separated.

ALTHOUGH frictional electrification is the oldest manifestation of electricity known to man, it still remains today quite obscure as to the mechanisms active.[1] Not only are its mechanisms little known, but most of the data obtained are not reproducible and, in general, appear to be highly inconsistent and to a large extent even contradictory.

Most studies of frictional electrification antedate 1933 and involved studies using macroscopic systems. Work at this time, though stimulated by industrial processes affected by such electrification, appears to have been abandoned, primarily because with the many uncontrolled variables, the existing techniques were inadequate to yield consistent results. This is not surprising since most studies concerned themselves with net charges produced using particles of different sizes on carefully treated surfaces with controlled surroundings, temperature and pressure. As will appear evident later, the net charge analysis concealed some very important phenomena whose existence is useful in interpretation. The conclusions drawn were that charging depends on properties of the surfaces and involved the nature of the contact. Very small changes in these factors sometimes entailed large variations in the observed effects. The work of D. Debeau[2] in this laboratory showed the reproducible influence of absorbed gas films on surfaces of Ni, quartz, and rock salt, as well as water vapor exhaled from the walls. Recent studies of Peterson[3] showed similar changes of quartz surfaces by condensation of impurities exhaled from metal surfaces after evaporation.

That perhaps more information might be gleaned by studies of the individual charges on large numbers of microscopic particles with large surfaces relative to their masses, seems to have occurred to numerous workers. Thus, H. Sachsse,[4] in 1932, determined the charges on dust particles using the Millikan oil drop method. Similarly, it occurred to L. B. Loeb quite independently, for in 1933 he assigned to S. Chapman[5] the analysis of spray electrified particles by the same method. The method is too slow and tedious to obtain good statistics. Nevertheless, Sachsse found the charges to depend on the material as well as the methods by which dust clouds were generated. In most cases, positive and negative dust particles were present in equal numbers with only a small number of neutral particles. Using compressed air for dispersal, the average charge was found to be roughly proportional to the particle surface, but in most other cases, it seemed to be proportional to the radius. The observed charges ranged from 50 to 2500 electrons. In general, Chapman's results with atomized liquid particles confirmed these findings. The charges of both signs were present with few uncharged droplets for materials of high dielectric constant. A pure hydrocarbon gave 25 percent uncharged particles and low charges of both signs on the rest. The magnitude of charge was nearly proportional to drop radius and charges of up to 800 electrons were observed for the largest drops of 10-microns diameter. In 1937, N. Rosenblum[6] studied the behavior of charged dusts in an electrical field of alternating polarity. The amplitude of the photographed motion of the particles gave the charge, while the vertical motion gave the mass. The findings, in general, confirmed those of Sachsse.

With the contemporary intensified study of the solid state, the nature of solid surfaces thus derived may ultimately serve as a guide to experimental studies that will reveal much of the nature of the charge transfer at work. The improved modern techniques now available should also facilitate study, using microscopic systems so as to lead to consistent results such as Debeau observed. Currently, however, the opportunity offered since 1938 to study the charges and sizes of individual

particles of a cloud of microscopic particles in a rapid fashion with good statistics seemed too good to pass over. Thus, as soon as the work of Hopper and Laby[7] on the evaluation of the electron using oil drops falling vertically in a horizontal electrical field and observed photographically by dark field illumination periodically interrupted by a rotating shutter was published, L. B. Loeb put students to the task of adapting this device for the study of dust clouds. The first attempt was interrupted by the war. In 1946, J. W. Hansen, an entomologist interested in the problem of insecticidal dusting, who had previously studied the electrification of such dusts using the older techniques, volunteered to set up the devices. Through his painstaking and skillful technique, the device was made to operate successfully and preliminary results were obtained.[8] Subsequently, the writer undertook to improve the device and with the improved techniques, which are described in a separate joint article by Hansen and the writer, the data here presented were obtained. As will be noted, the results obtained throw a considerable light on the mechanisms at work. There are still too many uncontrolled variables, as yet, to yield a complete picture of the processes at work, but certain mechanisms are definitely ruled out and other points clarified. The method has, of course, its limitations, but much more work with controlled atmospheres, as well as different systems, is still possible within the limitations encountered. Owing to the time involved in making the essential modifications for such work, this was not undertaken at this time. At a later date, it is possible that such studies will be undertaken.

EXPERIMENTAL TECHNIQUE AND LIMITATIONS

As indicated, the details of the apparatus and method of operation are elsewhere presented.[9] This paper will thus only concern itself with those features of the investigation affecting the results to be reported. As the studies do not require accurate evaluations of charges and particle magnitudes, certain inherent errors can be disregarded without correction, and measurements can be simplified in the interest of more data relative to accuracy of individual values.

Thus, uncertainties introduced by the irregular shapes of the particles and the consequent deviations from Stokes' Law were overlooked. The method, however, yields statistics for charge distributions for a whole cloud in relation to particle size, charge and numbers using random samples. While this method is capable of application to studies of carefully treated particles in well-controlled atmospheres, this was not attempted in the present study. Reasonable chemical and physical purification of the dusts was resorted to, and only dried room air was used. The dust clouds were dispersed by various means so as to extend from a gentle dispersion of the dusts with separation and a minimum of friction to more violent distribution with turbulence. Where needed, the blowing was controlled in as nearly a quantitative fashion as possible by means of an adjustable piston blow gun. The dispersion was also arranged so as to cover from a minimum of contact of the particles with surfaces to a maximum of such contact. Surfaces were as carefully prepared and controlled as contact with the room air permitted. Surfaces similar and different from the dusts, as well as mixtures of different dusts and pure dusts, were used. The measurements were checked as regards size distribution of the ultimate particles by microscopic examination of the dusts. This also served as a check on the absence of convection currents in the apparatus, which could seriously falsify both the statistics and charge sizes. For, if the size distribution as revealed by a microscopic study of the particles collected below the measuring field on a slide differs, especially in the region of small particles, from the distribution calculated from the rates of fall, there have been convection currents, either upward or downward, that produced the effect.

The principle of the method involved the production of the dusts by one of the various methods indicated below at the top of a settling tower of some meter in height (Fig. 1). At will, the cloud could be produced at different heights above the analyzing chamber. The cloud then settled down and along some small axial section fell through a slit into the observation or analyzing chamber containing a pair of vertical deflection plates, where it was photographed in a series of exposures on such a precalculated schedule to yield suitable sampling. The photographs indicated positive, negative and neutral particles in sizes ranging from 0.5

micron diameter to 30 microns. The charges varied from 0 to 30,000 electrons. The average charge per particle and the net charge of a sample depended on the substances used and processes of dispersion. By using large samples, these effects were reproducible. The cloud samples photographed in their measurements ranged from 200 to 2700 particles in a given cloud depending on the purpose of the investigation. The tracks of the particles observed consisted of a series of some ten dots separated by appropriate intervals, depending on the duration of the light flash and intervening dark time as set up on the rotating shutter in the optical parts (Fig. 2). Uncharged particles showed a vertical line of dots, unless the particle was largely irregular in shape. Particles out of focus by being too near the camera appear as circles; those too far away appear as stars. These appearances are predictable effects resulting from the optics. The tracks inclined to the one side or the other indicated charged particles of sign depending on the direction of the field used. The rate of vertical fall and the rate of horizontal movement allowed both charge and mass to be determined by insertion into the appropriate equations. In practice, the photographs were projected to a given scale of enlargement on a screen (usually 50×) and by means of a properly constructed nomographic scale, the charges

and sizes could be inferred within a sufficient degree of accuracy for the purpose of statistics directly. When greater precision was required, more accurate data could be taken.

It must be realized that when a cloud is blown at the top of the settling chamber, there will be a segregation of particle size in falling through the chamber. Very shortly after the cloud is blown, the first very heavy particles reach the slit of the analyzer. As time goes on, the heavy particles settle out, and later—in fact even hours later—the smallest particles reach the analyzer. Thus the analysis of the cloud will consist of a properly timed and chosen set of photographs of the transient particles in the analyzer. To understand this, it is best to consider a characteristic movement.

Assuming a spatially homogeneous cloud to have been blown at a time $t=0$, the experiment consisted of a series of photographs of particle tracks taken at certain intervals. The number of particles observed in this fashion represented a certain fraction of the total number of particles in the narrow column settling through the slit at the top of the analyzing chamber. This fraction α, however, depends on the rate of settling of the particles, i.e., on the size, $\alpha=\alpha(d)$, where d gives the particle diameter in microns. In other words, the sample observed was not completely random but contained a certain size selection. Although we were not primarily interested in an exact representation of the size distribution in this study, some correction for this selectivity had occasionally to be made. A first correction could be applied by assigning proper statistical weights to the size groups observed on a picture. If W was the height of the region photographed and $v(d)$ was the rate of settling of the particles of size d, then the number of such particles included in the exposure time t is proportional to $W+vt$. The total number of such particles present in the column between successive exposures is proportional to vT where T is the average time between successive observations. Thus, the proper weighting factor for the particles of size d observed in exposures of duration t taken at intervals T is $\alpha=vT/(W+vt)$. If t and T are varied during the course of the experiment such that α for the average size observed on the pictures is kept constant, the sample taken did not falsify the actual size distribution greatly.

On the supposition that the above condition was fulfilled, the particle sizes and charges measured were tabulated and sometimes plotted. The charge-size distribution diagrams thus obtained for various samples give a good impression of the characteristics of the dust clouds in question. Frequently, the average charge per particle was calculated for successive size intervals, and the total charge present in the samples was evaluated. The results obtained and represented in this form were, in general, sufficient to provide all the desired information. In many cases, it was sufficient merely to compare the numbers of positive and negative particles in the samples and to estimate their charges only very roughly. In such a highly simplified representation of the experimental results, the element of chance introduced by the fact that only a sample of the cloud was measured could be expressed in a very simple manner. Since the particles were practically always charged and since the total clouds were always very large compared to the samples measured, the chance of finding a certain distribution in a random sample is given by the well-known binomial probability distribution law assuming homogeneity of the cloud. For large samples, such a binomial coefficient function exhibits an extremely narrow and steep maximum at the point of the actual distribution in the cloud. A half-width of such a maximum can be defined as that variation in sample distribution for which the probability is, say, one-tenth of the maximum value. If the samples are large enough, this half-width does not depend very much on the position of the maximum and is, therefore, evaluated most easily for the case of an equal distribution; i.e., for equal numbers of positive and negative particles in the cloud. This has been done for all experiments and will, henceforth, be called the standard deviation of the particular measured distribution.

The method of analysis outlined above is valid only if the cloud does not have its particles change in size or charge with time in the settling chamber. This subject

had been thoroughly investigated in all its aspects in view of some early results of Hansen.[10] The conclusions arrived at are as follows. In general, dust particles that settle quietly will stick together when they touch, thus, effectively growing less in number and larger in average diameter. A calculation has shown, however,[11] that for the cloud densities we were dealing with, the probability of such agglomeration was entirely negligible. We concluded, therefore, that the large number of aggregates invariably present in the clouds existed at least from the moment of dispersion on. This conclusion is confirmed by the fact that the amount of aggregation observed does not seem to be related to the length of the settling column.

Comparing the particle size distributions of the dust clouds for the cases of dispersion with much turbulence to those where the turbulence was slight, no significant difference could be discovered. From this result, it was concluded that the aggregates or glomerates had existed as such in the packed powders and were never separated into the ultimate particles by the stream of air, rather than that they were formed out of single particles during the violent agitation at the time of dispersion.

Another potential source of trouble is that the charges on the particles will, in general, tend to decrease in time. This arises from the presence of gaseous ions of both sign. The ions are constantly created in the air by stray radiation, and despite recombination, they will be maintained at a finite ion density in the air of the settling chamber. Highly charged dust particles suspended in the air will have an appreciable chance of catching these ionic neutralizing charges. In fact, a simple calculation reveals that for cloud densities of a thousand or more charged particles per cubic centimeter, almost all the ions created in air will attach to the dust before they have a chance to recombine. Thus,

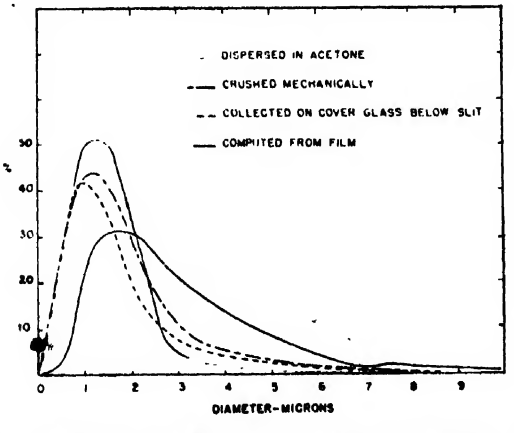

FIG. 5. Particle size distribution in precipitated sulphur. This graph shows the effect of a slight vertically downward convection in the analyzing chamber letting the particles photographed appear too large (settling faster than they should).

[10] J. W. Hansen, thesis, unpublished (1948).
[11] W. B. Kunkel, J. App. Phys. 19, 1053 (1948).

the total charge of one sign in a dust cloud will decrease linearly with time at a rate equal to the rate of ionization of the ambient air. As this rate is small, the decrease in charge is usually very slow, so that our experimental results will only be effected in the case of particles of very long settling times; i.e., for the very small particles. This is, indeed, what was observed. This problem has been investigated in detail and will form part of another paper. The results of the analysis allow of a proper computation of certain factors. Whenever an estimate of the initial charge of such extremely small particles is desired, an appropriate correction must thus be made. In addition, it should be borne in mind that the more highly charged particles will be neutralized more rapidly than those that were initially less charged. Thus, not only is the average charge of a cloud initially higher, but the initial spread of charges is larger. The corrections are not large compared to the charges involved and since little use will be made of the accurate evaluations, these corrections and their elaborate theoretical treatment will be omitted in this discussion.

THE POWDERS

The materials used in this study were chosen for a number of reasons. By selecting substances of widely varying physical and chemical properties, it was hoped, in the first place, to distinguish between the relatively important and unimportant variables limited, however, by three factors: the substance had to be easily obtainable in powder form of a grain size between 1 and 30 micron diameter; the powders had to be easily dispersible, with as little lumping as possible; and, lastly, the surfaces had to be reasonably clean. Unfortunately, this meant that neither hygroscopic nor chemically very active substances could be studied.

The desire for relative purity and chemical homogeneity, also, explains why no attempt was made to obtain and work with artificially rounded particles, rather than with the natural irregularly shaped substances.

The first part of this work logically undertook the study of the charges of as simple and elementary insulating substances as possible, in order to see what charges, if any, appeared on homogeneous systems. It was limited to two substances: quartz and sulphur only. These could easily be obtained in powder form of the desired grain size in fairly pure condition. The quartz was obtained by crushing and grinding. The sulphur was prepared by precipitation or crushing. The desired size range could be separated by sifting or, since neither of these are soluble in water, they could be sized by elutriation methods. Another advantage was that the containers could be made out of the same materials or in the case of sulphur, at least lined by the same material, so that sulphur only came in contact with sulphur and quartz with quartz. The main disadvantage with these substances was the particle shape, which, in general, was very far from spherical. Micrographs of

crystalline quartz are shown in Figs. 3 and 4. The electron microscope revealed that the surfaces frequently were far more irregular on a microscale than would be expected of crushed crystals. Although, in this sample most particles with diameters less than one micron had been carefully filtered out, a large number of invisible fragments were still present on the surface of the larger particle. They may have adhered to the larger particles on sizing, or they may have broken off the larger particles in the subsequent handling of the powder and then were later picked up. The presence of this coating of finer quartz dust in all observed particles must be borne in mind in the interpretation of the results. The sulphur particles were even worse in respect to regularity, with the additional drawback that they had a strong tendency to cling together very tenaciously, thus forming large aggregates of extremely irregular shapes. This could be ascribed to heavy electrostatic charging and small surface leakage. It was very difficult to break up these aggregates as shown in Fig. 5. Certainly, a gentle stream of air would be very inefficient in dispersing such a powder. This is characteristic of pure sulphur, so that in industrial practice, whenever a sulphur dust is desired, small admixtures of a suitable substance are added to prevent lumping. Since, initially, we were interested in the effect of sulphur on sulphur only, we could not make use of the dispersing admixtures. Thus, in our observations, the sulphur always contained a larger percentage of aggregate than the quartz. As indicated, the irregularity of the particles falsified the size and the charge as deduced by means of Stokes' Law,[12] and by sideways motion introduced apparent charges when none were present. To determine the magnitude of these simulated charges, test runs were made, photographing the dust as it settled under the influence of gravity alone. About 20 percent of the quartz particles showed slight deflections from the vertical, but the charges that would be calculated from these deflections in a usually fairly high field (about 200 v/cm) proved to be very small compared to charges actually appearing. Apparently, the constant tumbling motion in a field free space, due to Brownian rotation and differential heating of the settling dust particles, considerably reduced the amplitude of the helical motion,[13] which appeared to be much larger in the model study. There is evidence that in the presence of strong fields, these salutary rotations of the particles may have been absent. This came from the observation that the intensity of the light scattered by the particles fluctuated less when the electric field was present than otherwise. It is, thus, possible that, after all, the lateral drifts were somewhat larger in the actual charge measurements with the field. In the interpretation of the results, however, we shall consider these fictitious charges as negligible, inasmuch as they produce little error on multi-charged particles and, perhaps, gave a few more small lightly charged particles at the expense of neutrals than there were.

Another difficulty arose from the fact that both quartz and sulphur exist in different solid phases. It was, therefore, necessary to investigate in how far such a system could be regarded as homogeneous. The powder of precipitated sulphur was definitely rhombic, but when part of it was melted down to be used as a coating of the container, it would solidify in the amorphous phase. It was found desirable to allow at least two days to ensure that the coating had completely crystallized in the rhombic phase again. In the case of quartz, however, this procedure was not possible, since fused silica will not crystallize. We restricted ourselves, therefore, at first to crushed amorphous quartz powder in fused quartz containers, but later discovered that crystalline powder behaved in the same fashion. Either the surface of the carefully washed and thoroughly hydrated quartz powder stayed amorphous after dehydration, or the surface of the fused quartz assumed crystalline properties, or, possibly, in contrast to the sulphur, the difference between the two conditions was not sufficient to result in any detectable deviation from the homogeneous case. Consequently, the difference between amorphous and crystalline quartz was disregarded in subsequent work. Thus, the main study was done with a commercial grade of crushed quartz which was supposed to be quite pure. Since it might have been crushed in a metal mortar, it had to be washed in dilute hydrochloric acid and afterwards thoroughly rinsed in distilled water. After this treatment, the powder was dried for several hours at 120°C and stored in a closed glass jar. Nevertheless, it was found that the quartz would reach an equilibrium moisture content of a water layer of one to two molecules thickness surrounding the individual particles, which could only be driven off by prolonged heating to above 500°C. This dried powder would be so hygroscopic that it would acquire its former moisture layer very rapidly, even when placed in a dessicator containing phosphorous pentoxide. More surprising, however, was the fact that even in a very humid or almost saturated atmosphere, the water content of the powder, by actual observation, did not increase noticeably. Apparently, the average radius of curvature of these small particles was too small to permit water to condense on them in excess of the first layer that was adsorbed.

Similar observations were made on the sulphur powder, although the latter could, of course, not be baked out. An attempt to dry the sulphur at normal temperature in vacuum resulted in sublimation of sulphur, rather than in a removal of the last water layers. Only when the quartz and sulphur powders were placed in a supersaturated atmosphere could an increase in weight be detected; but in those cases, water condensed profusely on all surfaces, making the powders at once wet and lumpy. No intermediate stages of

[12] W. B. Kunkel, J. App. Phys. 19, 1056 (1948).
[13] E. E. Miller and Tanner, Phys. Rev. 77, 761 (1950).

moisture content seemed to be stable. Thus, the effect of water layers, if any, on the electrification of these non-hygroscopic substances could not be well-determined. It may be stated, however, that because of its relative stability, the monomolecular moisture film of such powders does not seem to be an important variable in the electrification phenomena. Certainly, the nature of these films rule out completely the old electrolytic ion exchange theory of tribo electricity.

The sulphur that was largely used in these studies was commercially produced, fairly pure precipitated powder, which happened to have just the right size distribution. Being a chemically fairly active substance, however, and moreover being produced in a chemical reaction, it was not expected to be completely free from impurities. Certainly, H_2SO_4 must have been present in spots, owing to slow oxidation in air. The insensitivity to moisture, however, indicates that these spots were few indeed.

Another substance which was chosen for its interest as a different type of powdered substance, e.g., a powdered carbohydrate, was a sample of very pure natural rice starch, the granules of which were very nearly spherical and uniform in size (between three and five microns in diameter). With this and some of the other powders mentioned, the studies had progressed so far that we no longer were interested in preventing the contact between dissimilar substances. Thus, it was possible to look at a wider range of powders which did not have to be made into coatings of the containers. Since it did not seem possible to take measurements on particles where the moisture had been completely removed and working in moisture-free systems without changing the experimental procedure, several runs were made with a talc powder, which was considered to be a naturally "dry" substance. The grain size and shape was very similar to that of the quartz powder.

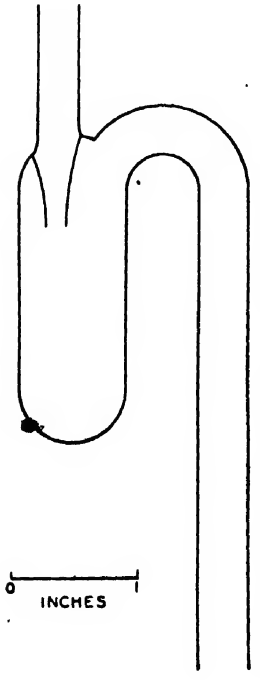

FIG. 6. Dusting tube made of quartz or Pyrex, sometimes lined with sulphur.

Obviously, among the simple elementary dusts, metallic powders come to mind. These are, however, very hard to produce in a satisfactory condition. In order to study the behavior of metallic particles, a nickel powder was prepared by rubbing a nickel rod with emery paper and separating the metal particles from the abrasive by means of a magnet. The powder had to be demagnetized and reduced in a stream of hydrogen. After this treatment, it appeared to be readily dispersible and of sufficiently fine grain size. The shape of these particles was, of course, extremely irregular, especially the larger ones, but since we had a nickel dust disperser, chosen because of its relative resistance to corrosion, it was considered desirable to investigate the behaviors of a powder of the same material. (It was only after the experiments had been discontinued that we were able to obtain a sample of the nearly spherical carbonyl iron powder. Such a powder, however, would be more heavily oxidized and, therefore, probably not representative of a metal surface.)

METHODS OF DISPERSION

In the interests of simplicity of operation, it was decided to employ dispersion by short blasts of air only. Since it was essential to the measurements that violent air disturbance in the settling tower be avoided, only a relatively small amount of air could be applied. For the same reason, more vigorous methods of cloud generation like explosions or mechanical shaking had to be discarded. We, thus, were rather limited in the range over which the factors involved could be varied. Nevertheless, as will be shown, this small range proved to be sufficient to permit the most essential conclusions.

In order to distinguish between some of the various mechanisms by which the charge separations might be effected, it seemed plausible, as a first step, to compare the result of a maximum of friction with that of negligible friction.

Hence, the simple dusting tube shown in Fig. 6 was designed so that even a gentle stream of air would cause strong turbulence, thus offering a maximum chance of frictional contact among the whipped up particles themselves and between the dust and the walls. Such tubes could easily be made of fused quartz or of Pyrex. One of the Pyrex tubes was carefully lined with sulphur. A similar duster was assembled out of nickel tubing. On the other extreme, it was impossible to disperse any of the powder without causing some slight friction between particles. However, it was attempted to reduce the contacts between particles in such dispersions after the initial separation to a minimum by blowing the powder very gently out of a small thimble-like container as indicated in Fig. 7. The motion in the clouds

thus produced indicated that turbulence was negligible in this case. The cups again could easily be made out of quartz or sulphur to avoid any possibility of contact between dissimilar substances when it was not desired. When, on the other hand, the effect of collisions of the dust particles with metal walls was to be studied, a third type of dusting tube was constructed especially designed to offer a large opportunity of particles striking the sides, Fig. 7. The number of baffles could be varied up to a maximum of fifteen per tube. The idea of forcing the stream of air into a zigzag path with sharp bends is fairly obvious and seemed to work well in many cases. The sample to be dispersed was placed on the second baffle from the top. Two of such tubes were constructed, one of nickel and one of platinum, avoiding all traces of foreign metals on the inside.

Early in the work, it was realized that the amount and velocity of the dispersing air stream had to be rather accurately controlled if reproducible results were expected. While the amount of charge appeared to be insensitive to the air blast, the amount of dust and thus the cloud density varied widely with the air stream used. Since these had to stay within certain limits to facilitate analysis and make statistical interpretation possible, it was clear that the air blasts had to be quantitatively reproducible. To achieve this, a blowing cylinder was devised, consisting of a brass tube of 6.25 cm diameter with a plunger bearing rubber "O" rings. This air gun had to be mounted upright above the dusting tube or cup. The outlet was at the bottom carrying a stopcock and a long thin detachable nozzle. The plunger could be lifted to entrap the desired amount of gas in the cylinder, the pressure could be regulated by loading the plunger with the proper weights. A further advantage of this design was that the blast to be applied did not necessarily have to consist of ordinary room air, but could consist of dried air or any gas which did not react with the tubing. This device performed very satisfactorily.

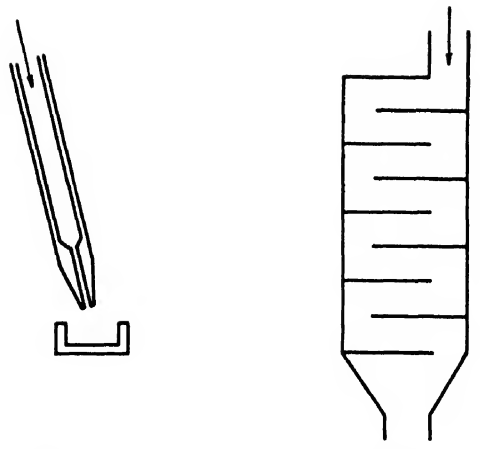

FIG. 7. Left: small cup and nozzle, made of quartz or sulphur. Right: metal duster made of nickel or platinum. The sample of powder to be dispersed was placed on the second baffle from the top.

THE RESULTS

All in all, more than eighty separate experiments were performed in this study, consisting together of more than 3000 exposures. Some 50,000 particles were photographed. The charge and size of not all of the particles were measured accurately. A large fraction of the charges and sizes were just estimated very roughly. The frequent repetitions of experiments under identical conditions showed the results to be completely reproducible. There is, therefore, little doubt that the findings here reported are reliable and of a general significance.

It must first be noted that every single cloud investigated *contained both positive and negative particles simultaneously*. Whenever any contact between unlike substances was completely avoided; e.g., blowing quartz powder out of a quartz tube or sulphur dust out of a sulphur cup, the numbers of positive and negative particles were about equal. Dividing the particles into groups of certain size ranges and calculating the average charge per particle for the various sizes, it was found that these were also equal for the two polarities. The average charge per particle increased, in general, somewhat more slowly than the square of the diameter, i.e., not quite linearly with the surface. This observation was quite general in all studies. Very few of the particles observed, in the range of sizes studied, were uncharged.

A good description of the charge, size and relative frequency distribution of the particles in such a dust cloud can be given graphically by representing each particle observed by a dot at the appropriate point in a charge-size plane (Fig. 8 for blown quartz dust). Since, in the particular experiment shown, more than 1500 particles were measured, only every fifth one was plotted in order not to overcrowd the graph. The averages drawn in, however, were computed from the total number. The picture indicated in Fig. 8 was typical of all of these homogeneous cases. Even the average charges never differed very much in these homogeneous studies, despite much variation in dispersion procedure. This is a rather remarkable result, since the amount of friction or the number of impacts between the particles presumably varied appreciably, depending on the amount of turbulence during dispersion. Particular values for fine quartz dust blown out of a quartz duster and out of a small cup, representing the extremes studied, are given in Table I. Similar values were found for sulphur dust. Several explanations of this unexpected behavior suggested themselves. The processes by which charge separation occurred apparently were not influenced by the difference in turbulence. This probably means that the charge separation occurred at the first separation of the contiguous particles and the charges only possibly redistributed themselves slightly at subsequent collisions which would not affect their magnitude appreciably. Whether these charges were

TABLE I.

[a] Here particles were considered neutral when their charges were too small to be determined; i.e. $q < 3$ for $d \approx 1\mu$ increasing to $q < 30$ for $d \approx 10\mu$.

already irregularly distributed in the packed powder, or whether the separation occurred at the moment of dispersion could, of course, never be detected by our method. But, since the powder as a whole was neutral, and since any charge is effective only when separated from its opposite, this question is of little interest. We could, also, assume that the charge distribution reached some kind of an equilibrium after comparatively little friction, so that any further impacts and additional friction would not change the resultant charge distribution noticeably. The difference between these two interpretations can be summarized in the following way: In the first cases, the main charge separation is supposed to occur at the first mechanical separation of the particles; whereas in the latter, it is regarded as a result of several collisions and possibly friction of very short duration. However, as later interpretation shows, the evidence is all in favor of a charge distribution on separation of contacting surfaces. There is, of course, a small chance that the strong variation in turbulence, contrary to expectation, did not effectively change the amount of friction and the number and violence of the impacts between particles. In that case, it would be expected that no difference in the observed particle charges would be found. At any rate, the electrostatic cloud characteristic shown in Fig. 8 was surprisingly independent of the conditions of dispersion.

Changing the moisture content of the surrounding atmosphere in the hope of varying the water layers on the dust particles, and thus the charging, produced no material change in the type of distribution shown in Fig. 8. But, as already pointed out, the water content of a fine non-hygroscopic powder was known to be remarkably unaffected by the relative humidity of the surrounding medium, so that any significant variation in charging due to moisture was hardly to be expected.

A short summary of the most important experimental results is given in Table II.

There it is seen that still more surprising than the invariance of the charges generated in homogeneous systems, was the fact that many so-called inhomogeneous systems showed nearly the same symmetric charge as in Fig. 8. When quartz, talc, or starch was blown out of a pyrex duster, the charges on the particles balanced just as before* and when sulphur was blown out of a quartz, Pyrex or nickel tube, the predominance of one sign of charge was only very slight.

Again, two different explanations are possible. First of all, there was little doubt that only a small fraction of particles actually hit the solid walls in the process of generation, most of them being surrounded by a layer of air all the time, and thus being cushioned by the air and failing to strike the walls. Larger particles had a better chance of impact than smaller particles because of their inertia. Thus, most of the charges were generated by dispersal into the cloud or by collisions between particles. Those particles that hit the walls either did not interact sufficiently with the wall lattice to cause any appreciable charge transfer, or else the differences in surface characteristics were not large enough on the average to disturb the initial symmetry perceptibly. Strangely, the sulphur powder did not show a very large asymmetry, even when forced through the nickel duster with as many as eight baffles. In that case, certainly, most of the larger particles must have hit the sides. We have not been able to account adequately for this fact, except, possibly, by noting that the observed samples could not be made large enough to yield reliable statistics. (The sulphur was not easily dispersible.)

The talc powder, when blown through the nickel chamber, did not show the slightest asymmetry in its

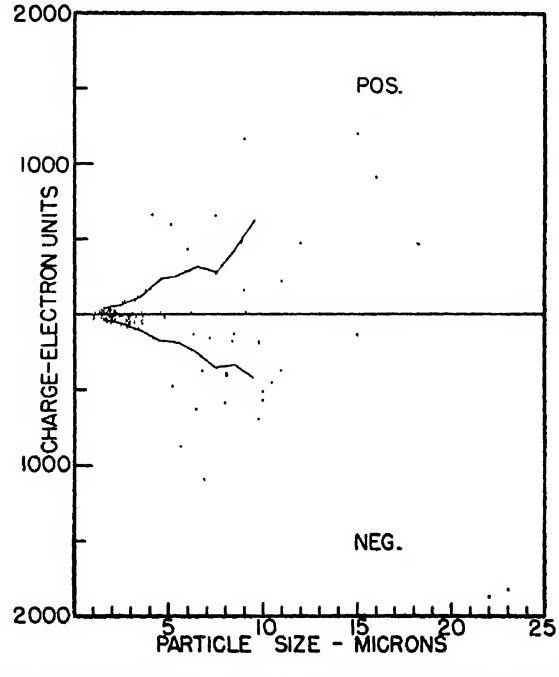

FIG. 8. Charge *vs.* size representation of a cloud of quartz powder blown out of a quartz cup. The average charges per particle are drawn in; the spread is seen to be large.

* A similar result was obtained by Hansen with $CaCO_3$ powder in a SiO_2 duster.

charge distribution. Here, however, the explanation was obvious. Opening the nickel duster after the experiment revealed that the inside was completely lined with a heavy layer of talc powder. This layer could not be blown off but had to be wiped away. Apparently, all talc particles hitting the metal sides stayed there, possibly attracted by their image charges, until all metal surfaces were covered, thus effectively reducing the conditions to those of the homogeneous cases.

The only fairly pronounced asymmetry in charge distribution involving solely non-conductors was obtained when a fine quartz powder was blown out of a sulphur lined duster. The negative sign predominated distinctly, which was in qualitative agreement with the fact that in the sulphur powder dispersed out of a quartz duster the positive charge was noticeably larger.

It was noted, at the same time, that the asymmetry was stronger in the larger particles, being very slight for the smaller sizes. All other strongly asymmetric cases contained metallic elements. When insulating powders were used with metal or vice versa, this insulating dust invariably acquired a predominantly negative charge, leaving the metal with the corresponding positive balance. The largest deviation from the symmetrical distribution occurred in a quartz cloud blown out of the platinum dispersing chamber with eight baffles. A plot showing every other particle is given in Fig. 9. It is seen that the negative charges predominated both in number and magnitude. Still a large number of positive particles, especially of small diameter, were present. None of the larger particles carried a positive charge. Evidently the quartz in contact with platinum was likely to acquire a surplus of electrons.

All large particles or glomerates hit the metal surfaces at least once, whereas many of the smaller ones never touched the walls, being carried along by the air stream well imbedded in the gas. Many of the small particles that succeeded in colliding with the sides of the chamber stuck there, forming a thin coating. A crude measurement of the positive charge imparted to the duster showed this to be of the same order of magnitude as the total net charge estimated to be present in the cloud. This can be considered as evidence that the observed negative surplus charge was not balanced by invisible positive particles left behind in the settling column. If desired, this conclusion could, of course, very easily be verified by employing any of the many well-known space charge detecting devices.

In agreement with these findings, a nickel powder blown out of the quartz dusting tube carried a predominantly positive charge with a spread otherwise similar to that shown in Fig. 9. Either the nickel particles, unlike those of sulphur, had a large chance of touching the sides of the tube, possibly because of their larger inertia for equal volumes (higher density), or the charge transfer between nickel and quartz is easier than that between sulphur and nickel. The

[a] Ni duster found coated with a layer of talc powder.
[b] Sulphur powder could not be well dispersed.
[c] The deviations from symmetry are expressed by the ratio $x = \frac{N_+ - N_-}{N_+ + N_-}$.

nickel powder, when dispersed out of the nickel duster, however, did not behave like the other homogeneous systems, very probably because the surfaces of the reduced Ni particles differed appreciably in their properties and constitution from the nickel plate walls. This was despite the fact that every common precaution possible had been taken to insure uniformity and zero contact potential.

As shown in Table II, an observed distribution is considered to be symmetric when the deviation from the exactly balanced distribution is less than the statistical standard deviation of the particular experiment. Similarly, if the deviation is only a little larger than the standard deviation, the distribution is called slightly asymmetric. If it is much larger, the result is regarded as asymmetric. In this way, the statistical factor, which is unavoidably connected with any measurement on random samples, is at least partially taken into account. This procedure of classifying the results merely according to the relative numbers of positive and negative particles instead of according to the magnitude of these charges is justified, since all experiments show a strong correlation between the relative numbers and the average charges of the particles of opposite sign.

Finally, in order to demonstrate most convincingly that much of the charge separation takes place during the very first phase of the dispersion, the fine quartz powder was mixed with the easily lumping sulphur and blown very, very gently out of a quartz cup by a slow vertical stream of air. In this case, the large particles seemed to be fairly randomly charged with only a slight excess of the negative sign; whereas the small particles which arrived later proved to be overwhelmingly negative. These latter were certainly mostly quartz; the former must have consisted partly of the large sulphur glomerates. Since both the contact between particles and dissimilar walls and the turbulence and friction between particles was presumably negligibly small, the charge separation must have become effective at the very first breaking of the close contacts between the dissimilar surfaces of the quartz and sulphur particles. It should be noted that in

cases like these, all elements of a static machine separating or segregating charges which could ultimately lead to sparks are present. The dissimilarity of large and small particles results in an asymmetry of charge by small particles having one sign larger than the other. Mechanical separation in the gravitational field or by air currents then leads to segregation of charges and local accumulation.

CONCLUSIONS

There appears to be no doubt that the act of separating a mass of particles of solid in contact with each other into a cloud of assorted sizes of particles, yields in all cases a cloud which as a whole is neutral, but in which practically all the particles are charged. In a homogeneous substance, where contact with heterogeneous surfaces are at a minimum, the numbers of positive and negative particles in each size group from about 0.5 micron to 30 microns in diameter are about equal. The average charge increases somewhat more slowly than proportional to the surface of the particles. Apparently the character and forces involved in the separation and the possibility of subsequent friction in turbulent clouds with violent blowing produce no notable change in the electrification, nor does the charge increase with increase in contact or the energy involved in the process. In the separation of an originally mixed dust of different average size for the two components, the study of the cloud indicates that the electrification occurs primarily at the instant of separation of the two components. If homogeneous clouds are blown so that they make contact with solid surfaces of a different sort in sufficient measure to affect a notable fraction of the particles, the separation of the heterogeneous system of dust and solid surface may impose an asymmetry on the equality of positive and negative particles from the dispersed cloud particles that did not contact the solid surface. Results are reproducible in any given system. However, in a surprisingly large number of impacts between dissimilar surface and dust, no great influence was observed. In general, the asymmetry is exhibited more strongly by the larger particles, which, because of their mass, were more likely to strike the solid surface. Very small particles of the order of one or two microns appear to be cushioned by the gas and do not make contact with the surface in some cases. In occasional cases, e.g., talc on metal, care must be taken in interpreting the results, since the dust may be so highly charged and insulating that it is held to metal surface and most of the cloud makes contact with the dust coating only, showing the charge distribution of a homogeneous substance. The direction of charge transfer between heterogeneous surfaces is unpredictable and depends on the substances involved. With some insulators, the character of the surface, whether crystalline or amorphous, appears to cause no asymmetry or charging. Thus, amorphous quartz and crystalline quartz showed no asymmetry. Likewise, Pyrex glass, a borosilicate glass, and quartz showed no asymmetric transfer. The most universal asymmetry observed was that of metal and insulators, where the insulator universally received a negative charge. In the case of a Ni powder reduced in H_2 against Ni or Pt sheet strong asymmetry was observed with the reduced Ni powder losing electrons to Pt and to the sheet Ni. This is to be expected in the case of Ni and Pt, for Ni has a low work, function relative to Pt. In some cases where asymmetry, owing to contact of dust and surface, predominated, the charge on the duster roughly equalled the total net charge of the opposite sign on the cloud. These results, as a whole, and especially those with metals, not only through their consistency and reproducibility, but through the signs of electrification obtained, give considerable confidence in the use of this method and the results it yields. In fact, it now appears that the method is ready to be applied to systems of exceptional purity and in carefully controlled atmospheres, in order to derive some hints as to the true character of the processes of charge exchange in non-homogeneous systems as related to the solid state.

Insofar as these studies go, they were done on reasonably clean surfaces and a fairly representative spread of substances to cover the field. The ambient gas was fairly dry and filtered air, subjected to the natural ionization by radioactivity in the surroundings and cosmic rays in the settling tower. Probably, in this connection, one of the most striking discoveries in the

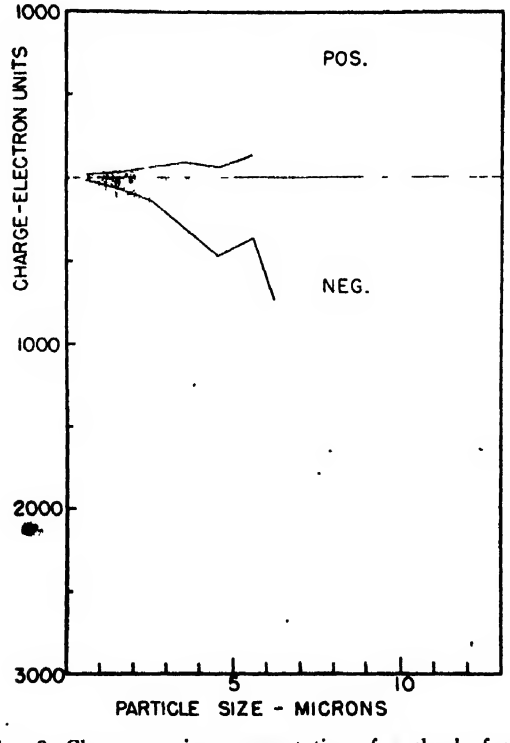

FIG. 9. Charge *vs.* size representation of a cloud of quartz powder dispersed out of a platinum duster. The average charges per particle are drawn in; note the large spread.

work with the normally dry dusts used, was the minor role played by the water vapor and moisture. Since trouble from this source was expected, considerable time was devoted to its study. Actual studies, especially on the quartz, indicated that if heated above 500°C, it lost all superficial moisture: On cooling to room temperature, or even to 120°C, it rapidly absorbed a small amount of water. By weight, it was equivalent to no more than enough to cover the average particle if spherical with, at most, a layer two molecules deep. From the electron microscope pictures of the particles of quartz, the surface is really so much greater than assumed that the layer could not be more than one molecule thick, and then the H_2O molecules may only occupy preferential spots. Changing relative humidity up to 90 percent at 20°C did not alter the layers at all. Above this, the surface became wet and the dust stuck together. Such dust did not disperse. From this it must be concluded that the water played a minor role in the electrification. Certainly, there was not enough water to give aqueous films, so that the classically conceived electrolytic ion exchange could account for the electrification.

It is probably too early to try to evolve a picture of the processes at work. However, the universal symmetry of charging on separation of homogeneous particles after contact and the asymmetrical charging of some of the heterogeneous systems, together with observations in the electron microscope, permit us to formulate a tentative theory of what happens. In the case of the homogeneous system, it is clear that the major portion of the charging comes from the separation of particles initially in contact. The very great sub-microscopic roughness of the surfaces which was observed, together with no evidence that this roughness constitutes a fine sub-microscopic dust which charges independently of the microscopic particles in the cloud, leads one to expect relatively strong pressures in contact points between the major aggregates microscopically observed. These pressures could *eliminate gaseous or surface films* and thus constitute intimate contact *between small areas of the homogeneous substance.* The separations on dispersal may take place along the actual region of contact, or they may take place by the actual fracturing of the small contacting points, depending on how intimately the pressure has welded the contacting points of the two larger pieces together. In any case, separation and dispersal into a cloud involves producing some sort of rupture between a large array of minute points. Doubtless, these points are of various sizes. If now one makes the assumption that for a contact area of some minimum size, i.e., radius σ involving, say, some 10^3 or 10^4 atoms of the crystal lattice, there is a good chance that crystal imperfections will leave one extra electron or ion of negative charge lying near the plane of fracture on one side of that plane; then that particular point of contact on breakage will contribute a negative charge to its large particle and the equivalent positive charge to the other particle. Such chances of separation are easily possible, due to imperfections in the lattice in which a negative ion or electron is out of place and is geometrically separated from the equivalent positive charge relative to a cleavage plane. Cleavage along such a plane will then cause a charge separation.

On this basis, statistical analysis enables us to compute the probability that a single large particle will have a certain excess charge, positive or negative. The larger the surfaces of the large particles in contact, the more points are ruptured and from pure probability considerations using the concept of a minimum area per unit charge imperfection, the statistics and relations may be derived.

If the powder contains a continuous spectrum of sizes, the contact area of a certain particle with its neighbors will be on the average proportional to its surface.

Let us define a *unit contact* as a region of extremely high probability (certainty) of transfer of one electron on particle separation. Thus, at each unit contact one particle is left with an excess and the other with a deficit of one electron of charge. Let us further assume that the number of such unit contacts is large on all particles to be considered and that the direction of charge transfer is completely random in any homogeneous powder.

Let the number of unit contacts of a certain particle be N. Thus, $\bar{N} \propto S$ (S=surface area of particle). If the number of electrons gained is K ($K<N$), then the number of electrons lost at the other contacts is $N-K$ and the net charge finally will be $n=(N-K)-K=N-2K$ elementary charges. The probability of such an event is given by

$$P_K{}^N=\frac{N!}{2^N(N-K)!K!}=\frac{N!}{2^N}\cdot\frac{1}{(N/2+n/2)!(N/2-n/2)!}.$$

(This assumes exactly equal chances of electron loss and electron gain.) Since N is large, we can use Stirling's formula and obtain

$$P_n{}^N\cong\left(\frac{2}{\pi N}\right)^{\frac{1}{2}}\frac{1}{[1+(n/N)]^{(N+n+1)/2}[1-(n/N)]^{(N-n+1)/2}}.$$

If N is large, such a binomial distribution curve can be very adequately approximated by $P(n)=(2/\pi N)^{\frac{1}{2}}\times\exp(-n^2/2N)$. The plot shown in Fig. 8, indeed, suggests such a Gaussian distribution of charge for constant particle size. The average charge will then depend in a simple fashion on the size as can be seen from the following discussion.

$$\bar{n}=(2/\pi N)^{\frac{1}{2}}\int_0^\infty n\exp(-n^2/2N)dn=(2N/\pi)^{\frac{1}{2}}.$$

Let $N=(\pi/2)\alpha^2 S$. Then $\bar{n}=\alpha(S)^{\frac{1}{2}}$. Here α is a constant factor, assuming that the statistical relation between N and S does not disturb the average. Thus, this theory

leads to the conclusion that the average charge per particle of one sign should be proportional to the square root of the particle surface.

For spherical particles $\bar{n}=Bd$ with d the diameter. Since, for the cases investigated, the particle shapes were very far from spherical, no such simple relation can be expected. Inasmuch as the irregularities always tend to increase with size, owing to the formation of aggregates, we should expect $\bar{n}$ to vary somewhat more rapidly than linearly with d which is exactly what is observed. This simple theory of random charge transfer at points of close contact then leads to conclusions in good agreement with observations. It must be noted that while the Gaussian distribution for the symmetrical cloud as deduced has a maximum at zero charge, the observations on, say, 100 particles in a given size range with some 1000 charges would not show the large number of uncharged particles of zero charge on purely satistical grounds. If this picture is accepted, the values listed in Table I will at once yield an estimate of the number of unit contacts on particles of a certain size. Thus, for the particles of diameters between 2 and 3 micron, the data give N as approximately $N=\pi/2\bar{n}^2 \cong 4000$. For those particles between 0.5 and 1 micron, the value of N is approximately $N\cong 400$.* Since, on the other hand, the surface area of the particles is known, at least very roughly, the maximum average size of a unit contact, as defined above, can be estimated. It is found from our data that for the quartz used by us, at least one electron is transferred at each area of contact of 10^{-10} cm^2. Similar magnitudes occur for all the particles observed. The differences existing are hidden in the uncertain knowledge of the surface areas involved. These values are maximum estimates. Actually, the average inhomogeneity at surfaces can well be confined to smaller areas, since only a small fraction of the total surface will be in actual contact. If the contacts are confined to 1/100 of the total surface, the average area of a unit contact will be 10^{-12} cm^2, which corresponds to about one imperfection for every 10^4 atoms, a figure that is more likely than one in 10^6.

In the case of heterogeneous surfaces, differences in structure, as well as in surface layers, will result, on the average, in charge transfers at contact points which can well be asymmetrical. This would be particularly likely where metals having free electrons can give these off to the ionic and other lattices having electro-negative elements. Even then, many of the contacts can be separated by fracture in the homogeneous substance leading to more homogeneous charging. Therefore, it will be expected that even in the most heterogeneous systems, the asymmetrical charging will never be complete. This is especially true, of course, where friction with dissimilar surfaces, as in the duster with many baffles, does not occur. It is probable, in view of what has been said, that it will be found that in heterogeneous systems the gas films and surface conditions play an important role, whereas they do not do so in the more homogeneous systems where possible pressure fusion and rupture of the minute points is more likely.

I am indebted to Professor L. B. Loeb, at whose suggestion this problem was undertaken and under whose supervision it was carried out, for his many valuable suggestions and assistance in interpretation, which were a constant source of inspiration. Also, I wish to thank Mr. R. J. Wijsman for his stimulation and verification of the statistical theory of mutual charging here presented.

* The observed average charge per particle was not corrected for neutralization by air ions in this case. Small particles, which were often photographed at a considerable time after their separation from the powder, would be expected to have lost some of their initial charge. Thus, the true value of N can be expected to be somewhat larger.

Charge Distribution in Coarse Aerosols as a Function of Time*

W. B. KUNKEL
Department of Physics, University of California, Berkeley, California
(Received April 3, 1950)

The interaction of small particles suspended in air with the ions normally produced in the air is discussed. The neutralization of highly charged dust particles, if suspended in air, is treated in detail. The result is found to be in qualitative agreement with experiment. The special case of final equilibrium is investigated. It is found that multiply charged particles should be present in appreciable number in coarse aerosols at all times. This is confirmed by experiments both for initially charged quartz dust and for initially neutral ammonium chloride smoke. The general nature of an equilibrium charge distribution is presented. Charges up to ten electron units are found to be not uncommon.

INTRODUCTION

IT has long been known that microscopic and submicroscopic particles and droplets suspended in air frequently carry electric charges.[1] Among others, Patterson in his extensive studies of aerosols[2] noted the fact and developed a theory involving the coagulation taking place in fresh aerosols of high density. Experimentally, Patterson and his collaborators found that the percentage of charged particles in originally uncharged clouds increased with time, the numbers of positives and negatives remaining equal throughout. Originally charged sols would remain charged. The magnitude of the charges were, however, not determined.

The processes by which these charges are acquired and/or altered can be divided into three groups. First, the violent creation of an aerosol, be it by a chemical reaction, by an electric arc, by the mechanical action of an explosion, or merely the dispersion through a blast of air, will in general leave the particles charged.[3] Such charging may be by triboelectric actions, by spray electrification, or possibly by direct ionization or thermionic emission due to strong local heating. These actions will determine the initial charges of the particles. Secondly, there may then be subsequent collisions between particles involving frictional charging, charge transfer and agglomeration. Such contacts caused by Brownian motion and turbulence in the medium can appreciably alter the initial distribution of charges in time. Finally, there will always be direct exchanges with the ions present in the ambient air, thus effecting a change of charge on the particles even when there is no contact between particles.

This study concerns itself with the effect of ionic charge exchanges of relatively large particles which are practically unaffected by Brownian motion, and it is limited to cloud densities small enough to render the probability of mutual impact of the particles negligible.

CHANGE OF CHARGE OF SUSPENDED PARTICLES

A small particle suspended in air is continually bombarded by gas molecules. Among the molecules there are a certain number of gaseous ions of both signs produced continually by various processes. These ions will have a finite chance of attaching to the particle or at least of being neutralized on impact, thus transferring their charge to the particle. If the particle was initially charged, this change of charge by one unit may represent either an increase or a decrease. The probability of such an event will depend primarily on the initial charge of the particle, on the ion density in the air, on the size, shape and material of the particle, on the temperature, and, if present, on any relative directed motion of the ions; e.g., on the average drift velocity of the ions, if there is an electrical field acting as in Millikan's oil drop study.

It is also possible for a particle to change its charge due to an ionizing process directly affecting the particle itself; e.g., caused by some radiation striking it, and ejecting one or more electrons. The probability of such an event will depend on the size and material of the particle, the total surface of the particles relative to the absorbing cross section of the gas molecules, and on the character, energy and amount of ionizing radiation. Owing to the values of the relative numbers of molecules to those of the particles, the direct ionizing effects for many types of radiation will be much smaller than the charging because of the ionization of the air. It is clear that the problem presented in charging of dusts by natural ions in the air as indicated above involves an equilibrium between the ions of both signs present in relatively small equal amounts, a problem apparently not solved before. On the other hand, the accumulation of charge on particles suspended in regions of relatively high ion densities of one sign as affecting electrical precipitation has been studied by many authors, notably by Arendt and Kallmann.[4]

In order to study the capture of ions in the air by particles such as are under discussion, we proceed as follows. Let us call $\varphi_1(q)$ the probability that a particle of charge q and of a certain size, shape and substance

[4] Arendt and Kallmann, Zeits. f. Phys. 35, 421 (1925).

suspended in a medium of a certain ion density and temperature gains an electron unit of charge in unit time. And let $\varphi_2(q)$ be the probability that an identical particle under identical conditions loses an electron unit of charge per unit time. Furthermore, let N_q be the number of such particles suspended per cubic centimeter. Then the change in the density of such particles in still air due to charge transfers, neglecting the settling motion, becomes:

$$\Delta N_q=[N_{q-1}\varphi_1(q-1)-N_q\varphi_1(q) -N_q\varphi_2(q)+N_{q+1}\varphi_2(q+1)]\Delta t. \quad (1)$$

If particles of various sizes are present in the volume element similar equations hold for each infinitesimal size range separately. Since agglomeration and evaporation or condensation are considered to be negligible, there is no change of particle size and these equations are independent of each other. Yet, inasmuch as φ_1 and φ_2 are generally unknown, Eq. (1) is of no great importance. Only in very special cases will certain simplifications enable us to make predictions.

NEUTRALIZATION OF A CHARGED SMOKE

If the individual particles of a cloud of smoke or fog are highly charged, and if the densities of positive and negative ions are of the same order of magnitude, φ_1 becomes negligible compared to φ_2 which will consist almost exclusively of the probability of neutralization by air ions. Moreover, since $q\gg1$, we can treat the changes of charge as infinitesimals. Thus we can write

$$\frac{\Delta N_q}{\Delta t}\rightarrow\frac{\partial N_q}{\partial t}dq=-N_q\varphi_2+\left(N_q+\frac{\partial N_q}{\partial q}dq\right)\left(\varphi_2+\frac{\partial\varphi_2}{\partial q}dq\right)$$

or

$$\frac{\partial N_q}{\partial t}=N_q\frac{\partial\varphi_2}{\partial q}+\varphi_2\frac{\partial N_q}{\partial q}=\frac{\partial N_q\varphi_2}{\partial q}, \quad (2)$$

where $\varphi_2(q)=-dq/dt$ is the average rate of loss of charge of a particle of charge q.

Equation (2) is of practical value only if $\varphi_2(q)$ is a relatively simple expression. To obtain a first approximation, we can assume that, on the average, ions, due to their heat motion, entering a sphere of radius r around a particle of charge q will be trapped, r being given by the relation

$$E_{\text{pot}}+E_{\text{kin}}=\frac{qq'e^2}{r}+\frac{3}{2}kT=0. \quad (3)$$

Here e is the electron charge, q the number of electron charges on the particle, q' the multiplicity of the ion charge, k the Boltzmann constant, and T the absolute temperature. The quantity r is positive only if q and q' are of opposite sign. This relation assumes a Maxwellian velocity distribution of the ions. Then the number of neutralizing events per second will be given by the well-known relation

$$\varphi_2=-dq/dt=n\pi r^2\bar{c}=g(t)q^2 \quad (4)$$

again to a first approximation. Here n is the density, $\bar{c}$ the average velocity of the ions, and $g(t)$ is a factor independent of q derived from Eqs. (3) and (4)

$$g(t)=\frac{4\pi\bar{c}e^4q'^2}{9k^2T^2}n(t)=\beta n(t). \quad (5)$$

It should be noted that in this case φ_2 is independent of the size of the particle as long as its radius $\rho<r$, so that the treatment will hold even if a cloud contains particles of various sizes as long as the cloud density does not change due to the difference in settling rates.

Substituting (4) and (5) into (2) we obtain

$$\frac{\partial N_q}{\partial t}=\beta n\frac{\partial}{\partial q}(q^2N_q). \quad (6)$$

This means that q^2N_q is independent of time if $q(t)$ is regarded as the charge on a particular particle changing according to (4):

$$q=\frac{q_0}{1+\beta q_0\int_0^t ndt}. \quad (7)$$

Thus

$$N_q(q,t)=(q_0^2/q^2)N_q(q_0,0), \quad (8)$$

where $N_q(q,0)$ is the initial charge distribution in the cloud and q_0 the initial charge of a particle of charge q at time t:

$$q_0=\frac{q}{1-\beta q\int_0^t ndt}. \quad (9)$$

The problem is therefore reduced to that of finding $n(t)$, the ion density in the region of the cloud to be considered. Unfortunately this cannot be solved rigorously since $n(t)$ is determined by the recombination equation:

$$dn/dt=\gamma-\alpha n^2-\beta n\int_0^\infty q^2N_q dq, \quad (10)$$

assuming, for the time being, equal numbers of positive and negative ions present. Again γ is the rate of formation of ion pairs per cubic centimeter and α the ordinary coefficient of recombination. α is very small so that in the absence of charged dust, n becomes fairly large until equilibrium is reached, but if charged particles are suspended in the air, the value of n is correspondingly depressed. Only certain extreme cases can be treated in more detail. If the aerosol is very dilute, the last term in Eq. (10) is very small compared to αn^2, and n will be practically the same as in dust-free air. It can there-

fore be regarded as constant in time if equilibrium between a constant ion production and recombination is established. This case is very simple since the integral in Eq. (9) is trivial.

On the other hand, if q is large and N_q not very small, the last term in Eq. (10) will easily predominate so that αn^2 effectively can be neglected. This means that practically all ions formed will attach to the smoke particles. It also presupposes that the suspended particles carry both positive and negative charges in about equal amounts, a case which seems to be frequently realized.[3] Moreover, if we make use of the fact that in this simplified case the rate of change of ion concentration is small compared to the ion production, we can reduce (10) to

$$0 \cong \gamma - \beta n \int_0^\infty q^2 N_q dq, \tag{11}$$

whence

$$\varphi_2 \cong \frac{\gamma q^2}{\int_0^\infty q^2 N_q dq} = -\frac{dq}{dt}. \tag{12}$$

The integral in Eq. (12) is a function of time and since the integrand is in general not known in detail, further

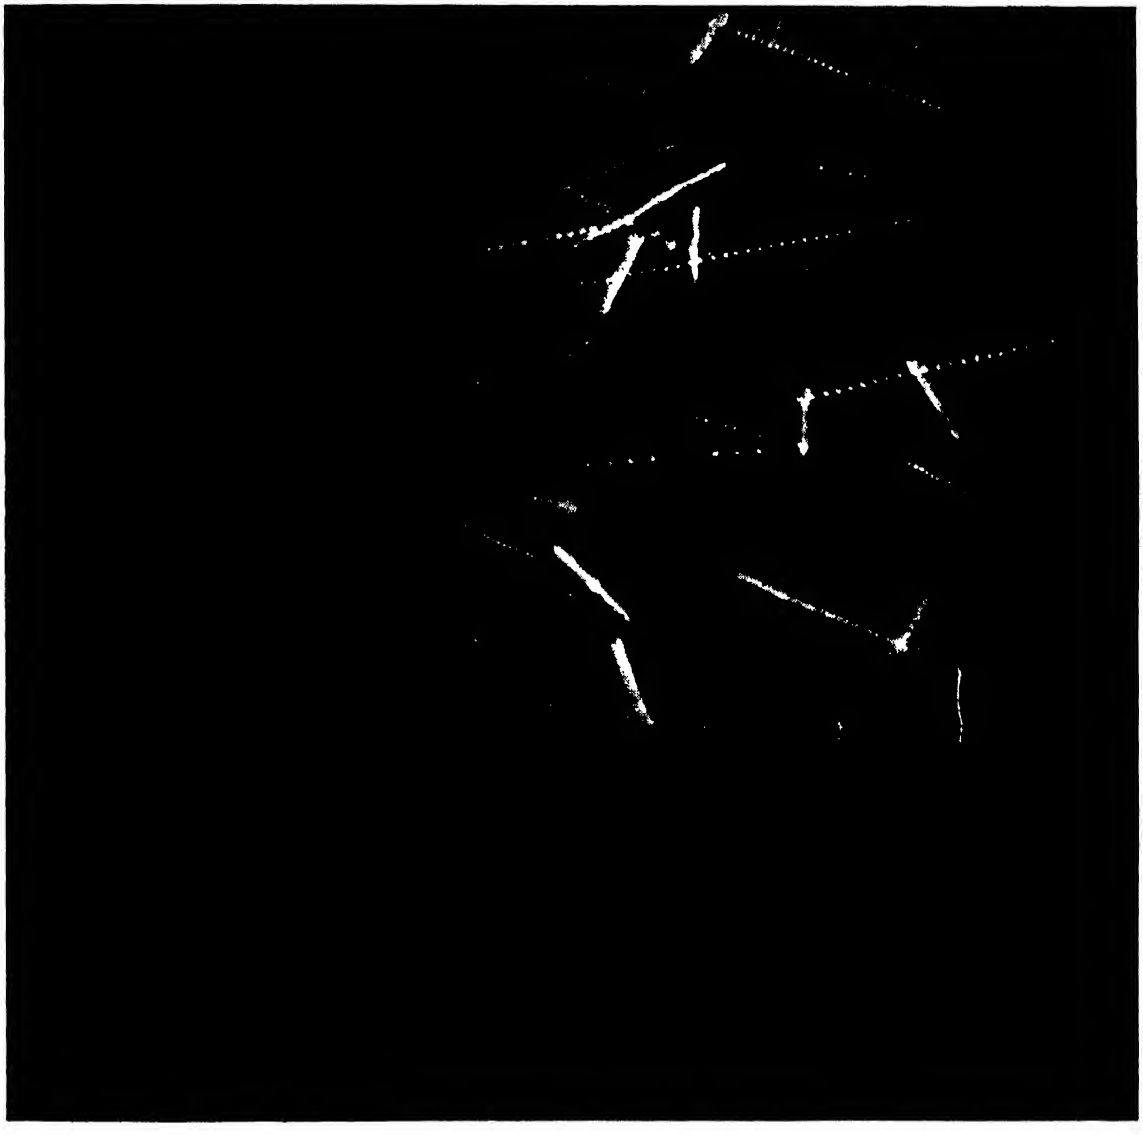

FIG. 1. Traces of quartz dust, 20 hours old, settling in air in a horizontal field of 560 volts cm^{-1}. Dark field illumination, 450 flashed $min.^{-1}$. Total exposure about 4 sec. Neutral particles settle vertically. Singly and doubly charged particles of both signs are easily recognized. For higher multiplicities the traces have to be carefully measured, for possible convection correction has to be made. Note the distinct effect of Brownian motion or differential heating on these irregularly shaped particles.

generalized development is impossible. However, by defining a root mean square charge

$$q^*(t)=\left[1/N\int_0^\infty q^2N_q dq\right]^{\frac{1}{2}} \tag{13}$$

and substituting this into (12), inspection shows that it is justifiable to write for the characteristic charge of the cloud $(dq^*/dt)=(-\gamma q^*/Nq^{*2})=-\gamma/N$ which yields

$$q^*=q_0^*-\gamma/Nt. \tag{14}$$

In other words, the r.m.s. charge in a symmetrically charged smoke cloud decreases linearly with time as long as the approximations introduced are justified. This is a rather remarkable result since the average charge of the smoke particles,

$$\bar{q}=(1/N)\int_0^\infty qN_q dq=Q/N \tag{15}$$

by our own definition decreases at the same rate:

$$d\bar{q}/dt=1/N(dQ/dt)=-\gamma/N,$$

where Q is the total charge of one sign per unit volume of the cloud.

Combining Eqs. (12)–(14), the most probable rate of change of charge of each particle is expressed as a function of its charge q and of the time, containing the initial r.m.s. charge q_0^* of the cloud element as a parameter:

$$\frac{dq}{dt}=\frac{-\gamma q^2}{N[q_0^*-(\gamma/N)t]^2}. \tag{16}$$

This is readily integrated, resulting in an expression analogous to (7), to wit:

$$q=\frac{q_0}{1+(\gamma q_0 t/Nq_0^{*2}-\gamma q_0^* t)}, \tag{17}$$

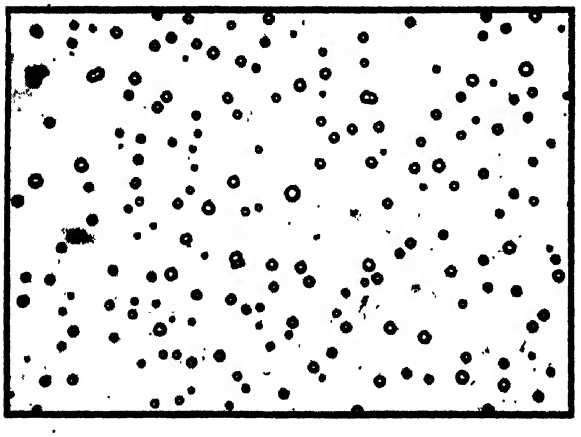

FIG. 2. Ammonium chloride smoke particles collected on microscopic cover glass at bottom of the dusting chamber. Sizes range from 0.7 to 3 microns in diameter.

or

$$q_0=\frac{q}{1-(\gamma qt/Nq_0^{*2}-\gamma q_0 t)}, \tag{18}$$

which has to be substituted in Eq. (8).

Unfortunately we have not been able to verify these simple relations quantitatively since, in our experimental arrangement,[5] it was not possible to keep a smoke homogeneously suspended for a sufficiently long period. Qualitatively, however, these ideas appear to be in good agreement with observations discussed elsewhere.[6]

EQUILIBRIUM DISTRIBUTION

The approximations introduced above are justified only if the charges are fairly large, say, with an average of 50 or more electrons per particle, and if the aerosol is not too dense. As the charges of the particles decrease, the ion-ion recombination gains in importance so that Eq. (11) can no longer be used and the second treatment breaks down. All we can say is that although the ion concentration will gradually increase, the rate of neutralization of the smoke will decrease more and more until φ_2 becomes comparable to φ_1 so that the latter no longer can be neglected. In other words we have to return to Eq. (1). Moreover we shall no longer be able to make use of differentials so that a rigorous treatment would be extremely complicated. Again, only the very extreme case of negligible change of charge distribution can be sufficiently simplified to permit a few quantitative conclusions. In this case the conditions of balance tell us that not only $\Delta N_q=0$ but that the terms on the right hand side of Eq. (1) have to cancel in pairs, i.e.,

$$N_{q-1}\varphi_1(q-1)-N_q\varphi_2(q)=0, \tag{19}$$

if the equilibrium is to be stable. Thus the equilibrium distribution can be expressed in the form

$$N_q=N_0\prod_{l=0}^{l=q}\frac{\varphi_1(l-1)}{\varphi_2(l)}, \tag{20}$$

if we define $\varphi_1(-1)=\varphi_2(0)=1$. Since φ_1 and φ_2 depend on the size of the particles, each size range will have a different distribution unless the size dependence cancels out in the expression. It is clear that $\varphi_1(q)$, the probability of charge addition, will decrease as q increases. The question arises whether $\varphi_1(2)$ for most smokes is not already negligible so that practically no particles with more than two elementary charges will be present in the cloud near equilibrium. Unfortunately many factors contributing to φ_1, such as the effect of the material and the shape, are largely unknown so that quantitative estimates cannot be expected to be reliable. We can assume, however, that the charges on a spherical

[5] W. B. Kunkel and J. W. Hansen, Rev. Sci. Inst. 21, 308 (1950).

[6] W. B. Kunkel, J. App. Phys. 21, 820 (1950).

particle arrange themselves on its surface at maximum equal distances (conducting droplets) and that all ions actually colliding with the surface will impart their charge to it. This very crude first approximation leads to the conclusion that in a smoke consisting of particles of about one micron diameter, multiple charges as high as five or even ten electrons are still quite likely.

This rather unexpected result is in qualitative agreement with the following experimental evidence. A small amount of fine quartz powder was dispersed by a short blast of air. The particles of the dust cloud thus generated were found to be quite highly charged, positive and negative charges being present in about equal quantity. The charges and sizes of the particles were determined by photographing their trajectories as they settled in a horizontal electric field with dark field illumination. The time scale was provided by using intermittent light of known flash frequency. This method has been described in some detail elsewhere.[5] After about one hour, all particles larger than one micron in diameter had settled out. Most of the small particles still present carried charges of between 10 and 20 electron units of either sign, the total range being from zero to about 100 electron units. A minute convection kept most of these particles suspended for 24 hours, after which time the charges were measured again. It was found that the average charge had decreased to about 3 electron units, charges of higher multiplicity still being present in large number. An example of the pictures of the falling particles obtained is shown in Fig. 1. There appeared to be no significant change in this distribution during the following few hours for which the suspension could be maintained.

In order to confirm the theoretical considerations above, it was next demonstrated that the charges observed were not merely residues of the initial contact electricity but represented a true equilibrium condition. A cloud of ammonium chloride smoke was generated by mixing ammonia and hydrochloric acid vapors in room air of 40 percent relative humidity at 20°C. The particles formed under suitable conditions were fairly uniform in size and quite round as seen in Fig. 2. Apparently aggregation between large particles did not take place, the growth consisting entirely of addition of very small particles or of single gas molecules of NH_4Cl to solutions of NH_4Cl in water. The surfaces appeared to be quite smooth and spherical under the electron microscope. A few minutes after complete formation of the cloud, analysis showed these particles to be mostly neutral, a certain fraction being singly charged. Three hours later the percentage of charged particles had markedly increased, multiple charges being already present in appreciable number. Again a part of the smoke was kept suspended by a slight convection in the chamber. The distribution found on the next day is shown in Fig. 3. The particles were grouped according to their charge irrespective of their size. Actually the average charge per particle increased somewhat with

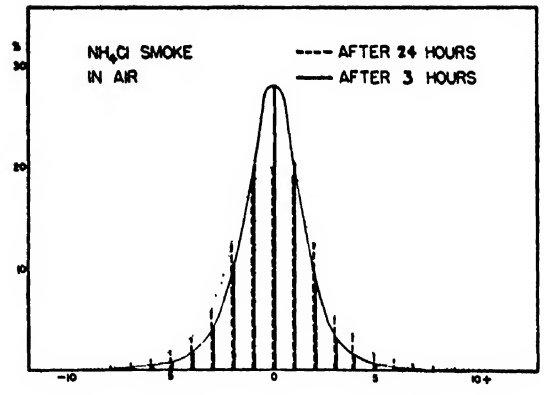

FIG. 3. Charge distribution in ammonium chloride smoke made by mixing the gaseous components. The curves are based on totals of about 1000 particles each.

the size of the particle, but since the numbers were not large enough to provide reliable statistics for separate size-groups, the all-over distribution for all particles together is shown. The general picture is very similar to the case of the quartz dust which started out charged, indicating that some kind of an equilibrium can actually be reached and is arrived at either by neutralization or by charging. It is seen that the number of singly charged particles is very little less than that of the neutral ones in agreement with the argument that $\varphi_2(1)$ can be only very little larger than $\varphi_1(0)$ for particles of this size. However, the observed curve falls off much faster than would be predicted by the simple theory indicated above. The most obvious explanation of this deviation is that ions colliding with particles do not necessarily impart their charge to the latter, especially not if the particle is already carrying an excess of the same sign as the ion. Nevertheless it is quite certain that an appreciable percentage of smoke particles in equilibrium are carrying multiple charges. The largest charge observed by us on an ammonium chloride particle of one micron diameter one day after formation was 18 electrons. It is interesting to note that this direct verification of the existence of multiply charged smoke particles in equilibrium with ionized air is a rather nice verification of the findings of G. Vassails,[7] who ascribed the appearance of groups of Langevin ions of somewhat smaller size to the multiple charges acquired from the natural ions in the air. The fact that the distributions always were practically symmetrical seems to indicate that both photoelectric effect and direct ejection of electrons by corpuscular radiation are negligible under normal conditions.

The work on dust electrification of which this is an interesting by-product was undertaken on an ONR contract at the suggestion and under the supervision of Professor L. B. Loeb. The writer desires to acknowledge his appreciation of the advice and encouragement given him in various phases of this work by Professor Loeb.

Double Crystal and Slit Methods in Small Angle X-Ray Scattering*

H. N. Ritland,† P. Kaesberg, and W. W. Beeman
Department of Physics, University of Wisconsin, Madison, Wisconsin
(Received February 17, 1950)

An angular resolution of about 10 seconds of arc may be obtained with a double calcite crystal spectrometer for Cu $K\alpha$-radiation. However, the shape of the rocking curve at large angles is such as to make the detection of radiation from weakly scattering materials difficult. Of the order of 10^6 counts per second are detected with a stationary, water-cooled copper target and parallel crystals. Wing intensities, even at large angles, do not fall much below 10^2 counts per second. Wing heights may be considerably reduced by the addition of a third calcite crystal. With this modification the crystal spectrometer is a useful instrument for most scattering experiments in which extremely high resolution is desired. It is inferior to a slit system and Geiger counter arrangement when poorer resolution may be tolerated but high sensitivity is required. A slit instrument with an angular resolution of 4 or 5 minutes of arc provides an effective incident flux of more than 10^6 counts per second while wing intensities may be as low as 1 count per second.

INTRODUCTION

THE study of small angle x-ray scattering involves a number of experimental difficulties in much more severe form than in conventional x-ray diffraction work. Among these are the requirements of high resolution and high sensitivity as well as good monochromatization and accurate measurement of intensity. These difficulties arise from the necessity of obtaining quantitative information about the rapidly changing scattered intensity in a narrow angular region about the primary beam.

In most small angle scattering studies higher resolution and sensitivity are obtained by making suitable refinements in photographic x-ray diffraction technique, principally involving finer slits and larger specimen-to-film spacing.[1] The diffraction chamber is usually evacuated to eliminate air scattering. Monochromatization is obtained by using radiation reflected from single crystals or by using selective filters. Accurate intensity measurements can be made only with difficulty because of the limited range of linear response of photographic film.

This paper discusses and compares the properties of two instruments which have been found useful for the study of small angle scattering, both involving Geiger counter detection. One utilizes crystals for collimation, while the other uses slits. The crystal apparatus has extremely high resolution, but has comparatively low effective sensitivity due to a background caused by diffuse scattering from the crystal surfaces. The slit apparatus has less resolution, but has high sensitivity.

The relative importance of resolution and sensitivity depends upon the scattering material being studied. A recently completed experimental study[2] of several proteins in solution illustrates the case where resolution requirements are not excessive but high sensitivity is required. Dexter and Beeman[3] describe a method for obtaining particle sizes from multiple scattering. Their method requires the resolution provided by the crystal apparatus.

TWO AND THREE CRYSTAL SPECTROMETERS

The two crystal spectrometer[4] (as well as the three crystal instrument to be described later) is shown schematically in Fig. 1. The first calcite crystal collimates the beam and is fixed in position so that line radiation from the x-ray tube strikes it at the Bragg angle. The scattering material is placed midway between the two crystals. The angular distribution of the radiation leaving the scatterer may be analyzed by rotating the second calcite crystal, since its reflectivity is high only for radiation impinging upon it at the Bragg angle. As the second crystal is rotated, that part of the scattered beam which will be reflected, does not continue to strike the same point in the crystal. As a result, the scattered radiation leaving the second crystal is focused to a point beyond it, at a distance equal to that between the second crystal and the scatterer. A thin window argon-alcohol Geiger counter is placed at this point and remains stationary as the second crystal rotates.

Slits placed at the tube window and before the sample sharply delimit the wave-length spread of the continu-

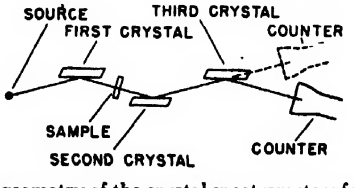

FIG. 1. The geometry of the crystal spectrometers for small angle scattering. In the double crystal arrangement only the first two crystals are used, and the counter position is shown by the dashed line drawing. The drawing has been distorted slightly in that the counter has been placed somewhat too far away from the second crystal. The full line drawing of the counter indicates its position for the three crystal arrangement.

ous spectrum striking the scatterer so that its effect is negligible compared with the desired line radiation. The $K\beta$-radiation may be eliminated by the proper filters. Second-order radiation is passed by the crystal and must be guarded against when strongly absorbing samples are used. However, in ordinary cases where the absorption of the line radiation is about a factor of three, second-order intensity is entirely negligible since it is only of the order of 1/1000 of the intensity of the $K\alpha$-lines at 30 kilovolts, and may be reduced further by decreasing the voltage. In addition, the Geiger counter, when filled to an argon pressure sufficient to absorb 90 percent of the first-order radiation, absorbs but 25 percent of second order.

With perfect calcite crystals and copper radiation the experimental half-width at half-maximum for a double crystal rocking curve (intensity *vs.* angle) is known to be about 5 seconds of arc. This is in good agreement with theoretical calculations.[5] Experimental rocking curves are available in the literature only for the central portion of the curve, but theory predicts that they decrease inversely as the angle squared for large angles.[6] However, it is not known to what angles this type of behavior persists in real crystals. In order to evaluate the advantage of the narrow width of the double crystal rocking curve, detailed information concerning the wing intensity at large angles must be had. For diffuse scattering the area of the central part of the rocking curve should be compared with the wing intensity, while for line scattering the significant ratio is the height of the rocking curve at the center to the wing height at the position of the scattered line.

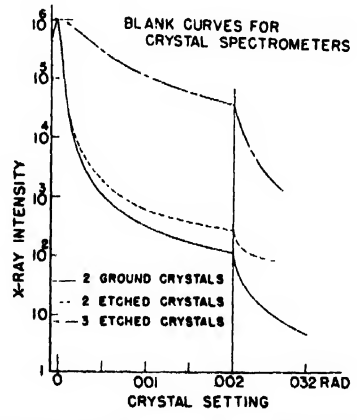

FIG. 2. The top curve is the double crystal rocking curve for a pair of calcite crystals that have been ground with carborundum to increase their reflectivity. The second curve shows the rocking curve obtained when these crystals were thoroughly etched with 0.5N hydrochloric acid. The lower curve shows the three crystal rocking curve that results when a third etched crystal is added (as described in the text). To facilitate comparison of their shapes, the three curves have been normalized to the same ordinate at zero rocking angle.

TABLE I. The table shows the effect of etching treatment with 0.5 N HCl on the shape of the rocking curve for a pair of ground calcite crystals. The intensities and the areas are in arbitrary units. Copper radiation was used.

	A Etching time	*B* Center intensity	*C* Rocking curve width	*D* Rocking curve area[a]	*E* Wing height at 1°	*F* Ratio *E/B*	*G* Ratio *E/D*
1.	0 sec.	100,000	116 sec. arc	130	140	$140 \cdot 10^{-6}$	1.1
2.	5	200,000	96	220	700	350	3.2
3.	10	250,000	60	175	300	120	1.7
4.	15	240,000	30	95	90	38	1.0
5.	20	230,000	16	45	45	20	1.0
6.	25	230,000	14.5	40	20	9	0.5

[a] Within 200 seconds of arc of zero rocking angle.

We have found that curves obtained with most calcite crystals as cleaved, or ground and sufficiently etched, very nearly equal the theoretical width and indeed have wings which decrease in intensity inversely as the angle squared to about 3 or 4 minutes of arc. But the wings then go down more slowly and vary considerably with the choice of crystals and with treatment of their faces. To determine some of the effects of crystal surface conditions upon the usefulness of the instrument, a series of rocking curves was taken with a pair of ground crystals (ground with No. 600 carborundum) as a function of the time of etching in 0.5 normal hydrochloric acid. Table I summarizes the results and Fig. 2 shows rocking curves for these crystals before and after thorough etching.

It may be seen that with a light etch the central intensity is considerably increased but then remains substantially constant with further etching. The wing heights are increased at first, and then reduced as the etching proceeds, but the reduction has become appreciable only after the central area of the rocking curve is small compared with its original value. It is thus apparent that the reflected intensity may be increased by misaligning some of the surface layers, but only at the expense of a great loss in sensitivity because of the increased wing background. These results strongly suggest that best experimental conditions occur when the crystals have been etched enough to obtain as narrow a rocking curve as possible.

If a third crystal is placed so that it is always parallel to the second crystal (and the two rotated together) it should reflect almost no radiation that leaves the second crystal at other than the Bragg angle, but should reflect Bragg radiation with little diminution of intensity. Such a modification is shown schematically in Fig. 1. With this modification one no longer has a focal point at which to place the Geiger counter, so that a counter with a sufficiently large sensitive volume must be used, or else the counter must be moved as well as the second and third crystals.

The addition of a third crystal does not greatly reduce the central (i.e., all three crystals parallel) intensity of the rocking curve since the radiation has already been highly collimated by the first two crystals. We observed reductions of central intensity by a factor of between two and three upon adding a third crystal. This is a

TABLE II. A comparison of the shape of the rocking curves for two and three crystal arrangements. The curves are normalized to 1,000,000 at the center. Iron radiation was used. These curves are for well-etched, near perfect crystals.

Seconds of arc from the parallel position	Intensity 3 crystals	Intensity 2 crystals
0	1,000,000	1,000,000
25	23,000	35,000
50	5,300	8,700
100	1,000	2,300
400	100	280
1,000	33	150
4,000	8	110
8,000	3	100

slightly smaller percent reflection than theory would predict for perfect calcite crystals.

However one expects the wings to be reduced about twice as much as the central intensity with the addition of a third crystal parallel to the second. This results from the fact that when the first two crystals are not parallel the radiation leaving the face of the second can be divided into two equal parts one of which is strongly and the other very weakly reflected by the third crystal. The two parts are a component reflected at the center of the single crystal diffraction pattern by the first crystal but at the wing by second crystal and a component reflected on the wing by the first crystal but the center by the second. Only the latter component is appreciably reflected by the third crystal. It is diminished by the third reflection by about the same factor as is the central intensity when all three crystals are parallel.

The three crystal rocking curve also should have wings diminishing as the reciprocal of the square of the angle from parallelism.

A glance at Table II shows that the three crystal wings go down more slowly than the predicted $1/\varphi^2$ at large angles but that the improvement on the two crystal arrangement may still be much greater than a factor of two. At the largest angles the three crystal wings are less than the two crystal by more than an order of magnitude. This implies that no appreciable fraction of the wing intensity above the theoretical $1/\varphi^2$ contribution leaves the second crystal at the Bragg angle.

The cause of the excess wing intensity is not clear. One of the components leaving the second crystal is an intense beam from the first crystal which is presumably only weakly reflected by the second. This beam may be the source of temperature diffuse scattering at the second crystal or of a broad scattering peak from very small crystalline domains.

Although the third crystal has a pronounced effect in reducing wing heights, they are still about 10 times room background for large wing angles (with a stationary copper target tube). Thus the sensitivity of the three crystal spectrometer, while higher than the two crystal instrument, is still inadequate for diffuse scattering studies with materials of low scattering power. Since the scattered intensity depends upon the square of the difference in electron density between the particles and their surrounding medium, this lack of sensitivity will exclude the important class of experiments in which the scattering specimens are biological materials in aqueous solution.

SLIT COLLIMATION APPARATUS

If slits, rather than crystals, are used for collimation, resolution, as well as intensity, is governed by the slit widths and separations. As a result, for a given distance between two collimating slits, the highest attainable resolution is determined by the lowest tolerable intensity. Thus, the Geiger counter, while not an essential feature of a slit collimating system (as it is in the crystal spectrometers), may be used to advantage because it has high efficiency for detecting radiation.

The instrument described in the succeeding paragraphs was designed to study the angular distribution of scattered x-rays from particles in the size range 20A to 200A in diameter. The slit geometry was such that a convenient level of scattered intensity could be maintained with weakly scattering protein solutions as scattering specimens and with a water-cooled, stationary copper or iron target, x-ray tube as the radiation source.

The geometry of the slit system is indicated schematically in Fig. 3. A pair of stationary tantalum slits collimates the beam incident upon the scatterer. A second pair of slits analyzes the angular distribution of the radiation leaving the scatterer. The second pair of

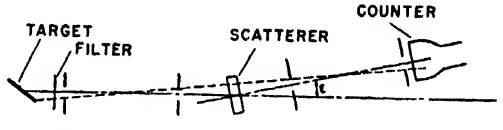

FIG. 3. A schematic drawing of the slit system described in the text. The scale has been greatly compressed in the horizontal direction. The angle ϵ is the smallest rocking angle at which the counter no longer sees the target.

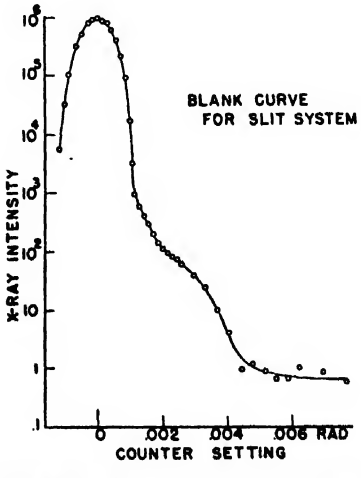

FIG. 4. The blank rocking curve for the slit system described in the text. The curve shown is for slit widths of 0.02 cm. The $4d/a$ angle is then 0.0027 radian.

slits, and also the specimen holder and the Geiger counter, are fixed to an arm which may be rotated, by means of a calibrated screw, about an axis through the center of the specimen. The distance between successive slits is 30 cm and the scatterer is halfway between the second and third slits. The slits are 1 cm high, but can be cut down by suitable apertures. The slit widths are adjustable, usually being between 0.1 and 0.4 mm wide. In order to reduce the loss by air absorption, the slits are mounted in two evacuated tubes with windows of 0.001-in. Nylon film at each end. Monochromatization is achieved by means of the Ross filter method. The differential filters are mounted on a slide in front of the x-ray tube exit window. The scatterer, Geiger counter, and filters are not in the evacuated region.

If intensity *vs.* angle is plotted for the slit apparatus with no scattering sample, a curve is obtained that is analogous to the rocking curve for two and three crystal spectrometers. This curve is shown in Fig. 4. The central part of the curve consists mainly of radiation that goes straight through all of the slits. Wing radiation arises from slit edge scattering, and from air scattering in the non-evacuated regions. If the slit width is d and the separation is a, the counter no longer sees the x-ray tube target at an angle of rotation of $2d/a$ from the straight through position (as shown in Fig. 3). Scattering from the edges of the second and third slits is eliminated at an angle of $4d/a$. Air scattering from the non-evacuated region around the sample falls off rapidly with angle, because the region where the two telescopes overlap decreases rapidly.

The most striking feature of the slit rocking curve (Fig. 4) when compared with the crystal rocking curves (Fig. 2) is its exceedingly low wing intensity. At angles only slightly greater than $4d/a$, the ratio of center to wing intensity is greater than 10^6. The three crystal rocking curve approaches this ratio only at comparatively large angles (see Fig. 2) while the two crystal curves are two or three orders of magnitude worse.

Under normal operating conditions a slit instrument with an angular resolution of 4 or 5 minutes of arc provides an effective incident flux of about 10^6 counts per second. This is approximately the counting rate for the three crystal spectrometer at zero rocking angle. However, a more significant comparison for diffuse scattering is the area under the central portion of the rocking curve for each instrument. The slit system curve area exceeds that of the three crystal instrument by a factor of 25.

We wish to thank the Kimberly-Clark Corporation for their support of the Kimberly-Clark Fellowship held by one of us (H.N.R.) during the year 1948–49.

Vacuum Tubes with Mutually Bombarding Oxide Cathodes

E. G. Hopkins

Electrical Engineering Department, The New South Wales University of Technology, Sydney, New South Wales, Australia

March 13, 1950

EXPERIMENTS in which two flat oxide cathode surfaces 3.5 cm long and 1.0 cm wide were mounted face to face to form a high vacuum diode and were caused to act alternately as anode and cathode in passing a current of 50 cycles per second between them have shown that such an arrangement can be made to operate stably after the removal of the initial heating source. If a 240-volt a.c. supply is connected to the cathodes through a series resistance at an instant when the temperature of their hottest parts is above a critical minimum (below the visible range), the current builds up to a value determined by the space-charge limited characteristics of the diode. One diode with a spacing of 3 mm was found to obey closely the law, r.m.s. amp. $=1.9$ (r.m.s. volts)$^{1.42}\times10^{-4}$ between 120 and 220 volts, the corresponding range of maximum cathode brightness temperatures measured on an uncoated nickel spot being 880 to 1260°K. The current wave form was quite symmetrical about the zero axis and showed no signs of saturation. Portions of the cathode below a visible temperature glowed with a pale blue fluorescence under bombardment. One sealed-off diode was allowed to run for seven hundred hours.

A triode was constructed consisting of two cathodes as described having a total separation of approximately 2 mm and a grid of molybdenum wires spaced equally between them. Tests were made with a grid voltage applied through a synchronous switch in such a way that for any half-cycle it consisted of a half-sine wave applied negatively relative to the particular electrode then acting as a cathode. By assuming the Langmuir equation for triode current to hold for all instantaneous voltages, the equation I_p (r.m.s.) $= K$ (E_b r.m.s. $+ \mu E_g$ r.m.s.)^n was used to estimate μ, the amplification factor from values of voltage and current read on r.m.s. reading instruments. This equation is useful when examining the possible use of such a triode to control a.c. power circuits.

The triode was made to oscillate at a frequency of 0.5 Mc/sec. in an oscillator circuit which included a synchronous switch to reverse the phase of the grid drive. When operating stably with a cathode brightness temperature of about 950°K, the oscillator drew 0.12 amp. at 220 volts and delivered approximately 5 watts to the load lamp.

These experiments demonstrate the possibility of utilizing the power usually wasted in anode dissipation to heat a cathode surface much larger than can be provided economically in conventional power tubes. It appears feasible from the data obtained from this work and from experience with conventional tubes that if the spacings of a practical tube based on the above principle were made as small as possible without causing excessive grid emission, hot spot formation, or mechanical troubles, then such a tube could be made to deliver useful amounts of high frequency power at acceptable efficiency without the use of transformers or rectifiers when operated directly from an a.c. supply of 240 volts or over.

These experiments, details of which will be published when the present work has reached a more advanced stage, were carried out by the writer at the Radiophysics Vacuum Laboratory in the Electrical Engineering School of the University of Sydney.

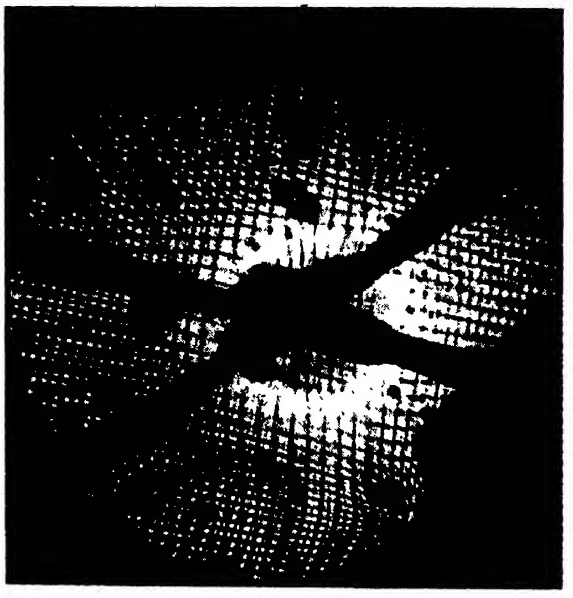

FIG. 1.

Electron Optical Properties of Space-Charge Clouds

L. MARTON AND D. L. REVERDIN
National Bureau of Standards, Washington, D. C.
April 13, 1950

THE space-charge lens has been repeatedly considered as a corrective element for the reduction of the aperture defect of electron lenses.[1] This is due to the recognition by Scherzer[2] that no axially symmetrical, time invariant, space-charge free field is free from the aperture defect, and that dropping of any of these conditions may improve the behavior of the lens. Gabor,[3] who was one of the first to propose the use of space-charge clouds as corrective elements, raised, however, a question and suggested an experiment: "Will the 'space-charge' cloud not act on the beam like frosted glass?" He proposed "to settle this point by the simple experiment of shooting a fast electron beam parallel to the axis through a static magnetron. It may be mentioned that such an experiment would also at once settle the question how nearly Hull's simple theory agrees with actual conditions in a magnetron as, on Hull's theory, the beam would suffer no radial deflection."

Gabor's proposed experiment forms the subject of a dissertation for a Ph.D. degree by one of us[4] and will be published separately. The present brief communication deals with a partial answer to Gabor's question about the suitability of the space-charge cloud as a lens-correcting element.

In the present experiment, a wide electron beam was sent axially through a static magnetron. Before reaching the magnetron, the beam passed one wire mesh, and a second wire mesh was placed in the beam's passage after the magnetron. The details of the experimental conditions are given in reference 4. A typical observation is shown in Fig. 1. This figure represents the photographed shadow patterns cast on a fluorescent screen. The shadows of the two wire meshes are plainly visible and in addition to them, there are two heavier shadows shown at approximately a 60° angle. These latter are the shadows of the filament supporting bars. Very marked in Fig. 1, also, is the bright ring located between the cathode (in the center of the picture) and the anode (dark circular shadow at the circumference of the picture). The outer edge of this bright ring lies approximately where the theoretical electron cloud radius would be according to the classical magnetron theory.

Approximate computations carried out on this pattern (Fig. 1), show that the bright ring is produced by a high intensity space-charge cloud acting as a divergent lens. Although experimental conditions prevented us from actually measuring the focal distance of this divergent lens, this latter could be estimated to be rather large. A comparison of the pattern shown in Fig. 1, with patterns taken in absence of the space charge, shows that a partial correction of the aperture defect is probably present, although we do not have quite definite indications due to the preliminary nature of this investigation.

The wire shadows in the bright region of the picture appear much less sharp than toward the periphery. When placing an oscilloscope in the plate circuit of the magnetron, we could observe that whenever the electron optical observation showed the presence of space charge, considerable random noise could be observed in the plate circuit. Although our experimental set-up does not exclude entirely the possibility of very high frequency oscillations, the probability of such oscillations being present is extremely reduced. Thus the lack of definition in the bright region can be fairly well correlated with the noise and the conclusion drawn that the image definition is reduced by random noise in the space charge.

The present experiments thus seem to indicate that, whereas a correction of the aperture defect may be possible by means of space charge, Gabor's suspicion of its acting as a "frosted glass" seems to be justified. The present observations, being mostly an outgrowth of the magnetron investigation, are not presented as arguments for abandoning all attempts toward correction of aperture defect by means of a space-charge cloud. They seem to show, however, that the reduction of the resolution in the image may outweigh considerably whatever advantage a space charge could offer as a lens-correcting element.

The Thickness Measurement of Thin Films by Multiple Beam Interferometry*

G. D. Scott, T. A. McLauchlan, and R. S. Sennett
Department of Physics, University of Toronto, Toronto, Canada

(Received February 2, 1950)

A method is described for the measurement of the thickness of thin films using the multiple beam interference techniques. Only simple equipment is required, but reduction of the order of interference to as low as *one* makes possible the measurement of average thicknesses down to 10A. Applications have been made to evaporated films of six different metals and the method appears to be useful for all stable thin films in thicknesses up to several microns.

Possible errors in the method and the precautions which may be taken to avoid them are discussed.

INTRODUCTION

VARIOUS applications of multiple beam interferometry to the study of surface topography have been discussed by Tolansky.[1] One of the important applications is to the measurement of the thickness of thin films by determination of the height of the step made by the edge of the film when formed on an optically smooth substrate. The method involves covering the film and adjacent substrate with a highly reflecting coating and then measuring the resulting step in the coating. Donaldson and Khamsavi[2] have shown that for silver films with a silver coating this procedure gives the true thickness of the film. However, Avery[3] has noted that errors may be introduced in some cases, for example when chromium is used as the reflection coating for measuring a silver film.

Reflection fringes with white light as viewed in a spectroscope have been found to be the most satisfactory type of fringes for such measurements. Reflection rather than transmission fringes are used since then the reflection coating can be made sufficiently thick to eliminate a possible difference in the phase change upon reflection at the coating which is on the film compared to that which is on the substrate alone. Silver is the best metal for the coatings since it has the highest reflection coefficient, at least in the most convenient region of the spectrum. White light and a spectroscope are employed rather than monochromatic light since then optical flats are not required for the substrates and all measurements can be made simply from the wave-length drum of the spectroscope.

EXPERIMENTAL

The general arrangement of the equipment is shown in Fig. 1. The interference plates are mounted on the table of a small goniometer, the arms of which carry the source and the projector lens, L_2. Light from the source, which was a 6-volt, 32-cp incandescent lamp, after passing through the condensing lens L_1 is reflected normally to the interference plates by a half-silvered mirror. An image of the plates is formed on the slit of the spectroscope by the projector lens. The focusing of the condensing lens is not critical, but a convenient adjustment is to have an image of the source formed at the aperture of lens L_2. To ensure sharp fringes the effective angular aperture of the projector lens should be less than 1/15. The spectroscope was a Hilger constant deviation instrument with calibrated wave-length drum. A 12× eyepiece with single vertical cross hair was employed. The projector lens was a 32-mm microscope objective which produced an image of the interference plates enlarged 3× at the slit of the spectroscope. Thus the over-all lateral magnification was 36×.

The details of the interference plates are shown in Fig. 2. Standard 1 in.×3 in. microscope slides were used for these plates. The front slide is coated with silver to give a 1 percent to 2 percent transmission; the back slide is the substrate for the thin film to be measured. A step or channel is made in the film along the length of the

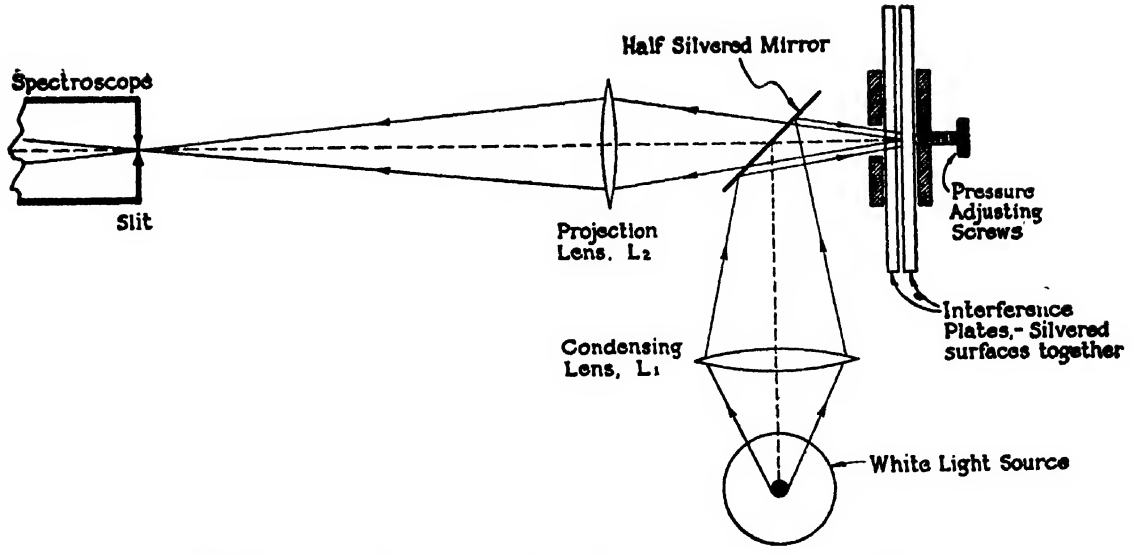

FIG. 1. Experimental arrangement for producing multiple beam interference fringes.

slide either during or after formation. The slide is then heavily coated with silver by thermal evaporation in vacuum. About 1000A is sufficient to eliminate the possible phase differences mentioned above. This silver surface thus has a step or channel, the depth of which corresponds to the thickness of the original film. It is important that the silver coatings have low optical absorption. In addition to the usual conditions for obtaining such coatings, it has been found that a rapid rate of deposition of the silver is also necessary.[4] The mounting which holds the plates on the goniometer table has a 3-mm aperture in the front and two small pressure-adjusting screws at the back. These screws control the separation of the plates.

The step or channel can be made in any convenient manner. It is desirable of course to have as sharp edges as possible. For metallic films, one method which was found quite satisfactory was to form a channel by gently drawing a not-too-sharp needle across the film. Some experience is required in order to remove all the metal yet not to scratch the glass substrate. The edges of the channel should be sharply defined and the bottom quite smooth. The slightest marring of the glass is readily detectable from the shape of the fringes. Another method is to form the film with the step or channel by using a suitable shield such as a narrow strip of metal foil. Both methods were found to give the same thickness measurements within the limits of error.

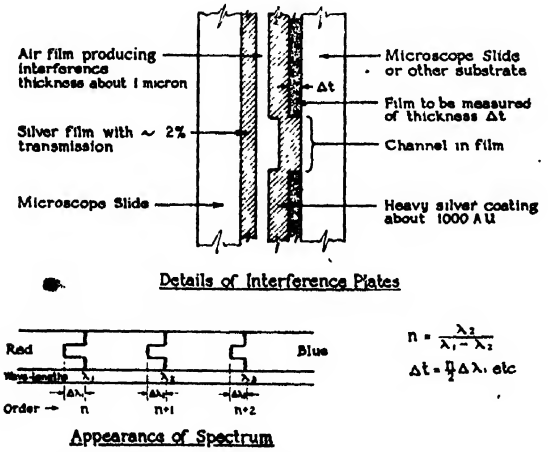

FIG. 2. Details of the coatings on the interference plates and a schematic diagram of the fringes from the plates.

A number of adjustments are required to obtain satisfactory fringes. The spectroscope is focused for monochromatic light and the slit width set for maximum resolution. The components as shown in Fig. 1 are aligned geometrically so that when the plates are in position a white light spectrum with interference fringes is observed in the spectroscope. Adjustments are made as follows.

1. Lens L_2 is focused to give sharp fringes.
2. The pressure screws are adjusted to make the fringes nearly vertical, at least in the region of the step.
3. Lens L_2 is moved laterally to locate the position where the fringes remain stationary. This corresponds to the area where the plates are exactly parallel and hence where the fringes have optimum sharpness and contrast.
4. The pressure screws are then set for the desired order and at the same time adjustment (2) is maintained, and (3) is checked.

While moving lens L_2 as in (3), fringes are viewed corresponding to various positions along the step. In this way local irregularities can be noted and avoided so that a final representative position is selected.

A schematic diagram of the spectrum observed is given in Fig. 2. The wave-length interval $\Delta\lambda$ corresponding to the height of the step Δt is measured directly, using the wave-length drum of the spectro-

[4] R. S. Sennett and G. D. Scott, J. Opt. Soc. Am. 40, 203 (1950).

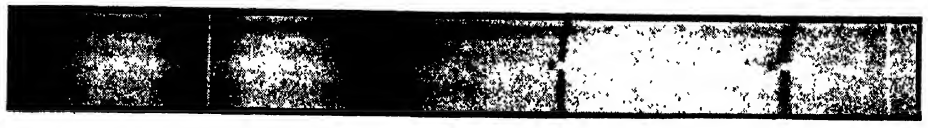

FIG. 3. Spectrogram of multiple beam interference fringes of orders 12 to 16. The mercury lines superimposed as wave-length references are the yellow doublet at 5770A and 5791A, the green line at 5461A, and the blue line at 4358A. The discontinuity in the fringe is caused by a channel in a silver film 115A thick.

scope. The order n for the fringe is determined as indicated by the formula in Fig. 2 and then Δt may be calculated: $\Delta t = (n/2)\Delta\lambda$. The spectrum of a typical fringe system at relatively high orders, *viz.*: 12 to 16, is shown in Fig. 3. Measurements were usually made at orders from 1 to 6. At order *one* for example, the "discontinuity" in the fringes of Fig. 3 appears as shown in Fig. 4. The mercury spectrum has been superimposed on these spectrograms merely to indicate the wave-length scale.

Since microscope slides are used in place of optical flats, the fringes are not in general straight; however, the use of the slides, which are relatively thin, makes it possible to obtain interference orders as low as *one* or *two* quite readily. Such low orders add greatly to the convenience with which readings can be made. It may be noted, for example, that for order *two* the wave-length interval at the step is just equal to the thickness of the film. If the fringe for order *two* is at the red end of the visible spectrum, the fringe of order *three* is in the blue, so that the order number can be immediately recognized. Furthermore it was observed that with microscope slides the fringes were about one-quarter the width of those obtained with ordinary optical flats. This presumably indicates that over distances of say 10 microns the microscope slides which are rolled or fire polished are smoother than the flats which are polished by an abrasive. Irregularities of 10 to 20A in the flats would account for the observed effect and it seems possible that these could be present in standard quality flats.

The fringes are produced by a very narrow area of the interference plates—the area corresponding to the image of the slit at the plates. With the arrangement described here, an individual setting on a fringe represents a position which averages heights over an area of about 5×50 microns on the plates. However, because of the necessary adjustments and the desirability of avoiding local irregularities, it is preferable to have available a film area of at least the order of 1 sq. mm.

It was found that within experimental error measurements of the depth of a step or channel were the same at all useful orders, i.e., from *one* to about *thirty*. For interference order *two* the wave-length settings on a fringe could be made in general to within 2A. Hence for a film 100A thick the measurement should be correct certainly within 5 percent.

A possible source of error in these measurements is the variation with wave-length in the phase change for reflection at a thick silver film. From a plot of $n\lambda$ against λ, it was found that this variation is quite small. The approximate correction for this effect in the measurement of the thickness Δt is given by: $\Delta t = (n/2)\Delta\lambda + [0.01(3)/2]\Delta\lambda$. It is evident that even at order *one* the correction is only ½ percent and hence for the sharpness of fringes at present obtainable this error can be neglected.

FIG. 4. The same channel as in Fig. 3, but at order *one*. The mercury yellow doublet and green line are superimposed on the spectrum.

As Tolansky[1] has emphasized, the method is capable of high resolution in the measurement of average heights. This fact is illustrated in Fig. 5 which shows a fringe at order *one* used to measure a silver film 15A in thickness.

DISCUSSION

The displacement of the discontinuity in the fringe certainly gives the depth of the channel or step in the silver coating, but whether this is precisely the same as the thickness of the original film must be considered in detail. It seems reasonable to assume that it is in the case of films which are continuous and of much the same nature as the glass substrate, such as Formvar films. However for films which are either aggregated or quite different in nature from the glass substrate, the assumption may not hold. Avery[3] has shown that when a chromium coating is used to measure silver films, the apparent thickness is about 30 percent greater than when silver is used as the coating. This may be explained by assuming that chromium does not fill the interstices of a silver film as completely as does silver itself. Alternately, it could also be assumed that the metal just adjacent to the glass is less aggregated for the chromium than for the silver. However, Donaldson and Khamsavi[2]

FIG. 5. The discontinuity in a fringe due to a silver film of average thickness 15A.

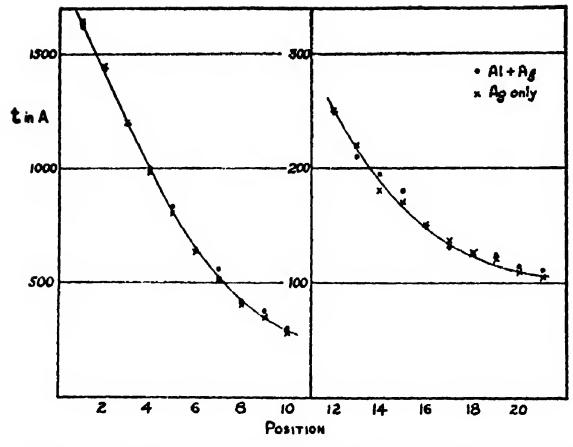

FIG. 6. Effect of an intermediate layer of aluminum on aluminum film thickness measurements using silver for the high reflection mirror.

have shown that when a silver coating is used for a silver film the measured thickness gives a density for the metal in the film equal to that of the bulk metal. This result is applied to films as thin as about 100A, which are known to be aggregated. Since electron diffraction shows that lattice spacings in thin films are essentially the same as in the corresponding bulk metals, it can be concluded that at least for the case of silver the multiple interference method yields the true average thickness for aggregated as well as continuous films.

For films other than silver the following method can be used in order to avoid errors due to the effects mentioned above. The film to be measured, A, is first covered with an intermediate layer, B, of the same material and deposited under the same conditions as A. The coating B is made sufficiently thick so that its top surface has the same structure over the substrate as over the film A. Finally the high reflection silver coating is added. It is evident that this procedure compensates for peculiarities (1) in the form of the material of the film in contact with the substrate and (2) the way in which the first layer of the silver coating may be deposited on the film material.

Thin films of the following metals, in addition to silver, have been measured in the range from 40A to 1500A: gold, copper, aluminium, antimony, and chromium. For each case at least two channels were made side by side through the metal films which varied in thickness along the length of the microscope slides. One channel was first coated with a thick film of the same metal, and then both were coated with a heavy silver film. For all the metals studied the thickness measurements were the same within the limits of error, either with or without the intermediate layer. As an example the results for aluminium are shown in Fig. 6. The measurements for the case of silver on chromium showed no discrepancy though Avery found that errors do occur when chromium is used as the coating for silver. It can be concluded that when silver is used as the reflection coating, the use of the intermediate layer is unnecessary for films of gold, copper, aluminium, antimony, and chromium.

It is essential to the method that the intermediate coating, or in the simpler case the silver coating, be of precisely the same thickness on the bare substrate as on the film. This condition is readily obtained when the films are deposited by thermal evaporation in vacuum, provided none of the incident atoms are reflected or scattered away from the surface which they strike. It is known that the distance of atomic migration over the substrate is much too small to be of importance in this connection. However, during the initial stages of the formation of these coatings, differences in the scattering of atoms from the films compared to the scattering from the substrates could occur. It is highly probable that this effect would only be important for films less than 50A in thickness. Because of the difficulties of making independent and accurate measurement of films of such a thickness, no experimental information on the importance of the effect is available. The possibility of such an error could be eliminated by forming the film on a substrate of the same material as the film itself.

CONCLUDING REMARKS

The method described here for the measurement of the thickness of thin films appears applicable to any stable thin film which can be formed on a smooth substrate and with a sharp edge. It is particularly suitable to film thicknesses in the range from 10A to 1000A, but can be used for films up to several microns in thickness. The precision at 100A is better than 5 percent.

The equipment required is simple and the results can be obtained quickly. After the film has been properly coated, about two minutes is usually sufficient time to make the adjustments and obtain a thickness measurement.

There are certain possible errors in the method, but in many cases these are not important. However each particular type of film and substrate should be considered independently to determine what precautions may be necessary.

Distribution in Energy of Johnson Noise Pulses

BEN R. GOSSICK*
NEPA Division, Fairchild Engine and Airplane Corporation, Oak Ridge, Tennessee
(Received August 22, 1949)

The distribution in energy of Johnson noise pulses (random thermal voltages in a resistor) is derived and checked against pulse-height measurements made with a linear amplifier and electronic counter. The following parameters are determined from the distribution function: (1) time of flight associated with a Lorentz mean free path, (2) the number of electrons which produce a pulse of a given height, and (3) the potential an electron falls through in a Lorentz mean free path.

DISCUSSION

NYQUIST'S equation[1]

$$d\langle V^2\rangle = 4kTRdf \tag{1}$$

applies to random thermal voltages across either an ohmic resistor or the radiation resistance of a Hertzian dipole. Bernamont,[2] and later Bakker and Heller,[3] using Lorentz electron theory and Fermi-Dirac statistics, obtained a proof of Eq. (1) in which the ohmic resistance appears explicitly. The distribution of random noise currents has been treated by Landon,[4,5] Norton,[5] Kac,[6] and Rice.[7] Norton draws upon Rayleigh's[8] solution for the amplitude distribution of a large number of unit vibrations with random phase.

The purpose of this paper is twofold: one, to present a solution for the Johnson[9] noise pulses by a method which is thought to be new, and two, to supply measurements of Johnson noise pulses made with a linear pulse amplifier and electronic counter. It is believed that such measurements have not been previously reported.

The distribution of noise pulses is analyzed here by Maxwell-Boltzmann statistics using a time-energy phase space. It is assumed that the resistor is in thermal equilibrium, and that the Johnson noise is a stationary random process. In considering the distribution of pulses by Maxwell-Boltzmann statistics, it is convenient to employ the familiar treatment of molecules as an analog. This analogy is given in Table I.

The probability of a distribution of pulses $p_1, p_2 \cdots$ becomes

$$W = p! \prod_i (g_i)^{p_i}/p_i!. \tag{2}$$

As the number of pulses is large, Stirling's approximation is applicable, so that (2) can be rewritten as

$$W = (p)^p \prod_i (g_i/p_i)^{p_i}. \tag{3}$$

In order to obtain the most probable complexion, $\ln W$ is maximized by the method of Lagrangian multipliers. The following equations of condition are adopted:

$$\sum_i p_i - (t'/\tau') = 0, \quad \tau' \geqslant \tau, \tag{4}$$

$$\sum_i p_i - (t'/\tau) = 0, \quad \tau' < \tau. \tag{5}$$

$$\sum_i p_i E_i - E = 0, \tag{6}$$

where τ is the time of flight associated with the Lorentz mean free path, τ' is the response time of the electronic system, E_i is the energy of a pulse in the ith cell of phase space, and E is the total energy of all pulses occurring in the interval $0<t<t'$. Equations (4) and (5) state that the total number of pulses in the counting interval $0<t<t'$ is invariant, and this is an approximation requiring that $t' \gg \tau$, and $t' \gg \tau'$. Because of the limitations of electronics, Eq. (4) is normally applicable. Equation (5) is included for completeness to the theory, and because it seems possible that it could be used in special cases, e.g., for τ across a biased barrier of a semiconductor-metal rectifier. Equation (6) follows from the original assumption that the resistor is in thermal equilibrium. Solving for the number of pulses p_i in the ith cell of phase space yields:

$$p_i = g_i e^{-1-\alpha-\beta E_i}, \tag{7}$$

where β and α are the Lagrangian multipliers associated with (6) and (4), respectively. Following the molecular analog, (7) can be expressed as the differential:

$$dp^2 = Ae^{-\beta E} dE dt, \tag{8}$$

which gives the number of pulses with energy between E and $E+dE$ arriving between t and $t+dt$, where A is a constant to be determined directly.

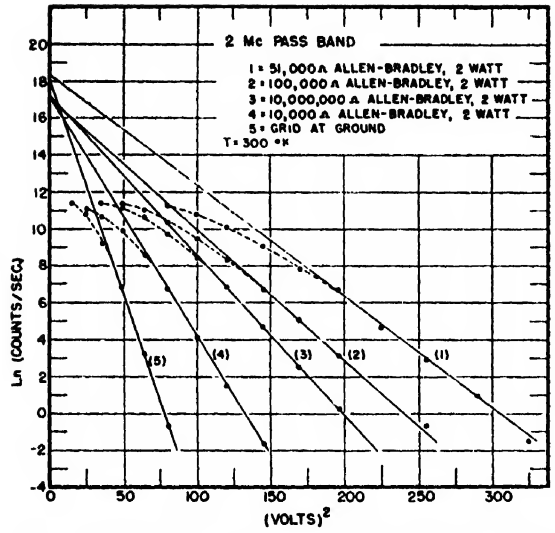

FIG. 1. (Volts)² refers to the square of the pulse-height selector setting at the A-1 amplifier. Hence, to relate these curves to (23) it is necessary to introduce the over-all gain G into (23) as follows:

$$p_{V_0} = (1/\tau') \exp(-V_0^2G^2/2\langle V^2\rangle G^2)$$
$$= (1/\tau') \exp[-(\text{volts})^2/2 \text{ (mean square volts)}]$$
$$\ln p_{V_0} = \ln(\text{count/sec.})$$
$$= -(\text{volts})^2/[2 \text{ (mean square volts)}] + \ln 1/\tau'.$$

The observable energy per pulse equals

$$E = V^2\tau'/2R, \tag{9}$$

where V is the amplitude of the voltage pulse. By means of (9) Eq. (8) can now be rewritten in terms of voltage as

$$dp^2 = (A\tau'V/R)dVdt \exp(-\beta\tau'V^2/2R). \tag{10}$$

As the total number of pulses which arrive in the interval t' is the quotient t'/τ', it follows that

$$t'/\tau' = \frac{A\tau'}{R}\int_0^{t'}\int_0^{\infty} VdVdt \exp\left(\frac{-\beta\tau'V^2}{2R}\right). \tag{11}$$

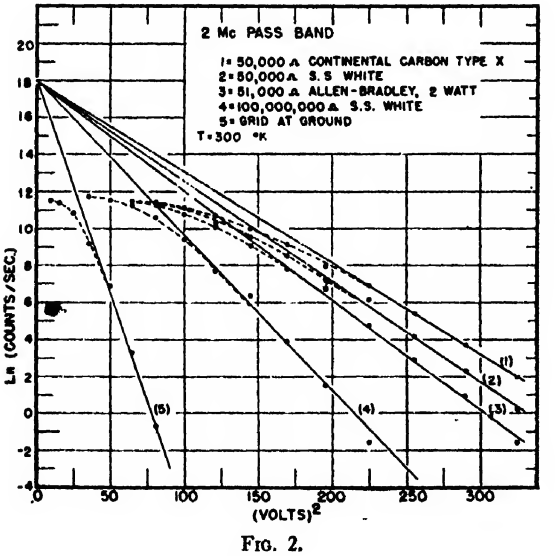

FIG. 2.

Solving (11) for A yields

$$A = \beta/\tau', \tag{12}$$

which can be used to rewrite (10) as

$$dp^2 = (\beta V/R)dVdt \exp(-\beta\tau'V^2/2R). \tag{13}$$

As it was initially assumed that the Johnson noise is a stationary random process, the function of interest is the mean pulse rate, hereafter denoted by $\dot{p}$. Thus

$$d\dot{p} = (\beta/R)VdV \exp(-\beta\tau'V^2/2R) \tag{14}$$

gives the average rate of pulses with amplitude between V and $V+dV$.

The constant β is evaluated immediately in terms of the mean power $\bar{P}$.

$$\bar{P} = \frac{\beta}{R}\int_0^{\infty} EVdV \exp\left(\frac{-\beta\tau'V^2}{2R}\right), \tag{15}$$

$$= \frac{\beta}{R}\int_0^{\infty} \left(\frac{V^2\tau'}{2R}\right)VdV \exp\left(\frac{-\beta\tau'V^2}{2R}\right), \tag{16}$$

$$= \frac{\beta\tau'}{2R^2}\int_0^{\infty} V^3dV \exp\left(\frac{-\beta\tau'V^2}{2R}\right), \tag{17}$$

$$\bar{P} = 1/\beta\tau'. \tag{18}$$

$$\beta = 1/\bar{P}\tau', \tag{19}$$

$$= R/\langle V^2\rangle\tau'. \tag{20}$$

Equation (13) is now rewritten, substituting for β the value just obtained in (20),

$$d\dot{p} = (VdV/\tau'\langle V^2\rangle) \exp(-V^2/2\langle V^2\rangle). \tag{21}$$

A convenient function to obtain experimentally is the average counting rate of the pulses which have a height exceeding the bias setting of a discriminator circuit. If the bias setting is V_0, it follows that the rate $\dot{p}$ should equal

$$\dot{p}_{V_0} = \frac{1}{\tau'\langle V^2\rangle}\int_{V_0}^{\infty} VdV \exp\left(\frac{-V^2}{2\langle V^2\rangle}\right), \tag{22}$$

$$= (1/\tau') \exp(-V_0^2/2\langle V^2\rangle). \tag{23}$$

Results which are essentially the same as (23) can be found in the excellent mathematical analyses of the noise current envelope by Kac[6] and Rice.[7] In order to demonstrate this agreement, it is necessary to apply their results to the number of times per second the noise voltage is expected to pass through V_0 with a positive slope, as seen on the output of a broad band linear amplifier.

Although the Lorentz mean collision time is not directly observable when $\tau' \gtrsim \tau$, the value of τ can be calculated by using (21) together with a random walk solution after Wang and Uhlenbeck.[10] These authors

[10] Ming Chen Wang and G. E. Uhlenbeck, Rev. Mod. Phys. 17, 323 (1945).

have shown that for a one-dimensional model, the probability of a resultant displacement $\nu = n - m$ out of a total of S unit random steps equals

$$P(n|m,S=)\frac{S!}{\left(\frac{\nu+S}{2}\right)!\left(\frac{\nu-S}{2}\right)!}(\tfrac{1}{2})^S. \quad (24)$$

If an assumption is made that $S \gg \nu$, and Sterling's approximation is applied, the following relation is obtained from (24),

$$P_{\nu,S} \propto \exp(-\nu^2/2S). \quad (25)$$

The number of random electron displacements S during an interval of observation τ' is given by

$$S = N\tau'/\tau, \quad (26)$$

where N is the total number of conduction electrons in the resistor. By combining (25) and (26) one obtains the following relation for the probability that ν-electrons will contribute to a pulse during the interval of observation τ'.

$$P_{\nu,\tau'} \propto \exp(-\nu^2\tau/2N\tau'). \quad (27)$$

As (21) and (27) are associated with the same event, it is permissable to equate the exponents of the two expressions. Thus

$$\nu^2\tau/2N\tau' = V^2/2\langle V^2\rangle. \quad (28)$$

It is necessary now to obtain the relationship between the pulse amplitude V and the number of electrons ν which contribute to the pulse in order to evaluate τ in (28).

The pulse amplitude V can be expressed by Ohm's law as the product of the peak noise current I (based on ν electrons) and the constant resistance R (based on the total number of conduction electrons N). Thus the current I and resistance R can be generally expressed as

$$I = \nu\epsilon\lambda/L\tau'\sqrt{3}, \quad (29)$$

and

$$R = L^2/N\epsilon\mu, \quad (30)$$

where ϵ is the electronic charge, λ is the Lorentz mean free path, L is the linear length of the resistor, and μ is the electronic mobility. A few simple steps of algebra applied to (28)–(30) yields

$$\tau = \epsilon\lambda^2 R/(3\langle V^2\rangle\tau'\mu). \quad (31)$$

Analyses of the mean square noise voltage $\langle V^2\rangle$ by Bernamont[2] and Moulin[11] show that a resistor and its distributed capacitance form a system in which the equipartition principle applies. Thus, $\langle V^2\rangle$ can be expressed as

$$\langle V^2\rangle\tau'/2R = C\langle V^2\rangle/2 = kT/2, \quad (32)$$

where C is the distributed capacitance.

[11] E. B. Moulin, *Spontaneous Fluctuations of Voltage* (Oxford University Press, London, 1938).

Substituting (32) into (31) obtains

$$\tau = \epsilon\lambda^2/3\mu kT. \quad (33)$$

It is felt that this derivation of τ gives a clear and convincing model of the Johnson noise. One can quickly obtain the same result by combining the well-known formula $\epsilon/m = \mu/\tau$ with the mean square velocity $\langle v^2\rangle$ from classical statistics,

$$\langle v^2\rangle = (\lambda/\tau)^2 = 3kT/m. \quad (34)$$

Assuming that N is known, the number of electrons ν which contribute to a pulse of a given height can be determined from (27) as

$$\nu = (N\tau' V^2/\tau\langle V^2\rangle)^{\frac{1}{2}}, \quad (35)$$

since τ' can be obtained from the experimental curve of (23) and τ can be obtained from (33). It is not surprising to note that if there were no limitations of amplifier resolving power, and (5) were substituted for (4), then it follows by (35) that

$$\langle \nu^2\rangle = N. \quad (36)$$

Furthermore, assuming still that $\tau' \geqslant \tau$, it follows by (32) that

$$\langle V^2\rangle/R = kT/\tau, \quad (37)$$

which has been derived by Bakker and Heller[3] using Fermi-Dirac statistics. By (37), the mean energy per pulse $\bar{E}$ equals

$$\bar{E} = kT, \quad (38)$$

and as the mean number of electrons involved in the pulse equals $(N)^{\frac{1}{2}}$ by (36), the energy contribution per electron E_0 is given by

$$E_0 = kT/(N)^{\frac{1}{2}} \quad (39)$$

which, in this model, represents the potential drop for an electron falling across a Lorentz mean-free path.

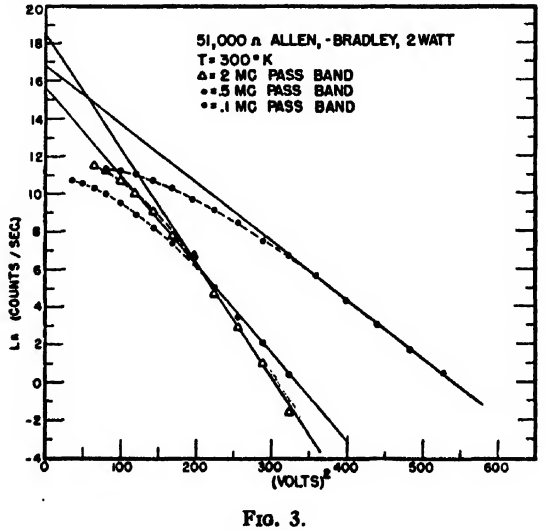

FIG. 3.

MEASUREMENTS

The measurements were taken with the following equipment all of which was made by the Instrument Department of the Oak Ridge National Laboratory: (1) A-1 linear preamplifier, (2) A-1 linear amplifier, (3) 64 scaler, Model Q-762, (4) 1024 scaler, Model Q-834. The A-1 linear preamplifier and amplifier have been described by Jordan and Bell.[12]

Pulse-height measurements taken with different types of commercial grid resistors are shown in Figs. 1–3; and these are the experimental curves which correspond to (23). Curve 5 (Fig. 1) with the input grid grounded gives the shot noise contribution. It can be seen from Figs. 1 and 2 that with the 2-mc pass band of the A-1 amplifier the resolution time of the system τ' extrapolates to $\sim 2.5 \cdot 10^{-8}$ sec. This is the time required by the pulse-height discriminator to receive enough energy to trigger, and consequently it is not inconsistent that it is less than the rise time of the amplifier, i.e., ~ 0.15 μsec. In measuring the random counting rate above $\sim 10^3$ counts/sec. a correction for the recovery time T was made using the equation[13]

$$n_1 = n(1-nT), \quad nT \ll 1,$$

where n_1 is the observed rate, and n is the true rate. The extrapolation of the curves in Figs. 1–3 is justified on the basis of this correction.

In order to predict the curves of Figs. 1–3 from Eq. (23) it is only necessary to have the parameters $\langle V^2 \rangle$ and τ' evaluated. $\langle V^2 \rangle$ can be determined by solving Nyquist's equation for a parallel RC circuit where C is the grid input capacitance, while τ' can be estimated from the design of the equipment.

Note on the Use of Reiner's Equation for Recognition of Pseudoplastics from Their Flow Curves

VERA OSMAN KRAKAUER
Interchemical Corporation, New York, New York

(Received March 17, 1950)

A method is described which has been found useful to determine by application of the Reiner equation whether certain flow curves obtained with a concentric cylinder rotational viscometer indicate pseudoplastic or Bingham body types of flow.

THERE has been an increasing use of concentric cylinder rotational viscometers suitable for obtaining complete rate of shear-shearing stress diagrams or flow curves, such as the one described by Green[1] from whose characteristics the rheological behavior of the measured sample may be determined. The several commercial viscometers of this type recently placed on the market are being used in diverse industrial fields, with the likelihood of encountering all types of rheological flow.

There is usually no difficulty in recognizing Newtonian flow from its curve of a straight line passing through the origin (Fig. 1A). Thixotropic plastics can be distinguished by the characteristic hysteresis loops formed between the slope of the up curve and the straight line of the down curve (Fig. 1B), particularly if measured to several top rates of shear,[2] and by the intercept on the shearing stress axis. However, non-thixotropic Bingham bodies, which have an intercept on the shearing stress axis, but then increase linearly with rate of shear (Fig. 1C), and pseudoplastics, whose flow curves show a less than linear shearing stress increase with increasing rate of shear, and which appear to start at the origin and to approach an asymptote (Fig. 1D) sometimes present a difficulty.

For pseudoplastics, the rheologist may be able to fit a straight line through the top points of the flow curve which will intersect the torque axis, with the lower points falling off, and obtain a seeming resemblance to Bingham-body flow curves where the lower points fall off due to plug flow caused by only partial shearing throughout the clearance, due to the yield value. In addition, over the practical range the apparent viscosity, which some investigators calculate as shearing stress divided by rate of shear at each point will continually decrease with increased shear for both types of flow. Therefore, at times, difficulties of recognition will arise. It is important to avoid erroneous conclusions and recognize the true nature of the sample in question that no misleading yield values be calculated for pseudo-

[1] H. Green, Ind. Eng. Chem. (Anal. Ed.) 14, 576 (1942).

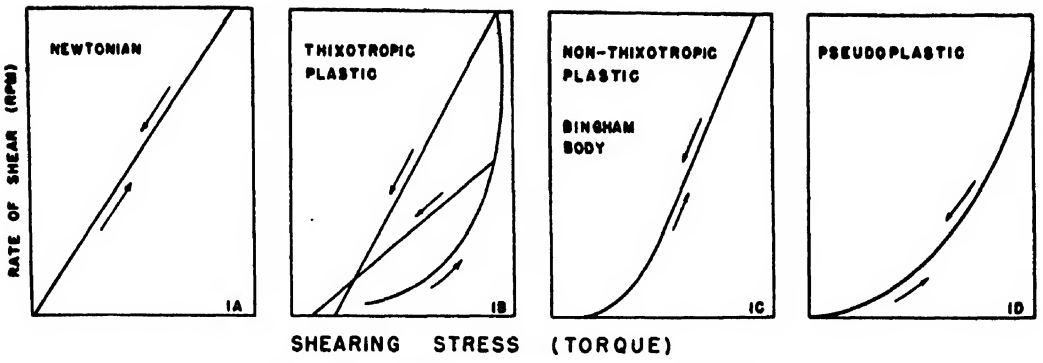

FIG. 1. Schematic flow curves for four types of flow.

plastics, which have none, or that no constant plastic viscosity be calculated for them.

Green points out this difficulty,[3] and suggests recourse to a microscopic method described previously,[4, 5] to help decide which type of flow is being encountered. This note describes a simpler, rapid method, that works well in the majority of cases, and requires merely an examination of the flow curve and a simple calculation.

Reiner and Rivlin, in the development of their equation of flow in concentric cylinder rotational viscometers point out[6] that for materials having a yield value, flow will not start immediately, but will only commence at a torque T_0 where,

$$T_0 = 2\pi r_b^2 hf$$

and completely laminar flow, which is never reached at finite flow rates in a capillary viscometer,[7] will commence in a rotational viscometer at a torque T_2 where

$$T_2 = 2\pi r_c^2 hf,$$

where r_c = radius of the cup (outer cylinder) in cm, r_b = radius of the bob (inner cylinder) in cm, f = yield value in dynes cm, h = immersed height of bob in cm. At T_2, for Bingham bodies the plug flow will be overcome and the straight-line portion of the curve, from whose slope the plastic viscosity, and from whose intercept (T_1) the yield value is calculated, will begin. This means that the individual points above torque T_2 should now fall directly on the straight line drawn through the upper points. Within limits of experimental error, this condition is realized for almost all of the collection of the non-thixotropic Bingham bodies measured at this laboratory over recent years. The measured points begin to fall on the line, at, or slightly above the calculated T_2 (Fig. 2). Thixotropic samples occasionally show larger deviations, possibly due to additional breakdown on the down curve.

However, when a straight line is fitted to the curve obtained for pseudoplastics to a certain top rate of shear, and T_2 is calculated for the yield value obtained from the intercept on the torque axis, it is seen that the individual points do not fall on the line until a much higher torque is reached than that attributable to plug flow if there were a yield value, often as much as 3 and 4 times the calculated value. Particularly when the measurements are continued to higher top rates of shear, it can be seen that the respective straight lines drawn will give materially higher intercepts with increasingly larger deviations from the respective calculated T_2 (Fig. 3), while for non-thixotropic Bingham bodies, measurements to successively higher rates of shear will

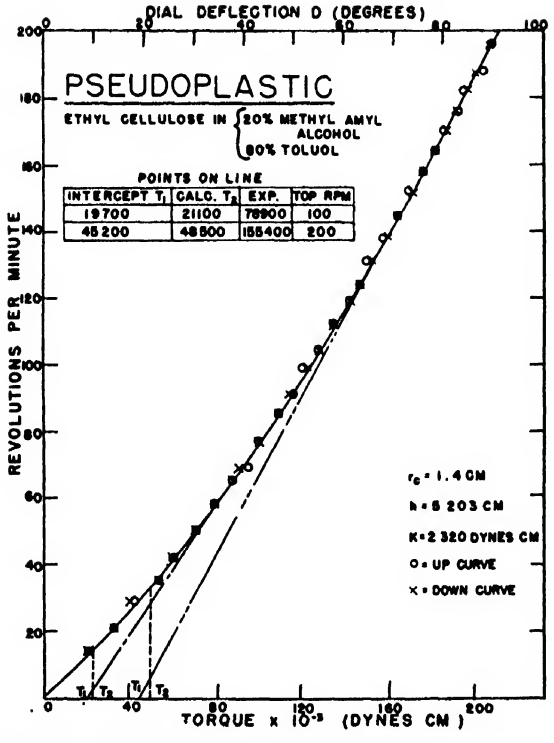

FIG. 3. Experimental flow curve obtained on rotational viscometer for a pseudoplastic, and calculations.

not affect either the yield value or T_2. Simple inspection of the flow curve and the number of points off the line will not usually suffice, since, depending upon the instrumental dimensions, the yield value, and the particular r.p.m. steps chosen, the number of points with too low a torque may vary for a particular Bingham body, while, depending upon the top r.p.m. chosen for the measurement of a pseudoplastic, and the number of points obtained, the amount of curvature may appear to vary. Therefore, it would be preferable to reach sufficiently high rates of shear and to calculate T_2 from the equation. When the flow curves for the McMichael type viscometer are simply plotted directly from the viscometer data as r.p.m. *vs.* angular deflection, changing the deflection values to torque can be avoided by dividing through by the torsion constant (K) of the spring, wire, or other torsion member used,

$$\frac{2\pi r_c^2 hf}{K} = D_2;$$

or, from the equation $f = T_1 C$, which is derived from the Reiner concept, where

$T_1 = D_1 K$,

D_1 = intercept on deflection axis,

$$C = \frac{(1/r_b)^2 - (1/r_c)^2}{4\pi h} \Big/ \ln \frac{r_c}{r_b} = \text{instrumental constant for yield value calculation;}$$

or one can substitute and altogether avoid calculation of f (which would be meaningless for pseudoplastics), using

$$2\pi r_c^2 hCD_1 = D_2,$$

where D_2 is the deflection at which laminar flow ensues and the point should fall on the line. Figures 2 and 3 were plotted from data obtained with a Precision-Interchemical viscometer at increasing and decreasing r.p.m. The coincidence of the "up" and "down" points indicates that no thixotropic breakdown took place. Both graphs could have remained in terms of deflection as indicated along the top of their abscissas. For the Bingham body (Fig. 2), the data for the lines at both top r.p.m. would have been $D_1 = 40.5$, $D_2 = 47$ and D actually on line also 47. For the pseudoplastic curve (Fig. 3), for the 100 top r.p.m. line $D_1 = 8.5$, $D_2 = 9.1$ and D actually on line $= 34$, and for the 200 top r.p.m. line $D_1 = 19.5$, $D_2 = 20.9$ and D on line $= 67$. Similarly, for the concentric cylinder modified Stormer type viscometer often used for non-thixotropic samples, whose flow curves are plotted as r.p.m. *vs.* weight where

$T_1 = (W_1 gS/G)$ and W_1 = intercept on weight axis
g = acceleration due to gravity
S = radius of drum to which weight is attached
G = gear ratio between drum and shaft of bob,

one can simply use

$$2\pi r_c^2 hCW_1 = W_2,$$

where W_2 is the weight after which for Bingham bodies the points should fall on the line.

Thus a convenient, rapid method is available to check when doubt exists as to whether a certain viscometric flow curve indicates a pseudoplastic or a Bingham body type of flow. When true yield value is present, the lower points will have too low a torque due to plug flow, but will fall on the straight line at or slightly after the torque at which completely laminar flow ensues, according to the Reiner equation. However, for pseudoplastics, where the intercept is simply a result of fitting a straight line to the upper portion of the curve resulting from the shear-produced reduction of torque, and where both the line and its intercept have no physical significance, the points will usually not fall on the line at or near the calculated value of T_2.

An X-Ray Study of Thermally Induced Stresses in Microconstituents of Aluminum-Silicon Alloys*

JOHN P. NIELSEN† AND WALTER R. HIBBARD, JR.‡

(Received March 13, 1950)

The changing width of high angle Debye x-ray diffraction lines from eutectiferous aluminum-silicon alloys during thermal cycling as measured by a recording Geiger counter spectrometer is interpreted in terms of stresses resulting from the differences in thermal expansion of the microconstituents.

IN a solid alloy containing a dispersed second phase, stresses theoretically should develop in the matrix during cooling from some stress-free state due to the difference between the thermal expansion coefficients of the two phases. If the matrix has the larger coefficient, the stress development process resembles that in shrink or interference fitting except that the components are microconstituents. László[1,2] developed the stress analysis techniques for a variety of such stresses, as they might occur in different ideal microstructures, labeling them "tessellated stresses." Metallographic evidence of the microstructural stresses reported by Boas and Honeycombe[3] consists of slip lines, cracks, and distortion produced by several heating and cooling cycles of certain alloys. The present work is a x-ray diffraction study of such stresses in aluminum-silicon alloys.

Eutectic and certain hypereutectic alloys of this system contain essentially silicon rich particles imbedded in an aluminum rich matrix below the eutectic temperature. Since the thermal expansion coefficient of aluminum is about seven times greater than that of silicon, the aluminum matrix tends to contract against the silicon particles on cooling these alloys, developing a pressure both in the matrix and in the silicon. If, as a first approximation, the silicon particles are considered as uniformly dispersed spheroids, the stress analysis of the matrix becomes that of the pressure on the inner wall of a thick spherical shell, producing radial compression and tangential tension, which depend upon the elastic moduli of the constituents and the dimensions of the shell. Based on physical constants from the 1948 *Metals Handbook* and the equations of László[1,2] and Love,[4] the calculated thermally induced stresses for certain of these alloys are given in Table I. These data indicate that the stresses may reach significant magnitudes and in real alloys where the silicon particles are far from spherical, the stresses at local points should readily exceed the yield strength of the matrix. It is to be noted that the difference between the radial and the tangential stresses at a point acts to produce plastic deformation, with the radial pressure considered as negative in sign.

EXPERIMENTAL PROCEDURE AND RESULTS

The measurement of the width of Debye x-ray diffraction lines appeared to be the best method for obtaining direct evidence of the thermally induced stresses in the aluminum matrix, since both tensile and compressive stresses would tend to shift the line slightly in both directions resulting in broadening. Aluminum-silicon alloys (12, 20, and 30 percent Si) were modified with NaF, chill cast, hot forged to further disperse the silicon particles, and annealed 20 hours at 500°C. A calibrated goniometer and a Geiger tube from a Philips x-ray spectrometer were assembled around a Seemann demountable-target-type x-ray tube so as to cover Bragg angles from 40° to 83°. By using a selected beam from a line focus source[5] fine slits of 0.005 in. at the source and at the Geiger tube permitted sufficient intensity for the delineation of line breadths in the back-reflection region. In order to take full advantage of the x-ray focusing principle,[6] the specimen was mounted so that the effective diffraction surface could be experimentally adjusted tangent to the focusing circle. To further enhance resolution, the scanning speed of the Philips goniometer was reduced to 0.05° Bragg per minute. Relative x-ray intensities were recorded with a chart speed such that one degree Bragg required 40 in. of chart. Line breadth measurements were made at several temperatures on cooling from 400°C to room temperature using the 420 diffraction line of the aluminum matrix and Cu$K\alpha$-radiation. The temperatures were maintained by an electrical resistance furnace which fitted over the specimen holder and contained narrow slits for the exit and entry of the beam. The temperature

was measured by a thermocouple placed in a hole drilled in each specimen and was controlled to within ±2°C. The deviation in line breadth produced by the 2°C variation was negligible. The results are tabulated in Table II.

TABLE II. Widths in radians, W_r, at half-maximum for the 420 Cu$K\alpha_1$-aluminum line from aluminum-silicon alloys at various temperatures (multiply by 10^{-3}).

0 percent Si		12 percent		20 percent		30 percent	
T°C	W_r	T°C	W_r	T°C	W_r	T°C	W_r
260	3.5	420	3.5	307	1.6	313	3.5
22	2.6	320	3.5	272	2.5	260	3.2
		262	3.5	214	3.2	206	5.1
		211	3.0	182	3.5	153	5.1
		142	3.3	144	3.2	96	5.4
		77	4.2	97	3.3	24	5.6
		12	4.0	31	3.7	360	4.3
				22	3.9	22	5.2

A metallographic confirmation of the stresses was attempted¶ similar to the Boas and Honeycombe experiments. It was found that polished specimens of these alloys would not develop slip lines[7] on thermal cycling, but neither could slip lines be developed by mechanical straining (squeezing in a vise), so that it does not appear possible to obtain metallographic support for the x-ray data.

EVALUATION OF RESULTS

As expected, cooling the aluminum (0 percent Si) specimen from 260°C to room temperature produced no line broadening, in fact, the high resolution even revealed a line sharpening. However, all alloys containing added silicon showed line broadening on cooling, as predicted by the stress analysis. No pronounced asymmetry was found in the shape of the lines, indicating no measureable difference in the magnitude of the tensile and compressive components. On reheating the 30 percent silicon specimen, it was found that the line width decreased somewhat, lending support to the thesis that elastic stresses were being detected. The gradient nature of the stresses together with the fact that the silicon particles were not spherical precluded any quantitative correlation with the calculated stresses. Furthermore, the x-ray measurements involved only the region at the surface of the specimen. Regarding the solid solubility of silicon in the aluminum phase, calculations indicate that the 0.05 percent to 0.48 percent solubility limits between room temperature and 400°C would disturb the x-ray lines less than the probable error of measurement. However, the gradient nature of the stresses and any cold working resulting from stresses exceeding the yield point of the matrix might have added to the line broadening on cooling.

¶ Experiment performed by W. H. Hawley, Jr., graduate student at Hammond Laboratory, Yale University.

[7] A "rumpled" surface indicating strain was visible to the naked eye, but, under the microscope, fine dark lines indicative of slip were not visible. For a similar phenomenon see Guy, Barrett, and Mehl, Trans. A.I.M.E. 175, 216 (1948).

SUMMARY

Thermally induced microstructure shrink-fit stresses produced in the aluminum matrix around silicon particles in duplex aluminum-silicon alloys are analyzed on the basis of elastic theory, and x-ray diffraction experimental evidence is presented to confirm their presence.

ACKNOWLEDGMENT

Acknowledgment is due the North American Philips Company, New York, New York for their generous loan of the Geiger counter spectrometer. The personal efforts of Dr. O. S. Duffendack, Director of Research, Dr. W. Parrish, and Mr. C. J. Woods, of that company in arranging for the loan are particularly appreciated. Dr. Kent R. Van Horn of the Aluminum Company of America, Cleveland, Ohio, arranged for the supply of specimen material. Professor L. W. McKeehan, Director of Sloane Physics Laboratory, Yale University and Dr. C. H. Mathewson Department of Metallurgy, Yale University kindly read the manuscript and offered helpful suggestions.

X-Ray Diffraction by Elastically Deformed Crystals*

J. E. White
*Acoustics Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts***
(Received March 20, 1950)

Published articles establish the fact that vibration or other inhomogeneous strain greatly increases the ability of a crystal to diffract x-rays. The present article gives experimentally determined relations between integrated intensity and strain for the rather simple case of static bending. All measurements were made on quartz plates, but a wide range of geometrical and crystalline parameters was covered nevertheless. In some cases, the integrated intensity for extreme bending was more than 20 times that from the unbent crystal. An approximate theory is developed which agrees well enough with the measurements to serve as a means of computing the effects of other types of strain or of other combinations of crystalline parameters. A qualitative study of vibrating crystalline plates is also described briefly.

NOMENCLATURE

e	electronic charge
m	electron mass
c	velocity of light
N	number of unit cells per unit volume
λ	x-ray wave-length
F	crystalline structure factor
θ	Bragg angle
ϕ	variable angle of incidence
l	distance traversed in crystal
R	radius of bending
$2s$	angular width for perfect reflection
w	"average" width
ϵ	extinction coefficient
ϵ_{ave}	average extinction coefficient
μ	linear absorption coefficient
A_0	integrated intensity for perfect crystal
B, L	integrated intensities
t	thickness of crystal
Θ	angle between crystalline plane and face of crystal
I	beam intensity
P_0	beam power
ω	angular velocity of crystal
E	energy diffracted in one traversal

INTRODUCTION

THE influence of elastic vibrations of a crystal on the diffraction of x-rays by the crystal has interested many investigators during the last twenty years.[1] One fact clearly established by their work is that Laue spots formed when an x-ray beam traverses a crystal vibrating in some resonance condition are much more intense than they are when the crystal is at rest. A similar increase for Bragg reflection off the surface was found. Statically bent quartz was also shown to exhibit this effect. The increased intensity was generally attributed to a reduction in extinction, either primary or secondary. A theory[2] treating diffraction by a crystal whose planar spacing varies sinusoidally in space and time was published, but extinction effects were not considered, and as a result, the integrated intensity of any reflection came out to be independent of vibration.

The principal objective of the work being described here is the determination of a quantitative relationship between increased diffracting power and degree of deformation. Since high frequency vibration patterns may be quite complex, static bending was chosen as a type of strain which can be realized experimentally and described easily. Quartz was chosen for study because of its excellent elastic properties and the high degree of crystalline perfection obtainable. The experimental procedure and results will follow the discussion of the approximate theory, since the terminology and basic objectives can best be presented in connection with the theory. The expressions derived provide a means of generalizing the results to other crystals and other types of strain, including some forms of vibration. No measurements were made on vibrating crystals, although the qualitative experiments performed provide further evidence that it is the local curvature of the crystal which controls the increase in diffracting power.

AN APPROXIMATE THEORY

The mathematical description of x-ray diffraction by a distorted crystal as developed here relies upon the Darwin[3] treatment of x-ray diffraction by a perfect crystal for fundamental constants required. He found that a plane monochromatic beam is perfectly reflected over a small angular range which can be expressed (for σ-polarization),

$$2s=(2e^2N\lambda^2F)/(mc^2\pi\sin 2\theta). \tag{1}$$

Outside this range, the reflected amplitude drops sharply. Even so, the area under the "tails" is one-third the area under the flat portion of the curve. The area under this curve is customarily expressed in units applicable to an experiment in which the crystal is rotated at a uniform angular velocity ω and the total energy E is measured as the region of reflection is traversed once. Expressed as a ratio to the incident power P_0,

$$\frac{E\omega}{P_0}=A_0=\frac{8N\lambda^2Fe^2}{3\pi\sin 2\theta mc^2}\frac{1+\cos 2\theta}{2}. \tag{2}$$

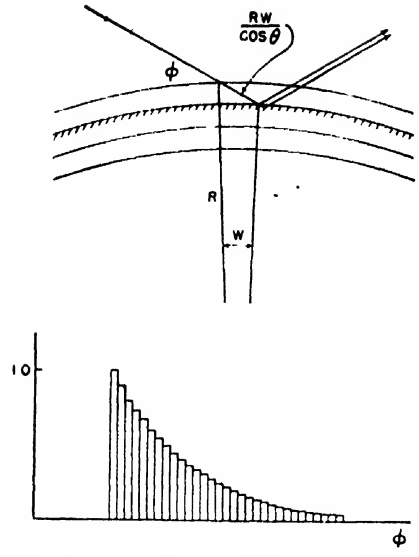

FIG. 1. Geometry for approximate theory (above) and resulting rocking curve (below).

This is the integrated intensity for a perfect crystal when the incident beam is unpolarized.

Darwin also found that the transmitted beam is rapidly "extinguished" within this angular range. The reduction in amplitude as the beam penetrates the crystal along a path l can be expressed as an exponential decay,

$$I_l = I_0 e^{-\epsilon l},$$

where

$$\epsilon = (2\pi \sin 2\theta)[s^2 - (\phi-\theta)^2]^{\frac{1}{2}}/\lambda. \qquad (3)$$

Within the region of perfect reflection, the extinction coefficient ϵ varies, being a maximum at the middle and zero at the edges. Outside the region of perfect reflection, ϵ is imaginary and therefore does not represent attenuation. The values of ϵ are such that reflection by a perfect crystal is practically a surface phenomenon.

The essential feature of the theory described here is the assumption that a distorted crystal behaves locally like a perfect crystal, the strains becoming apparent only when viewed at points many wave-lengths apart. It is developed for a crystal bent into a section of a cylinder of radius R. An expression for the area under the rocking curve as a function of bending is our objective. Before proceeding, let us make two simplifying approximations regarding the behavior of a perfect crystal. The first is that perfect reflection occurs over a range w such that the area A_0 is the same as that given by the Darwin treatment. This makes $w = 2.66s$ as compared with $2s$. The second assumption is that the extinction coefficient ϵ, which governs the depth of penetration of the beam before it is reflected, has the constant value ϵ_{ave} over the whole range w and is zero elsewhere. ϵ_{ave} is the linear average of Darwin's ϵ over the angular range w, and it is given by

$$\epsilon_{Av} = \frac{3\pi^2 \sin 2\theta s}{8\lambda} = \frac{3\pi e^2 N \lambda F}{8mc^2}. \qquad (4)$$

We are now ready to state how the integrated intensity from a bent crystal should depend on the radius of bending. As a bent crystal (Fig. 1) is rotated counter-

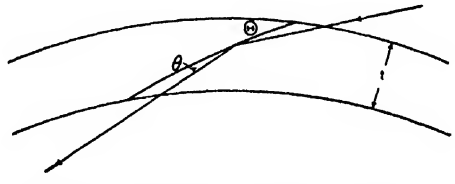

FIG. 3. Geometry for plane not parallel to surface of crystal.

clockwise, the conditions for reflection of the elementary pencil of x-rays shown will become satisfied for the region near the surface. Throughout a range w, reflection is perfect, and a contribution of A_0 is made to the integrated intensity. The beam penetrates only a very short distance controlled by ϵ_{ave}, and the rest of the crystal is shielded. As the angle proceeds beyond w, however, the beam is no longer reflected at the surface, but can penetrate with attenuation due only to ordinary absorption. After penetrating a distance $Rw/\cos\theta$, it reaches a region which has been bent through w with respect to the surface, counteracting the rotation w already given to the whole crystal, so conditions are right for reflection. (Since the whole angular range for reflection is very small, the angle can be considered constant at the Bragg angle θ for purposes of geometry.) During the next w radians, A_0 is contributed by the shaded area in Fig. 1, but the beam is reduced by $\exp[-(2\mu Rw/\cos\theta)]$ in twice traversing the surface layer, where μ is the linear absorption coefficient. In this fashion, the crystal is considered made up of discrete layers, each reflecting like a perfect crystal. This proceeds until the back side of the crystal is properly oriented, or until the total distance is $t/\sin\theta$, t being the thickness of the crystal. This process can be stated as a

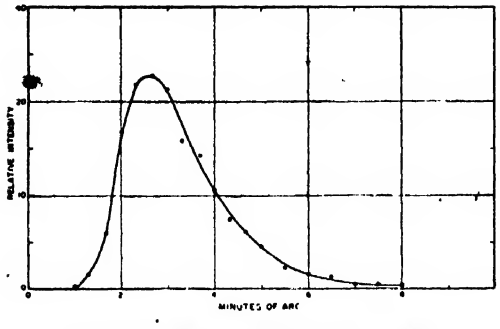

FIG. 2. Rocking curve for bent crystal.

summation,

$$B_0 = A_0 \sum_{n=0}^{\frac{t\cos\theta}{Rw\sin\theta}} \exp[-n2\mu Rw/\cos\theta],$$

$$B_0 = A_0[1-\exp(-2\mu t/\sin\theta)]/[1-\exp(-2\mu Rw/\cos\theta)].$$

It is apparent that as bending is increased, the layers described above become thinner, whereas the distance required for almost complete reflection remains fixed. In Fig. 1, the shaded area becomes deeper than a layer as bending becomes extreme. This "thin crystal" effect reduces the contribution of each layer and causes the curve of integrated intensity *versus* bending to flatten off. A statement of this effect was derived in the following way. In a thick perfect crystal, the transmitted beam is reduced exponentially, as derived by Darwin. Let us state that this is true for our crystal, and that ϵ_{ave} is the proper exponent. Thus $dI/I = -\epsilon_{ave}dl$. Let us further state that the rapid loss of energy from the transmitted

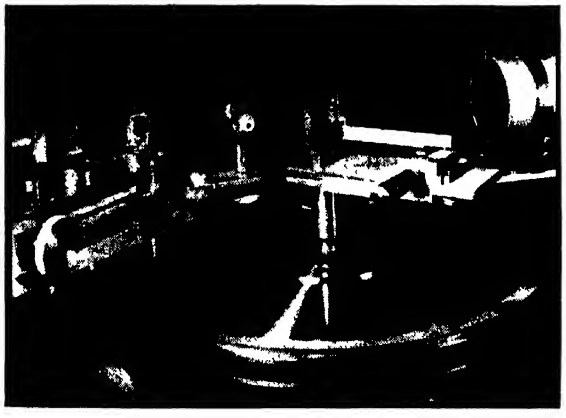

FIG. 4. Apparatus including monochromator, bent crystal, and counter.

beam is due to its transfer to the reflected beam, so that the rate of increase of the reflected beam equals the rate of loss from the transmitted beam.

$$dI_R = -dI = I_0\exp(-\epsilon_{ave}l)\epsilon_{ave}dl,$$

$$I_R = I_0\int_0^{Rw/\cos\theta} \exp(-\epsilon_{ave}l)\epsilon_{ave}dl$$

$$= I_0[1-\exp(-RW\epsilon_{ave}/\cos\theta)].$$

I_R/I_0 is the factor by which reflection is reduced when a crystal becomes thin. Hence, a complete expression for integrated intensity from a bent crystal is

$$B = A_0[1-\exp(-2\mu t/\sin\theta)] \times[1-\exp(-\epsilon_{ave}wR/\cos\theta)]/[1-\exp(-2\mu wR/\cos\theta)]. \quad (5)$$

The step-wise procedure described above would lead to a rocking curve as sketched at the bottom of Fig. 1. A

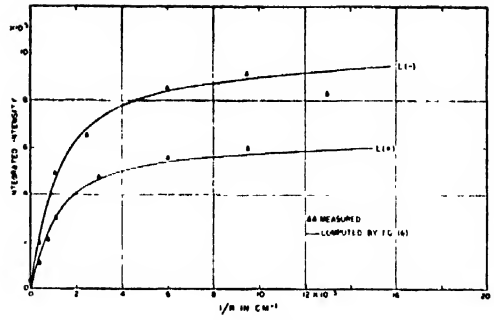

FIG. 5. Integrated intensity for 20.0 plane at 38°13′ with crystal face using Mo$K\alpha$.

highly monochromatic beam extremely limited in divergence and area gave the experimental curve in Fig. 2, which bears a strong resemblence to the shape suggested. The rocking curve obtained for no bending was narrower and symmetrical, and bending in the opposite direction gave correspondingly reversed asymmetry.

Although symmetrical Bragg reflection probably represents the most frequent usage of a crystal, it is nevertheless a special case, and it seemed desirable to work out an expression similar to the one above for diffraction by crystalline planes making an arbitrary angle with the surface of the crystal. The treatment is limited to crystalline planes which are parallel to the axis of bending. The geometry shown in Fig. 3 brings out the fact that an interchange of source and receiver changes the angle between the incident beam and the surface of the crystal. It turns out that the two cases lead to different expressions for integrated intensity, a result which may at first seem surprising. If the diffracted beam emerges on the same side of the crystal as the incident beam, corresponding to $\Theta<\theta$, it is referred to here as a Bragg reflected and designated by B. Similarly, if the beam traverses the crystal, corresponding to $\Theta>\theta$, it is called a Laue reflected and designated by L. In each case, plus and minus signs are added to differentiate the two possible angles of incidence. The steps leading to the expressions given below will not be in-

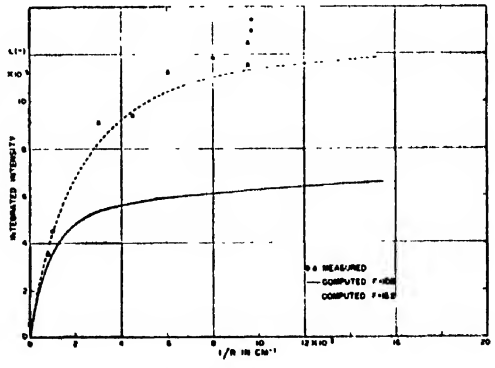

FIG. 6. Integrated intensity for 10.0 plane at 38°13′ with crystal face, using Mo$K\alpha$-radiation.

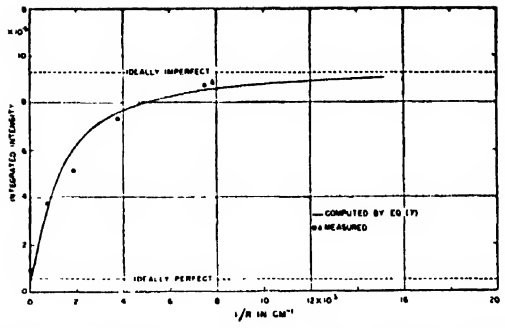

FIG. 7. Integrated intensity for 20.2 plane parallel to crystal face, using Mo$K\alpha$-radiation.

cluded, since the more involved geometry makes the derivation rather lengthy without adding anything to the viewpoint used in the simpler derivation.

$$L(\pm)=A_0\exp[-\mu t/\sin(\Theta\mp\theta)]\times\{1-\exp[\pm\mu t(\sin(\Theta+\theta)-\sin(\Theta-\theta))/\sin(\Theta+\theta)\sin(\Theta-\theta)]\}\times\{1-\exp[-\epsilon_{ave}wR/\cos\theta\cos\Theta(1+\sin^2\Theta)]\}/\{1-\exp[\pm\mu wR(\sin(\Theta+\theta)-\sin(\Theta-\theta))/\sin(\Theta\mp\theta)\cos\theta\cos\Theta(1+\sin^2\Theta)]\}. \quad (6)$$

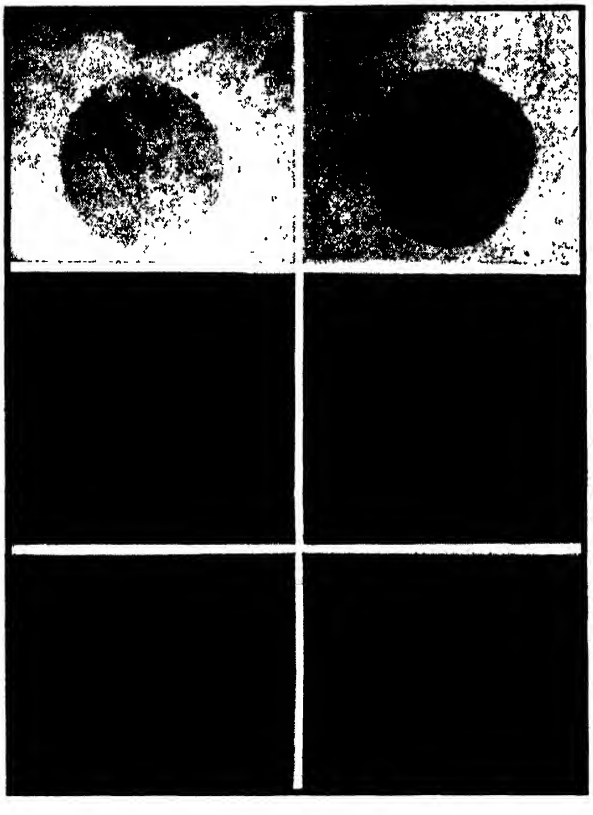

FIG. 8. Qualitative comparison of vibrating crystals (right) with the same crystals at rest (left).

$$B(\pm)=A_0\{1-\exp[-\mu t(\sin(\theta+\Theta)+\sin(\theta-\Theta))/\sin(\theta+\Theta)\sin(\theta-\Theta)]\}\{1-\exp[-\epsilon_{ave}wR/\cos\theta\cos\Theta(1+\sin^2\Theta)]\}/\{1-\exp[-\mu wR(\sin(\theta+\Theta)+\sin(\theta-\Theta))/\div\sin(\theta\pm\Theta)\cos\theta\cos\Theta(1+\sin^2\Theta)]\}. \quad (7)$$

In either case,

$$t\cos\theta\cos\Theta(1+\sin^2\Theta)/Rw\sin(\theta\pm\Theta)>5.$$

These are the expressions which have been compared with experiments on bent quartz. The assumptions made appear rather extreme. In particular, considering the contributions from different depths as a step-wise process is not justified unless there are many contributions. This means that the expressions are not applicable if the bending is too small, as indicated by the quantity following the expressions for integrated intensity. Setting this quantity to be greater than 5 rather than some other integer is arbitrary.

EXPERIMENTS WITH STATICALLY BENT QUARTZ

The apparatus for observing bent quartz is shown in Fig. 4. The beam strikes two calcite crystals set up as a double crystal spectrometer in the antiparallel position, thus achieving a wave-length spread in the final beam even narrower than the natural width of the α_1-line. A slit limits vertical divergence and beam area. The quartz slab is mounted on the axis of a precision turn-table in such a manner that motion of an ordinary micrometer at the end of a lever results primarily in a bending moment. Radius of bending computed from the lever position checked determinations by two other methods. The diffracted beam entered a Geiger tube which was mounted on a second turn-table geared to turn at twice the angular velocity of the first. Readings were taken at closely spaced angular positions by registering the number of counts in an accurately controlled minute by means of a scaling circuit. A plot of these readings, in arbitrary power units against angle in radians, constitutes a rocking curve. The power of the direct beam in the same units was measured by the Geiger tube and counter, although it was necessary to introduce a known absorption in the beam or effect a known reduction in tube output of a factor of 10 or so. The area under each rocking curve was divided by the incident power to obtain integrated intensity. Convex and concave bending were plotted together, and in agreement with the theory, have the same effect on integrated intensity. Measurements were made on two crystals with faces parallel to the 10.1 planes, and a third crystal with faces parallel to the 10.0 planes. In each case, the crystal was lapped to a thickness of about 0.05 cm and then etched for about two hours in 48 percent hydrofluoric acid. Fourteen curves were measured and computed, involving six crystallographic planes, some parallel to the crystal face and some not. Most of the curves were obtained with Mo$K\alpha_1$-radiation, the others with Cu$K\alpha$.

Agreement between computation and measurement was generally good, five of the curves being comparable with the two shown in Fig. 5. These curves illustrate the effect of interchanging source and receiver. Real discrepancies were found for all three curves involving the 10.0 plane, of which Fig. 6 is an example. The solid curve is based on the published structure factor.[4] The value of 10.8 for the 10.0 plane appears to be in error. A value of 16.3 brings computed curves into agreement with all three measured curves, and a computation based on the published structure yielded 15.2, suggesting that an error was made in the original calculation. The dashed curve is computed using 15.2 as the structure factor.

It is reasonable to suppose that the integrated intensity for any crystal lies between the value for perfection and the value resulting from such complete imperfection that extinction is of no consequence.[5] The former limit is given as Eq. (2). The integrated intensity for the ideally imperfect condition is

$$\frac{E\omega}{P_0}=\frac{N^2F^2\lambda^3e^4}{2\mu m^2c^4\sin 2\theta}\,\frac{(1+\cos^2 2\theta)}{2}. \tag{8}$$

These limits are shown as dashed lines in Fig. 7. The measured values almost cover the extreme range, and the computed curve is seen to approach a limit very near the ideally imperfect value.

EXPERIMENTS WITH VIBRATING CRYSTALS

Thin crystalline slabs of quartz and calcite were driven at frequencies of flexural resonance by means of a slender piezoelectric crystal cemented to the back faces of the slabs. The front faces were illuminated by a divergent beam of x-rays from a molybdenum target. The diffracted x-rays were observed on a film set parallel to the crystal and fairly near to the crystal. The crystal was rotated through an angular range such that each point had an opportunity to diffract the $K\alpha$-doublet. The film was mounted on an arm from a turn-table rotating at twice the angular velocity given the crystal. This procedure "scanned" the face of the crystal and gave an approximate picture. In each case, the crystals were etched before use.

Figure 8 shows three pairs of such pictures, illustrating the effect of vibration. The exposure times and photographic histories of both members of each pair are approximately the same, so the increased blackening observed is due to vibration. Other pictures of this kind pretty well established that radius of curvature is the parameter which controls this increased blackening. A more detailed description of the vibration studies is being submitted to the *Journal of the Acoustical Society of America*.

SUMMARY

The measurements given here show the increase in diffraction due to bending to be a gross effect, even a factor of 20 or more. It seems likely that this mechanism must contribute to the performance of bent crystal monochromators. The theory, although admittedly approximate, provides a means of predicting the effect of bending on various crystals whose crystal constants are known. The same procedure can be used to derive expressions for types of strain other than bending. The computed curve may also be used to compute a time average of diffracted energy when the radius is varying sinusoidally with time, as in flexural vibration.

ACKNOWLEDGMENT

The author wishes to express his appreciation for the suggestions and encouragement so generously given by Professor B. E. Warren during the course of this research and to thank Dr. W. Parrish of the Philips Laboratories for donating the quartz crystals used.

Some Effects of Nozzle Design on the Diffraction of Electrons by Gases

R. B. Harvey, F. A. Keidel, and S. H. Bauer
Department of Chemistry, Cornell University, Ithaca, New York
(Received March 20, 1950)

An evaluation has been made of some of the errors introduced into the electron diffraction of gases by failure of the sample to be localized, and by secondary and higher order scattering.

The degree to which poor nozzle design may contribute to these factors was investigated experimentally by measurements of the pressure in the camera and absorption measurements of the main electron beam when a small volume of gas was allowed to expand into the camera; and theoretically for the cumulative effects of higher order scattering on the final picture. This evidence was complemented by density measurements on photographic plates taken under similar conditions. The effect of using liquid air cooled surfaces around the nozzle was tested.

Of the nozzles tested, better "image to background" ratios were obtained with the "hydrodynamic" and "comparison" nozzles than with the "conventional" nozzle, but the gas must be admitted slowly enough so that less than about 10 percent of the main beam is appreciably scattered. The "image to background" ratios were always higher using adequate cooling on the condensing surfaces surrounding the nozzle. In the case of pressure and electron beam absorption measurements short exposures were advantageous, where secondary scattering was not directly considered, and high camera pumping speeds were always advantageous.

On the basis of these results some general design suggestions for electron diffraction cameras, and requirements for good efficiency in nozzles can be made. A nozzle design is proposed which would reduce materially the errors normally encountered in electron diffraction work.

INTRODUCTION

WHEN a stream of high velocity electrons is scattered by a gaseous sample, the intensity of the scattered radiation may be written:[1]

$$I_s = J_0\left[\frac{8\pi^2 me^2}{h^2}\right]^2 \frac{N}{R^2 s^4}[\text{atomic contribution} + \text{molecular contribution}], \quad (1)$$

where I_s can be defined in terms of the number of electrons crossing unit area per unit time at the focal plane of the diffracted ray; J_0 is the total intensity in the primary beam; N is the total number of molecules intercepted by the beam per unit beam area; $s=(4\pi/\lambda)\times\sin(\theta/2)$ where λ is the electron equivalent wavelength and θ is the angle between the primary and scattered rays; R is the distance from the sample to the focal plane; and $8\pi^2me^2/h^2=2/A_H$ where A_H is the "radius" of the hydrogen atom, and m, e, and h are universal constants. The "atomic contribution" factor is dependent only on the scattering functions of the individual atoms of the molecule, and so accounts for the structure independent contribution to the total scattered intensity, whereas the "molecular contribution" factor is in addition dependent on the interatomic distances in the molecule and so accounts for the structure dependent contribution to the scattered intensity.

The following are some of the assumptions made in the derivation of the above equation:

(1) The N molecules scatter independently with no mutual phase relations. This is satisfied for a gaseous sample.

(2) The sample is of infinitesimal thickness; diffraction occurs at one value of R only. This is practically never true for a gaseous sample.

(3) There is no secondary or multiple scattering (i.e., no scattered electrons are rescattered) in the sample region or in the space between the sample and the detector. This is generally not true for diffraction by a gaseous or a solid sample.

(4) The diffracted beam is perfectly focused at the plane of the detector. This is only approximately true.

A theoretical discussion of the errors which result when these assumptions are invalid appeared in a report[2] written for the Office of Naval Research.

The effects of various gas distributions about the point of gas injection were treated from the standpoint of image resolution, and it was found that indeed a loss of resolution was experienced, the loss becoming increasingly serious with large scattering angles, particularly for the high frequency terms. With regard to the use of a beam trap close to the nozzle to remove the main beam and to reduce the observed scattered intensity at small angles preferentially, so that the density range of the photograph may be reduced and excessive halation prevented, it was found that the positions of the inner maxima and minima of the pattern were not only subject to a similar loss of resolution but also to some lateral shifting of their positions. Experimentally it is also found that the use of a beam trap close to the nozzle leads to further difficulties insofar as edge scattering contributes appreciably to the general background.

A mathematical analysis of multiple scattering within the nozzle indicated that secondary scattering expressed as the ratio of [gain in background/loss in diffracted intensity] is dependent on the diffracting angle, although the fractional loss of any diffracted ray is probably independent of angle. The extent of multiple scattering was found to be independent of the sample distribution along the direction of the electron

beam but to be proportional to the sample density at the point of diffraction.

The treatment of the last assumption, that pertaining to the effects of imperfect focusing at the plane of the detector, showed that although there was no appreciable shifting of the peaks or valleys of the intensity curves, there was a loss of resolution (the ratio of observed peak heights to the theoretical peak heights was less than 1), and this loss increased with increasing distance for any atomic pair. A slight additional loss in resolution which has angular dependence is also introduced by the use of a flat detector (e.g., a photographic plate) instead of one curved to fit the focal circle.

Although Eq. (1) has been checked quantitatively, within rather broad limits of experimental error,[3] the cumulative effects of all of the specific errors listed above must be carefully evaluated before one may determine precisely the structures of molecules which must be formulated in terms of more than two structural parameters.

The extent of invalidity of assumptions two and three is particularly influenced by nozzle design. It is from this viewpoint that the subject of nozzle design is discussed in the present paper. Some aspects of this study also appeared in the previously mentioned ONR report.[2]

NOZZLE EFFICIENCY DEFINITIONS

Experimentally, in order to obtain a gas diffraction pattern, a jet or stream of gas is allowed to intercept the electron beam. It is therefore apparent that the distance along which electrons are scattered cannot be smaller than that dimension of the gas exit which is parallel to the direction of the electron beam. Actually the gas never leaves the nozzle in a perfectly collimated beam but rather tends to diffuse throughout the camera. Thus, contrary to assumption (2), one obtains, in practice, a superposition of patterns originating at various distances R, rather than a single pattern originating only at R_0, the distance of the nozzle axis to the plane of the detector. Maximum resolution will be obtained only if the spread in R over which appreciable scattering takes place is as small as possible, i.e., when the function $N(R)$ is negligibly small except in the vicinity of R_0. However, a nozzle having a thin slit perpendicular to the electron beam will not be satisfactory in this respect because the issuing gas stream is then poorly collimated. In any case, an estimate of the amount of extraneous scattering could be obtained if the distribution of the gas in the camera could be plotted. It appeared reasonable that if the gas stream intersecting the electron beam directly over the nozzle gave rise to the principal diffraction pattern, then this might be called "useful diffraction," while the gas existing throughout the camera volume would give rise to many overlapping patterns, thus constituting a background, and this diffraction might be termed "harmful." One measure of the ratio of the "useful diffraction" to the total diffraction is then

$$E_p(t)=\frac{Q_{\text{nozzle}}}{Q_{\text{nozzle}}+Q_{\text{camera}}},$$

where Q_{nozzle} is the fraction of the total available sample that is in the electron beam directly over the nozzle, averaged up to time t; and Q_{camera} is the fraction of the total available sample that is in the rest of the electron beam (considered as a cylinder) averaged up to time t. One sees from reference to Fig. 1 that the ratio of the "useful diffraction" to the total diffraction is actually equal to

$$\frac{C_1+C_3}{C_1+C_2+C_3+C_4},$$

where C_n is the relative contribution of process n in Fig. 1, to the total intensity. Therefore a high efficiency $E_p(t)$ indicates that relatively little extension of the sample occurs beyond the dimensions of the nozzle and hence that the loss of resolution due to sample extension alone is small, regardless of how much resolution is lost as a result of multiple scattering (process 3).

We shall also discuss another measurement of efficiency:

$$E_{ab}(t)=\frac{C_1+C_3+C_4}{C_1+C_2+C_3+C_4},$$

which may be estimated from data on the absorption of the main electron beam. Values of $E_{ab}(t)$ should agree fairly well with corresponding values of $E_p(t)$ because process 4 contributes only slightly to the total scattered intensity. It is convenient to distinguish (2a), that part of process 2 taking place inside the chimneys surrounding the nozzle from (2b), that part taking place outside the chimneys. Then, if no liquid air cooling is used, we may write:

$$E_{ab}\text{ (no liquid air)}=\frac{C_1+C_3+C_4}{C_1+C_{2a}+C_{2b}+C_3+C_4},$$

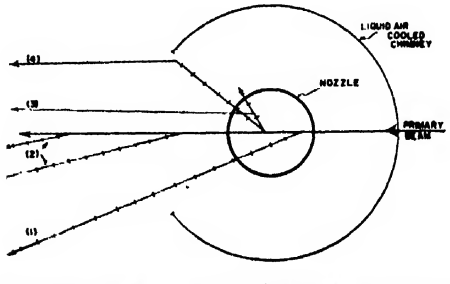

FIG. 1. Schematic representation of various scattering processes (1) Primary diffracted ray—within nozzle. (2) Primary diffracted ray—outside nozzle. (3) Secondary diffracted ray—within nozzle. (4) Secondary diffracted ray—outside nozzle.

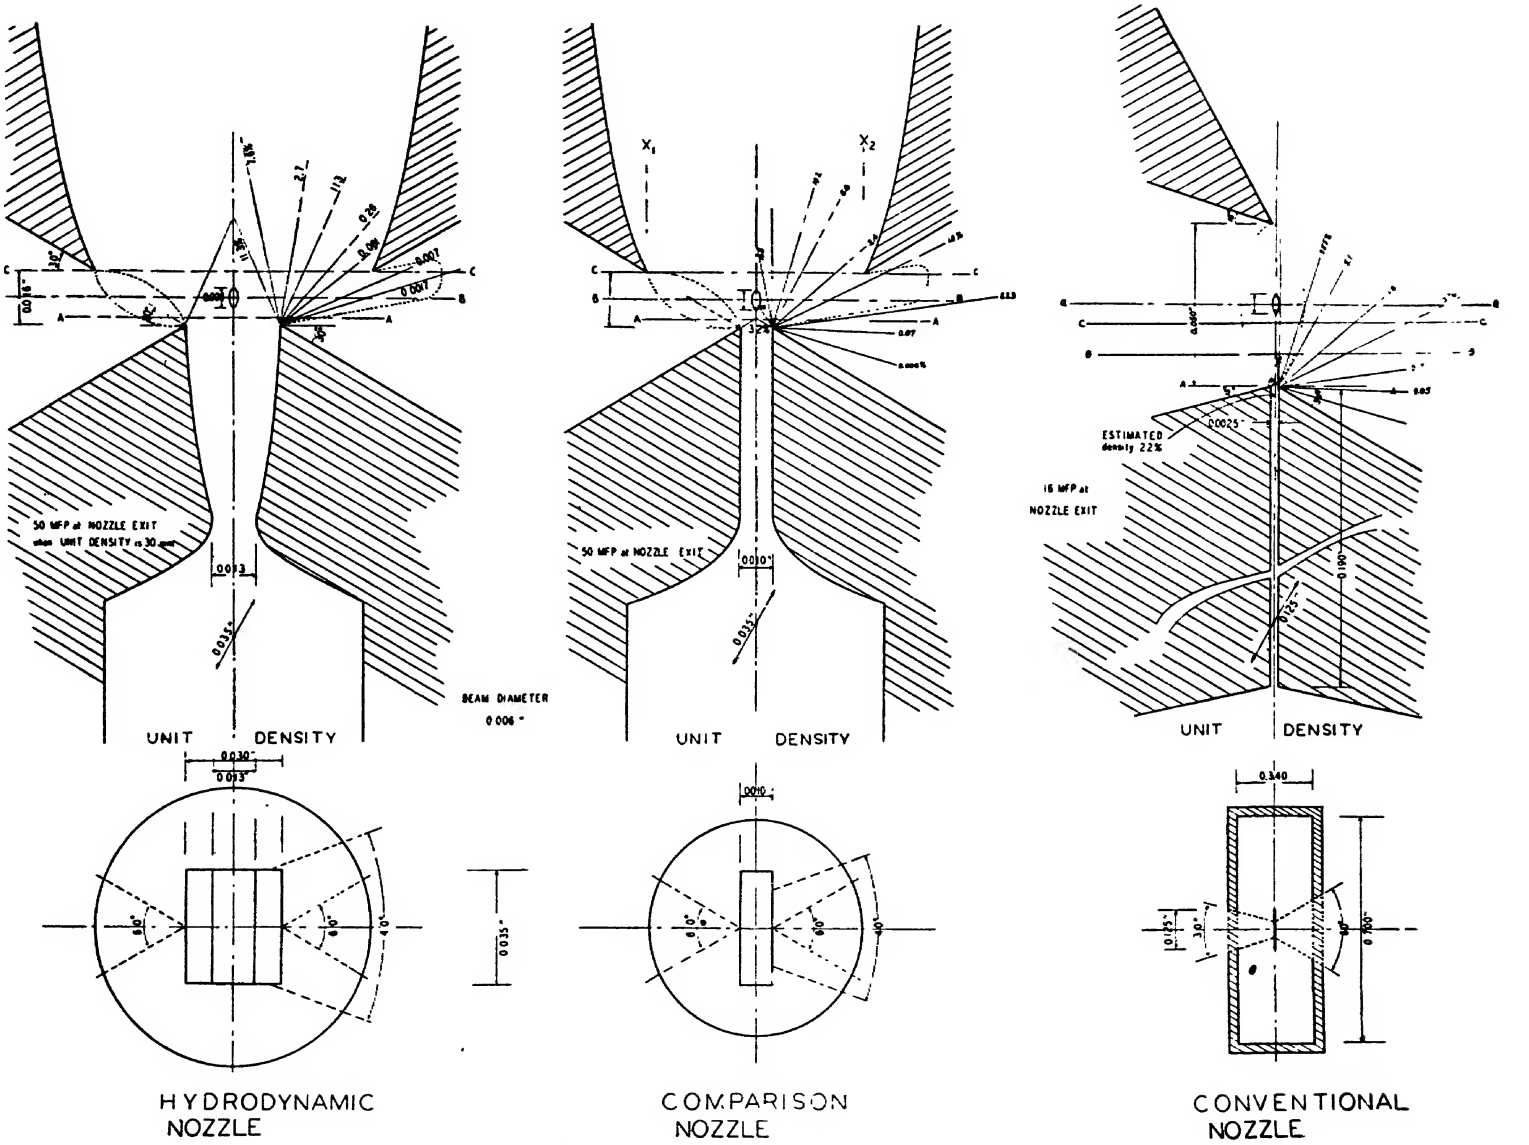

FIG. 2. Vertical and cross sections. Rectangular nozzles designed for two-dimensional flow. The computed isodensity lines just above the exits are given in percentages of the density present in the reservoir. The circle 0.006" diameter shows the position and relative dimension of the electron beam. The electrons proceed from left to right in the figures. The scale for the cross section of 2c is smaller than that of the other figures.

whereas, if liquid air cooling is used, process C_{2b} becomes negligible, and

$$E_{ab}{}^{la}=\frac{C_1+C_3+C_4}{C_1+C_{2a}+C_3+C_4}.$$

The beam absorption data mentioned above are probably more valuable as a means of obtaining an estimate of the extent of multiple scattering relative to the total scattered intensity, once the theoretical relation between these quantities has been established.

From the above discussion it is apparent that an estimate of the merit of a nozzle with respect to sample distribution alone or to multiple scattering alone can be obtained for any specified set of operating conditions as functions of time.

Before these measurements are discussed in detail, it is well to point out that a third definition of efficiency as a function of s, can be obtained from photographic data. This is

$$E_s=\frac{(C_1)_r+(C_3)_r+(C_4)_r}{(C_1)_r+(C_2)_r+(C_3)_r+(C_4)_r},$$

where $(C_n)_r$ is the amount of C_n, integrated over the time of exposure, appearing per unit area on the photographic plate at that radial distance r which corresponds to s for an ideal sample.

DESCRIPTION OF NOZZLES

The manner in which gas flows into the electron diffraction camera depends on the design of the nozzle. In these experiments the three nozzles illustrated in Fig. 2 were tested. First is the so-called "hydrodynamic" nozzle designed by Dr. A. Kantrowitz, of the Graduate School of Aeronautical Engineering of Cornell, to have supersonic flow; the second is referred to as the "comparison" nozzle and has throat dimensions similar to those of the hydrodynamic nozzle but a parallel walled flow channel; the third is the "conventional" nozzle which also has a parallel walled flow channel of about the same cross-sectional area as that of the comparison nozzle but with ratio of width perpendicular to the electron beam to length parallel to the electron beam equal to about 50.

In Fig. 3 is shown the computed gas density destribution across the mouth of the nozzles at three distances from the outlet, *A–A*, *B–B*, and *C–C*. For the conventional nozzle a further line was computed along *Q–Q*. These graphs show the degree of spreading of the gas from the nozzle mouth, and it is clear that the hydrodynamic nozzle tends to give the best directed flow of gas while the conventional nozzle acts more as a source of gas effusion. In some experiments to be described later a *constriction* was placed in the entrance to the *comparison* nozzle, so that the rate of gas flow was reduced and was more along the order of the conventional nozzle.

It is reasonable to expect that little gas should escape from the side ports (through which the electron beam passes) of the hydrodynamic nozzle, but more from the comparison nozzle, and a relatively large amount from the conventional nozzle. This is really a question of the components of molecular velocity perpendicular to the direction of the electron flow. By measuring the flow rates for the three nozzles under similar conditions, and comparing the observed rates with those calculated from flow formulas, we obtained a rough estimate of the pressure drop along the nozzle. Comparison of the estimated pressure drop with that obtained from the inlet and outlet pressures used in the experiments, gave a measure of the number of molecular collisions on the side walls, as the gas proceeds along the nozzle and thus an estimate of the components of velocity perpendicular to the nozzle axis.

It was shown that the hydrodynamic nozzle had virtually no pressure drop along its length; and only about 5 percent of the applied pressure differential

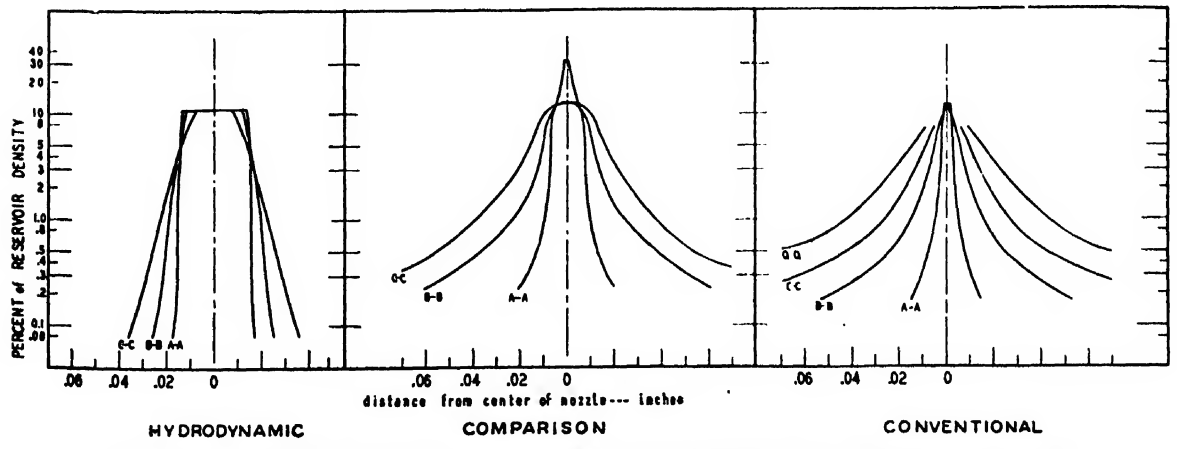

FIG. 3. Computed densities along the ray lines *A–A*, etc. The values for Fig. 2a are reliable; those for 2b are approximate; those for 2c are little better than guesses.

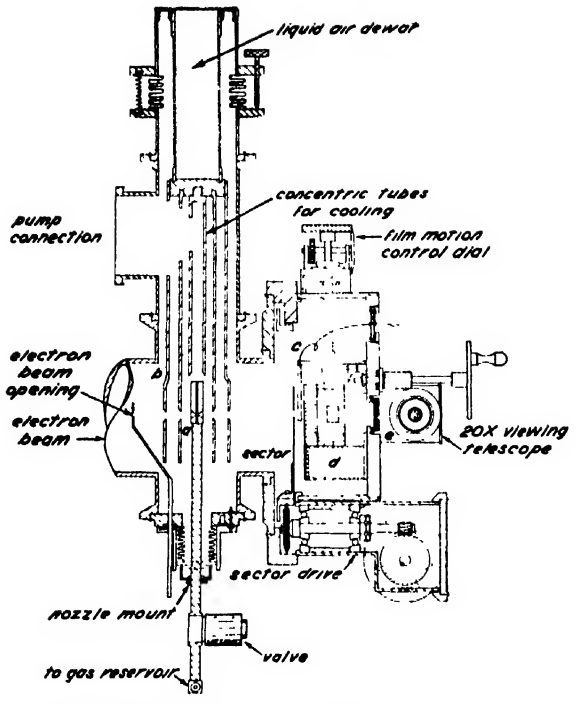

FIG. 4. Side view of electron diffraction apparatus, showing nozzle mount (a), concentric tubes for cooling and condensing the sample (b), pump connection, roll film camera, and sector drive. (c) is a Faraday cage connected to a d.c. amplifier for electron beam control; (d) is a tube carrying a fluorescent screen which is pushed down as the film frame is set in place—the screen remains coplanar to the film; (e) is a short range telescope for viewing the focused spot when the fluorescent screen is in the central position.

was taken up along the walls in the case of the comparison nozzle. Hence the gas exits from the nozzle mouth at a density close to that present at the inlet, and most of the pressure differential is dispersed in the region beyond the nozzle. For the conventional nozzle, one-third to one-half of the applied pressure differential was taken up along the nozzle channel and so the gas must leave the nozzle with comparatively large velocity components perpendicular to the direction of flow. The question may be raised as to what fraction of the gas stream intercepts the electron beam as it fans out from the mouth of the nozzle. It can be shown that under usual operating conditions, most of the gas passes through the beam although with the conventional nozzle the molecules on the average remain in the beam longer so that if comparable gas densities in the diffraction region and exposure times were used for the three nozzles, the observed photographic density would be highest with the conventional nozzle but so would the relative extent of multiple scattering and sample diffusion.

Figure 4 shows a cross-sectional view of the nozzle as placed in the camera. Three concentric chimneys which surround the nozzle can be cooled by filling the metal dewar with liquid air. They also serve to lead the injected gas directly away from the nozzle to the diffusion pump.

THE CALCULATION OF E_p AND THE EFFECTS OF SAMPLE DIFFUSION ON RESOLUTION

The equation for the rate of pressure decrement due to flow of gas at pressure P_s from a volume V_s through a nozzle, into a volume V_c at pressure P_c, may be written

$$-\frac{dP_s}{dt}=\frac{kAu}{V_s}(P_s-P_c)=j(P_s-P_c),$$

where A = area of opening in nozzle, u = velocity of sound, k = flow constant for nozzle, $j=kAu/V_s$. If the volume V_c represents an electron diffraction camera being pumped out at a rate proportional to the pressure P_c, we also must have

$$\frac{dP_c}{dt}=\frac{V_s}{V_c}j(P_s-P_c)-lP_c,$$

where l is a constant depending on the speed of the evacuating pumps. Solution of the above system of differential equations leads to the result

$$P_c=2\frac{mP_0}{b}\left[\exp\left(-\frac{m+l+j+b}{2}t\right)-\exp\left(-\frac{m+l+j-b}{2}t\right)\right],$$

where $m=jV_s/V_c$, $b=((m+l+j)^2-4lj)^{\frac{1}{2}}$, and P_0 is the value of P_s at $t=0$. For the case where V_c/V_s and j/l are much larger than one, this expression may be approximated by

$$P_c=(P_0V_s/V_c)(1-e^{-jt})e^{-lt}. \tag{2}$$

This result is the one which is used in the following considerations.

Since the factor $(1-e^{-jt})$ in the above expression represents the fraction of the gas originally in V_s that has passed through the nozzle in time t, the value of Q_{nozzle} in the expression for E_p may be written

$$Q_{\text{nozzle}}=(1-e^{-jt})(2r/W_n)(\pi r/2\mu),$$

where $(\pi r/2\mu)$ is the average time spent by molecules in traversing an electron beam of radius r, when their average component of velocity perpendicular to the beam is μ, while W_n is the width of the nozzle opening.

$$Q_{\text{camera}}=(\pi r^2R/V_c)Z,$$

where R is the electron beam path length through the camera and

$$Z=\int_0^t(1-e^{-jt})e^{-lt}dt.$$

Hence

$$E_p = \frac{(1-e^{-jt})(2r/W_n)(\pi r/2\mu)}{(1-e^{-jt})(2r/W_n)(\pi r/2\mu)+(\pi r^2 R/V_c)Z}. \quad (3)$$

Aside from apparatus constants our equations require the evaluation of the exponential constants "j" and "l." j is a function of the flow rate through the nozzle and l is a function of the rate of evacuation of the camera; hence two sets of measurements were required. To determine j a large fixed volume of gas was allowed to expand through the nozzle into a vacuum, and the pressure of the volume was recorded as a function of time. From the formula $ln(P_2/P_1) = -j(t_2-t_1)$ we get $j=[-ln(\frac{1}{2})]/t_{\frac{1}{2}}$, wherein $t_{\frac{1}{2}}$ is the time at which $P_2=\frac{1}{2}P_1$.

The determination of l was a little more complex, and to do this an ionization gauge was connected to the electron diffraction camera. The output of the ion gauge was fed to a d.c. amplifier and a permanent record obtained with a Brush recording oscillograph. The variation of pressure with time which was thus obtained is shown in Fig. 5 for a typical case. The sharp rise is characteristic of the factor $(1-e^{-jt})$ and the exponential decrease is due to the (e^{-lt}) factor. The value of l can be determined from the curve since the camera pressure at any time is given by $P=(P_0V_s/V_c) \times(1-e^{-jt})(e^{-lt})$. The calculation of all the constants in the efficiency equation is now straightforward and efficiency can be calculated as a function of time.

Pressure measurements were made under two sets of conditions. By means of the cooling chimneys (Fig. 4) we can condense out most gases before they can diffuse throughout the camera. The curves in Fig. 5a are for the case of the chimneys at room temperature, while those in Fig. 5b are for the chimneys cooled with liquid air. The pressure scale is compressed by a factor of about 5, and the time scale by a factor of about 10 in the latter. Efficiencies were calculated as a function of time, with and without the use of liquid air cooling, and the results plotted in Fig. 6. The following may be pointed out:

(a) E_p begins at 100 percent for $t=0$, and drops for increasing t.

(b) The E_p of a nozzle without adequate liquid air cooling is less than that for a nozzle with adequately cooled condensing surfaces around it.

(c) The comparison nozzle shows the greatest E_p of the three for no liquid air cooling—probably due to the fact that the molecules remain in the beam a longer time than in the case of the supersonic nozzle.

(d) The conventional nozzle is least efficient up to 0.6 second regardless of conditions.

(e) It would follow from the efficiency equations that a high pumping rate would favor higher efficiencies. Liquid air cooled surfaces fulfill this requirement to a substantial extent for most gases. Similarly a *small* camera volume would be desirable, or else one so large that the injection of a gas sample would not raise the pressure appreciably in the camera.

The appearance of electron diffraction photographs was correlated theoretically to the value of the efficiency E_p by comparison of the integrated background intensity (atomic contribution) and of the molecular contribution for an extended sample with the corresponding quantities expected from an infinitesimally thin sample. It was found that when no beam trap is inserted close to the principal region of diffraction, and the sector is placed at the plane of the detector, little departure from unit background is introduced (<2 percent) if the sample is relatively concentrated, as in (a), (c), and (d), Fig. 7. However, for a uniformly distributed sample (Fig. 7, curve *e*), the density at small s is 15–20 percent higher than at large s. The computed effect on the molecular terms due to diffusion of the sample is quite marked. Inspection of the curves in Fig. 8a, b, c will show that due to the overlapping of patterns arising at different sample-detector distances (process 2, Fig. 1) the high frequency terms are more readily damped at large "s" than are the lower frequency contributions. As a consequence the unwary investigator will be led to assign too large temperature factors to the long inter-atomic distances. The above integrations were carried out graphically.

THE CALCULATION OF E_{ab} AND THE EFFECTS OF SECONDARY DIFFRACTION ON RESOLUTION

An estimate of E_{ab} was obtained from measurements of the loss of current in the main electron beam after

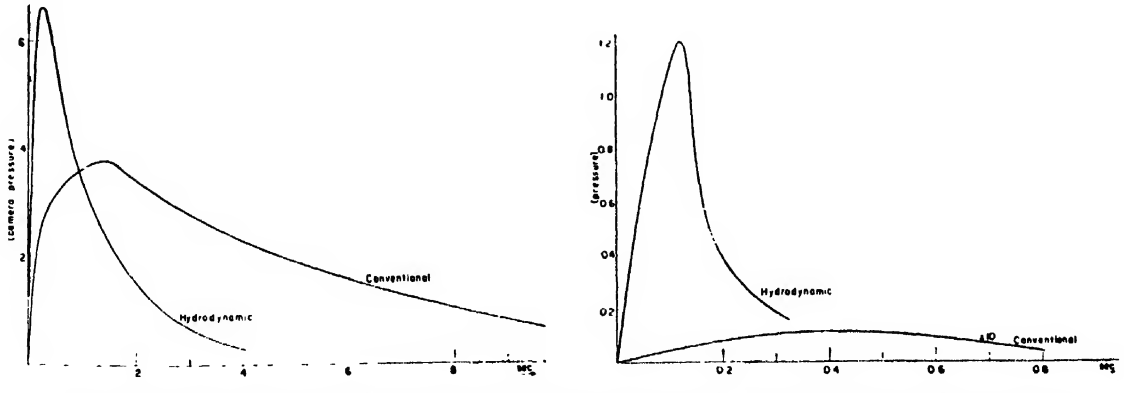

FIG. 5. Pressure transients in the camera. (a) Chimneys at room temperature; (b) Liquid air-cooled chimneys.

it had passed through an injected gas sample under the following set of arrangements:

(a) The main beam was allowed to pass through the nozzle, with the surrounding chimneys at room temperature. Absorption of the beam is by processes 1, 2, 3, and 4.

(b) The nozzle was tilted so that the main beam passed beside it; the nozzle surroundings remained at room temperature. Absorption is by process 2.

(c) The main beam was allowed to pass through the nozzle but the surrounding chimneys were liquid air-cooled. This measures absorption by processes 1, 3, 4, and that part of 2 between nozzle and condensing surfaces (process 2_a).

(d) The main beam was allowed to bypass the nozzle as in (b) but the surrounding surfaces were cooled. Absorption of the beam is by diffraction between the nozzle and the condensing surfaces (process 2_a).

On the basis of measurements such as these one can compute E_{ab} as the ratio of diffraction over the nozzle to the total diffraction at any time during which the sample is in the camera.

The absorption measurements were made with the aid of a d.c. amplifier and Brush recording oscillograph connected to a collecting electrode (cup) of five millimeter diameter placed in the path of the main electron beam at a distance of 19 cm from the nozzle. In Fig. 9b a typical curve of the variation of the main beam current with time is shown for the cases cited above. In curve 1 we have the case of maximum absorption followed by a fairly rapid decay. Case (2) has a much smaller maximum, but it is shifted appreciably to the right indicating, possibly, that gas diffusion around the condensing surfaces and through the camera is a comparatively slow process. Case (3) shows a very sharp rise and rapid decay, for the diffraction taking place over the nozzle. Case (4) failed to give any measurable change in beam current which indicates that absorption of the beam by ambient gas within the cooled condensing surfaces was so small that it was not detected by our instrument. Figure 9a shows a curve of efficiency calculated from the absorption curves.

A fairly good comparison of the nozzles is obtained by quoting $t_{\frac{1}{2}}$ values, i.e., the time for the maximum of the curve to be reduced by 50 percent. See Table I.

In Table II are given the percentages absorption of the beam for the case of three nozzles under various experimental conditions. The values are those of maximum absorption, and the times for maximum values to be reached are also quoted.

The comparison and hydrodynamic nozzles are closely similar and both are more effective on the basis of E_{ab} values than a nozzle of slow gas admittance. If one computes the ratio [diffraction over the nozzle/diffraction elsewhere in the camera] one finds a value of 12 to 13 for the comparison and hydrodynamic nozzles and only about 1.5 for slow gas admittance. With liquid air cooling, the absorption in the camera was not measurable on our apparatus and the E_{ab} values were close to unity in all cases.

It must be pointed out that slower gas flow rates mean lesser absorption of the main beam and as a result less multiple scattering.

In order to use the absorption measurements as a means of estimating the extent of multiple scattering, the following relation, derived in Appendix C, may be used:

$$J_2/J_1=1+[(J_0/J_1)-1]\ln[1-(J_1/J_0)], \qquad (4)$$

where J_0 is the total intensity of the incident main beam, J_1 is the total intensity of scattered radiation, and J_2 is the total intensity of electrons which have been scattered more than once. For values of J_1/J_0 up to about 0.2, J_2/J_1 is fairly well approximated by $0.5\ J_1/J_0$; for J_1/J_0 equal to 0.3 and 0.5, J_2/J_1 equals $0.56\ J_1/J_0$ and $0.61\ J_1/J_0$, respectively. Since J_1/J_0 is measured directly in the absorption experiments, we

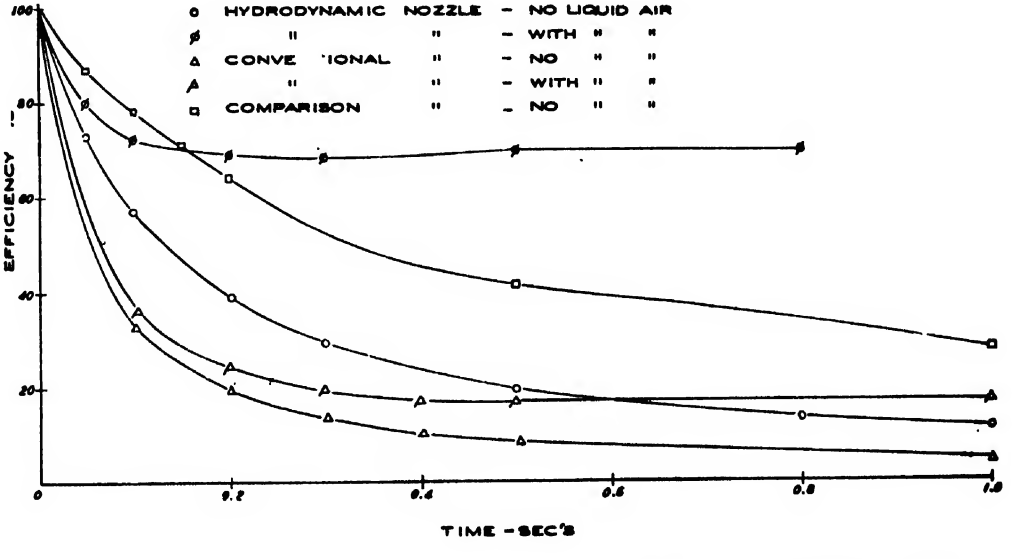

FIG. 6. Nozzle efficiencies (E_p) as a function of the time.

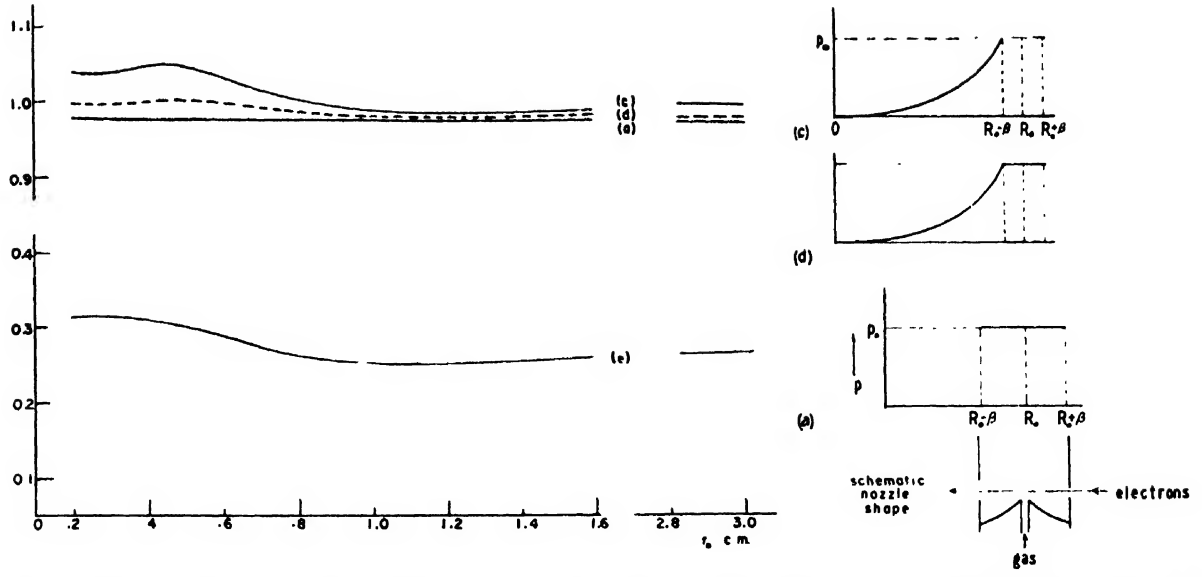

FIG. 7. Relative background intensity curves, for an extended sample compared to that for a sample of the same size concentrated at R_0. The sector is at the plane of the detector, and no beam trap is interposed. The curves correspond to the pressure distributions indicated below, with $R_0=19.33$ cm. $\beta=0.475$ cm. $p=[(p_0\beta^2)/(R_0-R)^2]$ for $R\leqslant(R_0-\beta)$. r_0 is distance along the plate. Curve (*e*) is for a uniform pressure distribution throughout the camera.

have a very simple way of estimating the relative extent of multiple scattering.

For rapid gas admittance (hydrodynamic nozzle), as much as 30 percent of the incident main beam may be absorbed. This means that J_1/J_0 equals 0.30 and hence that the ratio of the amount of multiple scattering to total scattering equals 0.56 times 0.30, or 0.17. For the case of slow gas admittance where the maximum beam absorption may be only 2 percent; we find then that J_2/J_1 equals 0.50 times J_1/J_0, i.e., 0.01, so that the relative extent of multiple scattering has been reduced by a factor of 17 as compared with the case of rapid gas admittance.

In order to correlate these results with the observed appearance of electron diffraction photographs, we must estimate the ratio of the loss of intensity, (I^*-I), resulting from multiple scattering in a ray reaching a particular point on the plane of the detector, to the gain, I_n, of background intensity resulting from the contribution at this point of intensity rescattered from all other rays. In formulating the integrals for this additional background it soon became clear that the general case is very involved; hence we have simplified the discussion by not considering the dependence of the result on the degree of sample extension in the direction of the electron beam. Thus it is assumed that the sample is restricted to a region $(R_0+\beta)$ to $(R_0-\beta)$ directly over the nozzle, and that $\beta/R_0\ll1$ so that rays diffracted at an angle θ originating in any part of the sample all arrive on the plane of the detector at essentially one distance from the central beam. It was also assumed that the gas density is sufficiently low that all of the multiple scattering may be considered to be secondary scattering and that the intensity of the main beam may be considered constant while passing through the sample. Finally, it was found convenient to approximate the variable "s" by $2\pi r/(\lambda R_0)$ where $r/R_0=\tan\theta$. The particular molecule used as an example was carbon tetrachloride, and for it the following empirical relation was fitted:

$$\text{(Atomic contribution + molecular contribution)}\times(2\pi/\lambda R_0)^4 1/s^4=\frac{4280}{(s^2+22)^2}+\frac{310}{(s^2+0.6)^2}. \quad (5)$$

The values of $I_n/(I^*-I)$ which result from these calculations are plotted in Fig. 10. It is apparent that the background intensity is decreased at small s and increased at large s as a result of secondary scattering. It may be demonstrated that the *fractional loss* is independent of s (Appendix A).

To consider a definite example, suppose that the measured absorption of the beam is 20 percent, so that the ratio of the amount of multiple scattering to total scattering is 0.1. Then, assuming for simplicity that at some value of s, say $s=8$, the background intensity I^* that would be obtained if there were no multiple scattering is equal to one, the actual contribution, I, from electrons scattered only once will be $(1.0-0.1)=0.9$, while the contribution I_n resulting from multiple scattering of all other rays will be roughly $2(I^*-I)=0.2$. Hence the total background intensity will be $0.9+0.2=1.1$. Therefore if the ratio [(molecular contribution)/(atomic contribution)] is equal to x under conditions where no multiple scattering occurred, it

will only be equal to $(0.9/1.1)x$ under the actual conditions stated. Indeed, the value will be even less than this because we have not taken into account the fact that rescattering of the molecular contribution will result in a preferential addition of intensity to the valleys of the molecular contribution curve.

Because the background contribution to the total intensity is large compared to the molecular contribution for large values of s even in the ideal case, it is obvious that every effort should be made to reduce the extension, it is apparent that whether the observed background happens to be too high, flat, or too low for small s depends on the balancing of two opposing factors; extension of the sample tends to raise the background (Fig. 7, e) while secondary scattering tends to lower it (Fig. 10). It is quite clear why some observers who failed to consider these complications in nozzle design were misled by the extraneous backgrounds into believing that the atom form factors are necessarily incorrect.

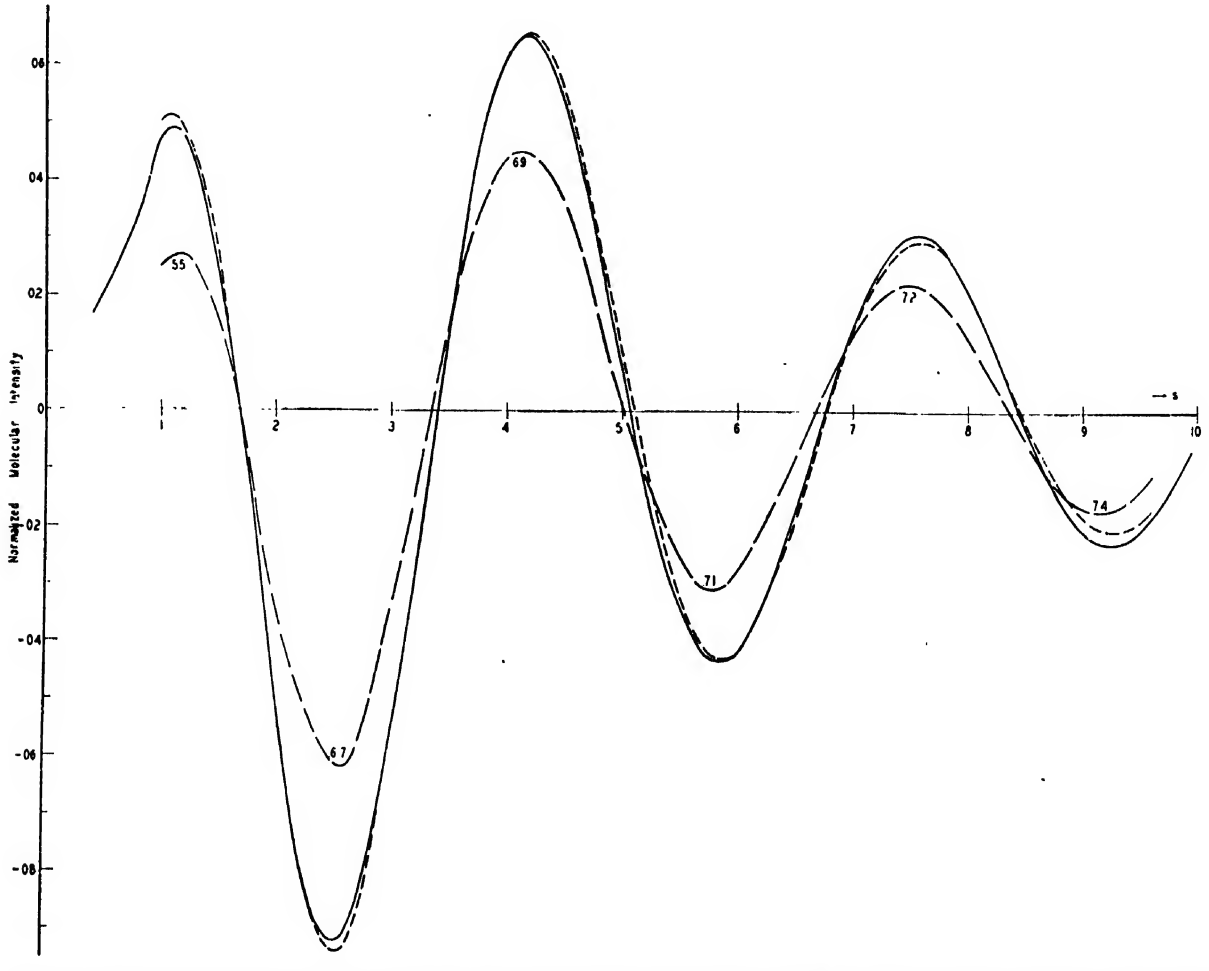

FIG. 8a. Molecular intensity curves for an extended sample using the B–B term of B_2H_6, utilizing a sector and beam trap. Curve Inf. is for an infinitesimally thin sample at $R_0=19.33$ cm; $\lambda=0.06359A°$. $2f_{B^2}e^{-.00415s^2}\times(\sin 1.86s)/1.86s$. In curve a we assumed that the pressure distribution was uniform, extending from $(R_0+\beta)$ to $(R_0-\beta)$, and zero everywhere else. $\beta=0.475$ cm. In curve b the pressure distribution was assumed to be uniform, and to extend from R_0 to $(R_0-\beta)$; i.e., an unsymmetrical nozzle. Note the effect of the beam stop on the positions of the maxima and minima, and on their relative intensities. The numbers on this curve indicate the fractional intensities of the corresponding peaks compared to curve Inf. [The broken line curve should be designated a above the abscissa and b, below. The solid line curve should be marked Inf.]

beam absorption in the nozzle to a low value. To do this requires of course that the sample density be decreased and that the exposure times be correspondingly lengthened to an extent consistent with the limitations imposed by stability of the electron gun, high voltage, pumping rates, etc.

Also, from these results and the ones for finite sample

PHOTOGRAPHIC EVIDENCE OF LOSS OF RESOLUTION

A series of photographic records (i.e., actual electron diffraction pictures) was made using cooled condensing surfaces in some exposures and none in others, and tilting the nozzle so that diffraction by gas in the camera could be measured. We can thereby define an

efficiency, E_s. If the photographic plate is read with a microphotometer and a record obtained, a line can be drawn through the fluctuations of the curve in such a way as to represent the background. Comparison of this background when the beam passes through the nozzle (case of normal diffraction procedure) to the background when the nozzle is tilted and the beam passes through the gas in the camera only, gives

$$E_s=\frac{D_{\text{nozzle}}}{D_{\text{nozzle}}+D_{\text{camera}}}=\frac{(C_1)_r+(C_3)_r+(C_4)_r}{(C_1)_r+(C_2)_r+(C_3)_r+(C_4)_r}.$$

E_s values can be determined for the case of liquid air cooled surfaces around the nozzle and for the surfaces at room temperature. The measurements were made on Eastman Commercial plates when no sector was used, and on Eastman Microfile when a sector was used. Sensitometric curves were determined on both of these emulsions so that the photographic densities could be converted to electron intensities. The photographic densities were measured with a Leeds and Northrup recording microphotometer. CCl_4 vapor was used as a condensable gas throughout the experiments.

E_s values are plotted in Fig. 11 for the hydrodynamic nozzle and for the comparison nozzle with a constriction so that the gas entered slowly. The hydrodynamic nozzle with the surrounding chimneys at room temperature allows a considerable amount of gas to diffuse through the camera so that the efficiency is considerably less than 100 percent. The observed dropping off of the efficiency with decreasing s should be expected because of the fact that the background contributed by that portion of the sample which has diffused through the camera falls off more rapidly with s than that contributed by an ideal sample, and because of the fact that multiple scattering in the dense gas directly over the nozzle lowers the background contributed by it at small s values. Therefore from the standpoint of this latter factor, the apparent increase in efficiency with s is actually an indication that resolution is *reduced* at large s values. With liquid air cooling the efficiency remains at about 99 percent irrespective of the angle of diffraction; this indicates that the liquid air-cooled shields effectively remove the diffracted gas but implies nothing about the seriousness of multiple scattering. It is interesting to note that the nozzle of slow gas admittance (comparison nozzle plus constriction) gives better E_s values than the hydrodynamic nozzle. This may be a result of more efficient operation of the evacuation pumps when the pressure in the camera is kept low, as will be the case if the gas is injected into the camera slowly. With the chimneys liquid air-cooled, efficiencies of about 99 percent were again obtained for slow gas admittance.

The actual resolution for the diffraction patterns can be determined by reading the height of the peaks above the valleys in ratio to the background and comparing this to the theoretical ratio of peak height to background. These figures give us, then, the loss on intensity of the peaks and gain of intensity of the background. That secondary scattering and diffraction by an extended sample do lead to a loss in resolution can be demonstrated in the following simple way. Suppose

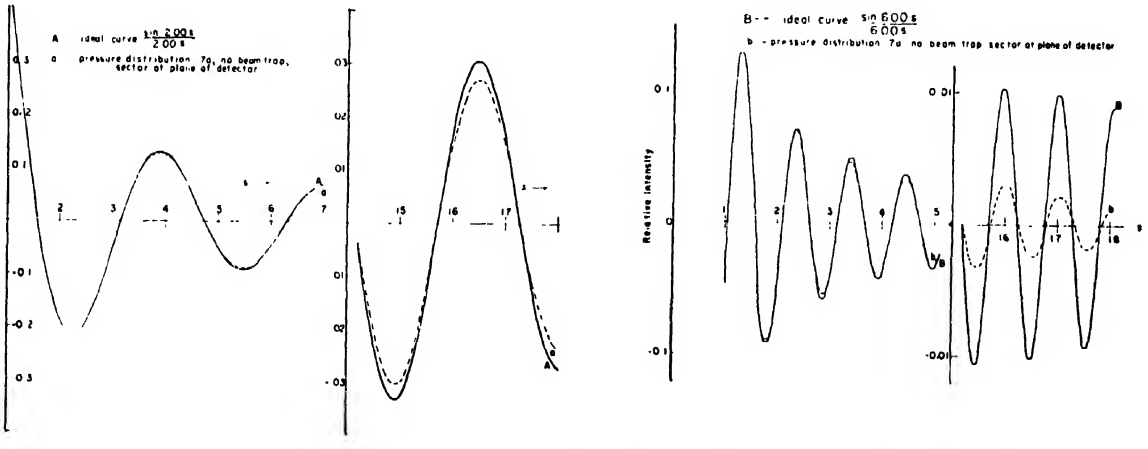
$$I_{\text{theoretical}}(s)=A_1(s)+A_2\sin\gamma s$$

with $A_2<A_1(s)$, which is a slowly varying function. Let the fraction $(1-\beta)$ be lost through multiple scattering, and let the total gain in background be $[B_1(s)+B_2(s)]$. Then

$$I_{\text{observed}}(s)=[B_1(s)+B_2(s)]+\beta[A_1(s)+A_2\sin\gamma s].$$

A measure of the resolution is the magnitude of the observed "relative fluctuation," i.e.,

$$\frac{2\beta A_2}{[B_1(s)+B_2(s)]+\beta A_1(s)}\left[\frac{2A_2}{A_1(s)}\right]^{-1}\cong 1-\frac{B_1(s)+B_2(s)}{\beta A_1(s)}.$$



FIGS. 8b and 8c. No beam trap correction was inserted in these integrations, and the sector was placed in the plane of the detector. The pressure distributions [they should be marked 8a rather than 7a in both parts of the figure] postulated were the same as for Fig. 8a, curve *a*.

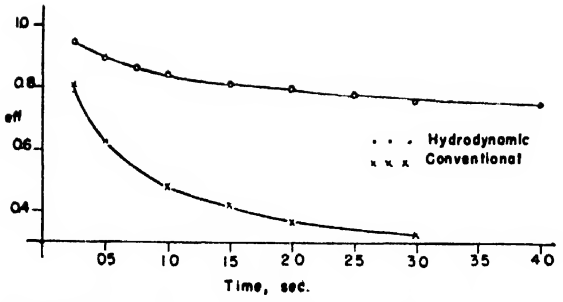


FIG. 9a. Nozzle efficiencies (E_{ab}) as a function of the time.

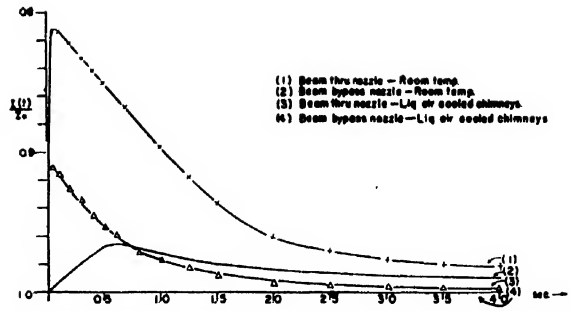

FIG. 9b. Records of beam current absorption curves.

Thus, the resolution is diminished by a factor which is inversely proportional to the fraction of each ray which gets by without suffering secondary scattering, and directly proportional to the gain in background. Further, it is probable that $B_2(s)$, which arises from the secondary scattering of the A_2 term, is a harmonic function of s, but with a phase which does not match that of $\sin\gamma s$; this effect will introduce a further decrease in resolution.

By measuring the beam absorption and computing the ratio of peak height to total intensity (at the 7th peak for CCl_4) for a series of inlet pressures we obtained the results listed in Table III. This table shows very clearly the effect of the rate of gas admittance on the resolution since we reduced our efficiency by a factor of 3 for increase of gas pressure in the reservoir by a factor of 7 or so. As the beam absorption increases from 8 percent to 16.7 percent, the resolution, as measured, drops by a factor of almost 2. Actually, our beam absorption figures are smaller than they should be, for the Faraday cage introduced to remove the main beam between the nozzle and the detector must be larger than the beam in order to avoid edge scattering. Hence a part of the diffracted pattern is trapped with the main beams when gas is admitted.

To conclude this section it would be in order to say a word about the effects on resolution of imperfect focus at the plane of the detector. A large scale microphotometer record was prepared from an etched gold foil diffraction pattern. From this the distribution of intensity over a ring, $K(s_0-s)$, was determined, due not only to the finite size of the beam but also to the finite size of the slit in the L and N microphotometer. The observed net effective width at half maximum for the (111) ring was 0.03 cm,[4] with $R_0=19.33$ cm. By comparing the integrated $\int K(s_0-s)I(s)ds$, with the ideal $I(s)$ gas diffraction patterns, it was found that:

(1) there is no lateral shifting of the maxima and minima;
(2) the ratio of the observed peak heights to the theoretical peak heights is less than unity, i.e., there is a loss of resolution;
(3) This ratio is independent of s, but decreases with increasing interatomic distances. This effect, similar to that arising from extension of the sample, also leads to the assignment of false temperature factors.

Interatomic distances	1.86	5.58	7.44
Ratio $\frac{\text{integrated}}{\text{ideal}}$	0.97	0.84	0.72.

Actually, a slight dependence of resolution on s is introduced in most electron diffraction apparatus through the use of a flat plate instead of one curved to the focal circle. However, the additional broadening is quite small (at $s=23$ the effective increase in half-width of the diffraction peak is less than 1 percent).

TABLE I. Values of $t_{\frac{1}{2}}$ for beam absorption measurements.

Nozzle	No liquid air		Liquid air	
	In beam	Out of beam	In beam	Out of beam
Hydrodynamic	0.5 sec.	1.3 sec.	0.36 sec.	0.00 sec.
Comparison	0.57 sec.	2 sec.	0.45 sec.	0.00 sec.
Comparison +constriction	6 sec.	6 sec.	2 sec.	0.00 sec.

A MOLECULAR BEAM NOZZLE

From the data presented above, one is led to speculate on the desirability of using a molecular beam in order to avoid the effects of secondary scattering and spreading of the gas through the camera. The principal difficulty in using a conventional molecular beam is that the gas densities are not sufficiently high to avoid making unmanageably long exposures. However, it is

TABLE II. Absorption of main electron beam and time to maximum absorption.

Nozzle	No liquid air		Liquid air	
	In beam	Out of beam	In beam	Out of beam
Hydrodynamic	31 % at 0.08 sec.	2.1% at 0.37 sec.	27 % at 0.06 sec.	0.0%

[4] Later, measurement of a trace of the direct beam showed that at half maximum, it is 0.0035 cm wide, so that the effects computed below are much larger than those actually present. The diffraction broadening due to our gold foil is approximately 10 times the diameter of the focused spot.

not necessary that a molecular beam used for electron diffraction work have the degree of collimation required for other types of studies. A possible design for a nozzle satisfactory for electron diffraction is indicated below. Experimentally we found that in order to obtain sufficient photographic density in the diffraction photographs ($D=0.2$ at $s=25$ for microfile film), there must be approximately $(5\times10^{+14})/ti$ molecules in the electron beam per square cm of beam cross-sectional area, where t is the duration of the exposure in seconds, and i is the total beam current in microamperes.

Let us begin by supposing that a source slit S_1 (see Fig. 12) of dimensions 0.01×0.1 cm is used. The small dimension of such a slit determines the maximum gas sample density which may be used without obtaining an appreciable number of collisions in the gas stream beyond S_1. The maximum density is the one at which the gas molecules have a mean free path equal approximately to the small dimension of the slit. Thus for a slit 0.01 cm wide, the maximum sample pressure which one may safely use is about 0.5 mm; or N, the number of molecules per cc in the reservoir, is about 1.5×10^{16}.

The gas density which appears directly above S_2, where the electron beam passes by, is approximately[6] $N'=Na/4\pi l^2$ where N' is the gas density in molecules per cc at S_2, a is the area of the source slit S_1, and l is the separation of S_1 and S_2. However, what is actually required is not N', but N'', the number of molecules in the electron beam per square cm of beam cross section; this quantity may be obtained simply by multiplying N' by that dimension of S_2 which lies along the direction of the electron beam. Therefore if this dimension is 0.1 cm, we find that

$$N''=\frac{1.5\times10^{16}\times1.0\times10^{-3}}{12.5l^2}\times0.1=\frac{1\times10^{11}}{l^2}.$$

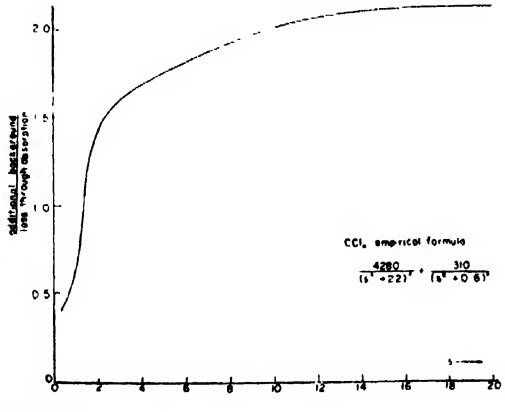

FIG. 10. Computed values for the ratio

$$\frac{\text{Addition background due to secondary scattering}}{\text{Loss in background due to absorption}}$$

as a function of s.

[6] R. G. J. Fraser, *Molecular Rays* (Mcamillan Company, Inc. New York, 1931), p. 14.

TABLE III. Observed resolution.

CCl_4 press	Absorption % (as measured using 5 mm collector)	Peak height / Total intensity ×100	Resolution (%)
—	0	12.0 (theoretical)*	100
16.5 (−12°C)	8	11.5	96
32.9 (0°C)	16.7	6.8	57
119.5 (26°C)	46.5	3.9	33

* Note: the theoretical curve was constructed using the temperature factors $e^{-0.0018s^2}$ and $e^{-0.0021s^2}$ for C−Cl distances and Cl−Cl distances, respectively.

From this relation the approximate exposure times required to give satisfactory electron diffraction photographs can be calculated as a function of l. Assuming that the main beam current i equals one microampere, we thus find that the time of exposure t equals 2×10^4, 800, and 110 seconds for l equal to 2, 0.4, and 0.15 cm, respectively.

From the standpoint of short exposure times one would like l to be small. On the other hand, if l is made very small, not only will the angular divergence of the beam be large, but also molecules which hit the bottom edges of S_2 will require too many additional bounces from the surfaces of S_1 and S_2 to reach the wide throat of the pump; the greater the average number of bounces required, the greater will be the probability for any one of these molecules to go through S_2 along an undesirable path rather than to the diffusion pump. For this reason we wish to select a compromise value—to make S_2 wide enough to allow a good fraction of the molecules leaving S_1 to go directly through S_2, but still to maintain molecular beam characteristics. The practical limit is determined by the maximum sample extension which is to be allowed. With $l=0.15$ cm and S_2 0.1×0.1 cm, the total angular divergence will be about 42° so that the maximum sample extension along the direction of the electron beam at a distance 0.1 cm above the bottom of S_2 will be 0.2 cm, a not unreasonable value. Roughly 55 percent of the molecules leaving S_1 will go directly through S_2 in this case.

Table IV summarizes some of the characteristics and requirements of this type of molecular beam nozzle, and Fig. 12 illustrates its physical outlines.

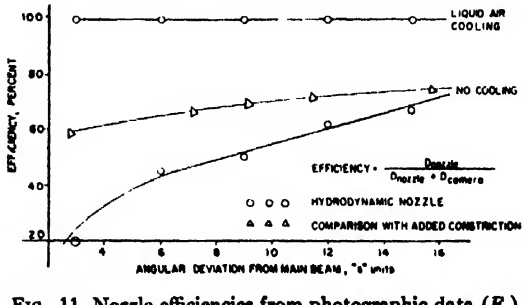

FIG. 11. Nozzle efficiencies from photographic data (E_s), as a function of s.

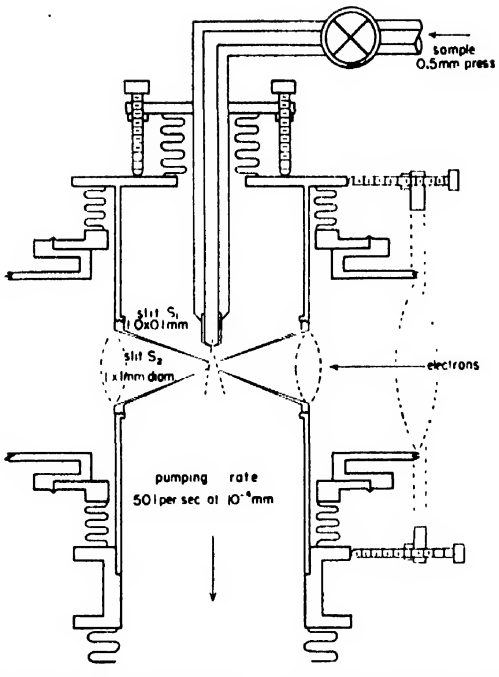

FIG. 12. Proposed molecular beam nozzle and pumping section.

If the gas densities achieved by this nozzle are found to be too low, or the angular divergence too great, a source of high gas density has been designed by Dr. A. Kantrowitz[6] of the Graduate School of Aeronautical Engineering at Cornell, utilizing supersonic flow. Under comparable conditions a molecular beam intensity about 75 times that obtainable with standard molecular beam geometry can be produced. However, due to its added complexity and inefficient sample utilization it would not be advantageous unless the factors of higher gas density, and lower effective temperature of the gas (approximately 72°K for a Mach number 4) were necessary for the investigation in hand.

TABLE IV. Properties of modified molecular beam nozzle.*

Property	Calculated value	
Dimension of slit S_1	0.01×0.1 cm	
Dimension of slit S_2	0.1×0.1 cm	
Pump capacity (on nozzle—Fig. 12)	50 l/sec. at 1×10^{-4} mm	
Molecules in electron beam per unit area of electron beam	6×10^{11}	
Molecular velocity	5×10^{4} cm per sec.	
Effective molecular temperature	300°K	
Consumption of sample	3×10^{-7} moles/sec.	
Exposure time and total beam divergence	time	angle
S_1-S_2 distance 2 cm	5.5 hrs.	3°
4 mm	13 min.	14°
1.5 mm	2 min.	42°

* With beam current increased by a factor of 5 (to 5 microamperes) the exposure time in the last case will be reduced to 24 seconds.

DISCUSSION AND CONCLUSIONS

We have attributed the lack of resolution of the diffracted electron image on the detector to failure of assumptions (2), (3), and (4) listed in the introduction. The data obtained may be summarized as follows:

Pressure Measurements

(i) $E_p(l)$

$$= \frac{\text{molecules coming from the nozzle}}{\text{molecules from nozzle}+\text{molecules from camera}}$$

(ii) Better efficiencies are given by the hydrodynamic or comparison nozzles than the conventional, with or without the use of liquid air.

(iii) Efficiencies are always higher for shorter exposures, and for high camera pumping speeds.

(iv) It is desirable to beam the gas through the camera and directly into a diffusion pump.

Beam Absorption Measurements

(i) $E_{ab}(l)=\dfrac{\text{beam absorption over the nozzle}}{\text{beam abs. over nozzle}+\text{beam abs. in camera}}$

This is greater for the hydrodynamic or comparison nozzles than for the nozzle of slow admittance by a factor of 50 percent when no liquid air cooling is used.

(ii) Beam absorption with the hydrodynamic or comparison nozzles may be as great as 30 percent, and secondary scattering within the nozzle will be serious.

(iii) Liquid air-cooled surfaces *do not* reduce secondary scattering over the nozzle exit.

Photographic Measurements

(i) The efficiency is an integrated value over the exposure time, being defined:

$$E_s=\frac{\text{Photographic Density from gas out of nozzle}}{\text{P.D. out of nozzle}+\text{P.D. with beam by-passing nozzle}}.$$

(ii) At room temperature the efficiencies become strongly dependent on the angle of diffraction.

(iii) With liquid air-cooled surfaces around the nozzle the efficiencies are close to 100 percent.

(iv) Secondary scattering may be serious; it is dependent on scattering angle; and the shape of the background can be appreciably changed with density of the sample gas (probably due to the differences in secondary scattering). When absorption of the main beam exceeds about 10 percent, resolution is considerably impaired.

In the analysis of secondary scattering it was shown that an angular dependence existed, although secondary scattering was not dependent on the sample distribution. The ratio of [gain in background/loss of primary diffraction] rises to 1.6 (at about $s=3$), and continues

to increase to a value about 2 for larger values of s. The secondary scattering is chiefly a function of N, the number of molecules available to the beam. The conventional nozzle, because of its slow gas admittance, will give rise to the least multiple scattering but allows a great deal of sample extension to occur. The hydrodynamic nozzle, under optimum conditions, gives a much better defined gas stream but for hydrodynamic principles to apply, a gas density so high that multiple scattering becomes very serious must be used and hence this nozzle has little if any advantage over the comparison nozzle, especially if liquid air-cooled chimneys which reduce the seriousness of sample extension can be used. As a means of avoiding to a large extent the effects of both sample extension and multiple scattering, a design for a modified molecular beam nozzle suitable for electron diffraction work is offered. With any type of nozzle, the escaping gas should be able to flow in a straight path directly into a diffusion pump of high speed.

With proper nozzle and camera design it should be possible to achieve nearly maximum resolution in the electron diffraction patterns of gases.

ACKNOWLEDGMENT

Several grants made the completion of this investigation possible. We wish to thank sincerely: The Canadian Defence Research Board—a fellowship for R. B. Harvey; The Office of Naval Research—a research assistantship for F. A. Keidel (under contract No. N6-ori-213, Task I NR 052-040); The Guggenheim Memorial Foundation—a fellowship for S. H. Bauer. All of us are indebted to Professor A. Kantrowitz for his assistance with nozzle designs.

APPENDIX A. ANGULAR INDEPENDENCE OF ABSORPTION OF DIFFRACTED RAYS

The statement that the absorption of the diffracted rays is independent of s may be justified on the assumption that the actual gas distribution in the vicinity of the nozzle is cylindrically symmetric about the axis along which the main stream of gas flows into the camera, while the incident electron beam enters along a diameter of this cylinder. Then, if J_0 is the intensity reaching a primary beam collector when no sample is present, and $N(R, t)$ is the distribution in the number of molecules per unit volume, as a function of distance from the gas stream axis and time, the primary beam intensity, observed when a sample is present, will be

$$J(t)=J_0\exp\left[-\pi\sigma^2\int_0^{R_0+\xi}N(R,t)dR\right], \qquad \text{(A1)}$$

where σ is the electron-molecular collision radius, and is in a sense defined by the above absorption equation, and $(R_0+\xi)$ is the maximum extension of the sample, so that the limits 0 to $(R_0+\xi)$ include all the gas molecules which intercept the beam, from the last aperture in the magnetic lens to the camera.

If there were no higher order scattering, the intensity per unit area of collector at some point r in the plane of the observer, measured from the undeflected ray, would be

$$I^*(r/R_0,t)=J_0B^2\int_0^{R_0+\xi}N(R,t)\frac{(\text{atomic}+\text{molecular})}{R^2[s(r/R)]^4}dR, \qquad \text{(A2)}$$

where

$$B^2=\left[\frac{8\pi^2me^2}{h^2}\right]^2;\quad s(r/R)=\frac{4\pi}{\lambda}\sin\frac{\theta}{2};\quad \theta=\arctan\frac{r}{R}.$$

Equations (1) and (A2) are identical except that the former is valid only if all the N molecules are located at R_0, whereas in (A2) we have permitted the sample to be distributed as per $N(R, t)$. Thus it gives the intensity for all rays diffracted by an extended sample assuming no secondary scattering. However, higher order scattering introduces an effective absorption so that the actual intensity of electrons scattered only once will be

$$I(r/R_0,t)=B^2\int_0^{R_0+\xi}J_0\exp\left[-\pi\sigma^2\int_R^{R+\xi}N(R,t)dR\right]N(R,t)\times\frac{(\text{atomic}+\text{molecular})}{R^2s^4}\exp\left[-\pi\sigma^2\int_0^{R}N(R,t)dR\right]dR. \qquad \text{(A3)}$$

The first exponential factor allows for the attenuation of the primary ray in proceeding from $(R_0+\xi)$ to R; the second allows for the attenuation of the diffracted ray in proceeding from R to the plane of the detector (at 0). Hence, subject to the assumption that *the angles of diffraction are not large*,

$$I(r/R_0,t)=I^*\exp\left[-\pi\sigma^2\int_0^{R+\xi}N(R,t)dR\right]. \qquad \text{(A4)}$$

Thus *no selective loss* is to be expected for any ray, be it primary or diffracted. Similarly, both the atomic and molecular contributions will be reduced by the same fraction.

APPENDIX B. COMPUTATION OF COLLISION CROSS SECTION

The absorption coefficient $\pi\sigma^2$ may be estimated in the following way: Circumscribe around a sample located in its entirety at R_0, a sphere of radius R_0. Then an element of area on that sphere is given in terms of the solid angle $\Delta\theta\Delta\phi$ by $[R_0\sin\theta\Delta\phi R_0\Delta\theta]$. The intensity of electrons scattered into this element of solid angle by $N_0(t)$ molecules (per unit area of the incident beam),

$$j(\theta,t)=J_0B^2N_0(t)\frac{(\text{atomic}+\text{molecular})}{s^4}\sin\theta\Delta\phi\Delta\theta. \qquad \text{(B1)}$$

Hence, the fraction lost from the primary ray, for a *sample of infinitesimal thickness*,

$$\frac{dj(t)}{J_0}=2\pi\int_0^{\pi}\frac{j(\theta,t)d\theta}{J_0}=2\pi B^2N_0(t)\int_0^{\pi}\frac{(\text{atomic}+\text{molecular})}{s^4}\sin\theta d\theta=\pi\sigma^2N_0(t). \qquad \text{(B2)}$$

Hence we have

$$\pi\sigma^2=2\pi B^2\left(\frac{\lambda}{2\pi}\right)^2\int_0^{4\pi/\lambda}\frac{(\text{atomic}+\text{molecular})_s}{s^2}ds. \qquad \text{(B3)}$$

The above integral may be evaluated through the use of Bewilogua's tables.* For CCl_4 this reduces to 1.71×10^{-17} cm^2, provided one makes appropriate assumptions as to the atom form factors at small angles. We also measured this quantity by making preliminary estimates of the magnitude of

$$\int_0^{R_0+\xi}N(R,t)dR \quad \text{and substituted in (A1).}$$

This leads to 2.1×10^{-17} cm^2 for the value of σ^2 for CCl_4.

We have thus demonstrated that the *fractional loss* due to higher order scattering is independent of the angle, and is directly measurable through the attenuation of the primary beam. For CCl_4 under conditions which are typical for most electron diffraction experiments, we estimated the average secondary and higher order scattering to be, after writing $N(R, t)=N_0(t)N_1(R)$,

$$\frac{1}{t_x}\int_0^{t_x}\frac{(I^*-I)}{I^*}dt=\frac{\pi\sigma^2}{t_x}\int_0^{t_x}N_0(t)dt\int^{R_0+\xi}N_1(R)dR=(4\text{ to }11)\times10^{-2} \qquad \text{(B4)}$$

* L. Bewilogua, Physik. Zeits. 32, 740 (1931). See also W. Heisenberg, Physik. Zeits. 32, 737 (1931).

where t_s is the exposure time. These are values which we believe are typical for most current electron diffraction experiments, and they certainly are greater than the error we wish to allow.

APPENDIX C. THE RATIO OF TOTAL MULTIPLE SCATTERING TO TOTAL SCATTERING

Divide interval 0 to $(R_0+\xi)$ into n slices of thickness $(\Delta R)_m$ so that each slice contains the same number of molecules, c/n, per unit area. Set $\pi\sigma^2=K$.

Then the amount of diffraction in the main beam occurring in slice m between R_m and R_{m+1} is

$$J_1(m)=J_0\left\{\exp\left[-K\int_{R_m+\Delta R_m}^{R_0+\xi}NdR\right]-\exp\left[-K\int_{R_m}^{R_0+\xi}NdR\right]\right\}$$
$$=J_0\left\{\exp\left[-K\frac{c(n-m)}{n}\right]-\exp\left[-K\frac{c(n-m+1)}{n}\right]\right\}.$$

The total amount of diffraction is therefore

$$J_1=\sum_{m=1}^{n}J_1(m)=J_0\{1-\exp[-Kc]\}.$$

From this we find at once that the total amount of intensity rescattered from the rays originating in slice m is given by*

$$J_2(m)=J_0\left\{\exp\left[-K\frac{c(n-m)}{n}\right]-\exp\left[-K\frac{c(n-m+1)}{n}\right]\right\}\cdot\left\{1-\exp\left[-K\int^{R_m}NdR\right]\right\}$$

and the total scattering from all rays originating in all the slices is

$$J_2=\sum_{m=1}^{n}J_2(m)=\sum_{m=1}^{n}J_0\left\{\exp\left[-K\frac{c(n-m)}{n}\right]-\exp\left[-K\frac{c(n-m+1)}{n}\right]\right\}\cdot\left\{1-\exp\left[-K\frac{m}{n}C\right]\right\}$$
$$=J_1+\sum_{m=1}^{n}J_0\left\{-\exp[-Kc]+\exp\left[-Kc\frac{n+1}{n}\right]\right\}$$
$$=J_1+nJ_0\{-\exp[-Kc]+\exp[-Kc(n+1/n)]\}$$
$$=J_1+nJ_0\{-1+\exp[-Kc/n]\}\exp[-Kc].$$

Now the value of

$$\lim_{n\to\infty}n\{e^{-Kc/n}-1\}=\lim_{n\to\infty}n\{-Kc/n\}=-Kc.$$

Hence

$$J_2=J_1+J_0\cdot(-Kc)\exp[-Kc]$$
$$=J_1+(J_0-J_1)(-Kc)$$
$$=J_1+(J_0-J_1)\ln[(J_0-J)/J_0]$$

or

$$J_2/J_1=1+[(J_0/J_1)-1]\cdot\ln[1-(J_1/J_0)].$$

* Ignores slight increase in path length because of angle and any change in gas density as a function of the distance *perpendicular* to the electron beam. These will be very small effects ordinarily since most of the intensity appears at small angles.

Studies with an Aerodynamically Instrumented Shock Tube*†

A. Hertzberg and A. Kantrowitz
Cornell University, Ithaca, New York

(Received April 6, 1950)

A shock tube has been set up at Cornell University to begin the study of two-dimensional wave propagation. Pressure waves initiated by the shock itself were used to trigger the spark source for the schlieren flow-observation system, to time the instant of exposure and to measure the strength (speed) of the shock waves. These techniques were employed to study the propagation of a wave in a converging channel. Fair agreement between the one-dimensional method of characteristics and these experiments was obtained.

INTRODUCTION

A SHOCK tube is a device in which simple normal shocks are produced by the sudden bursting of a diaphragm separating regions of higher and lower pressure gases. The compression waves produced in the lower pressure region rapidly steepen into a shock which propagates with a front normal to the axis of the channel. This device has proven convenient for many studies of shock wave phenomena.[1-5]

A shock tube has been constructed in the Graduate School of Aeronautical Engineering at Cornell and has been used for studies of the limitations of the one-dimensional characteristic theory.[6,7] Most previous shock tubes have used electronic instrumentation for measuring the strength of the shock wave generated and to trigger the spark at a desired time. The central idea in this work has been to simplify the instrumentation by using aerodynamic wave phenomena. Thus, weak waves traveling at nearly sonic speed were photographed simultaneously with the phenomena under study and

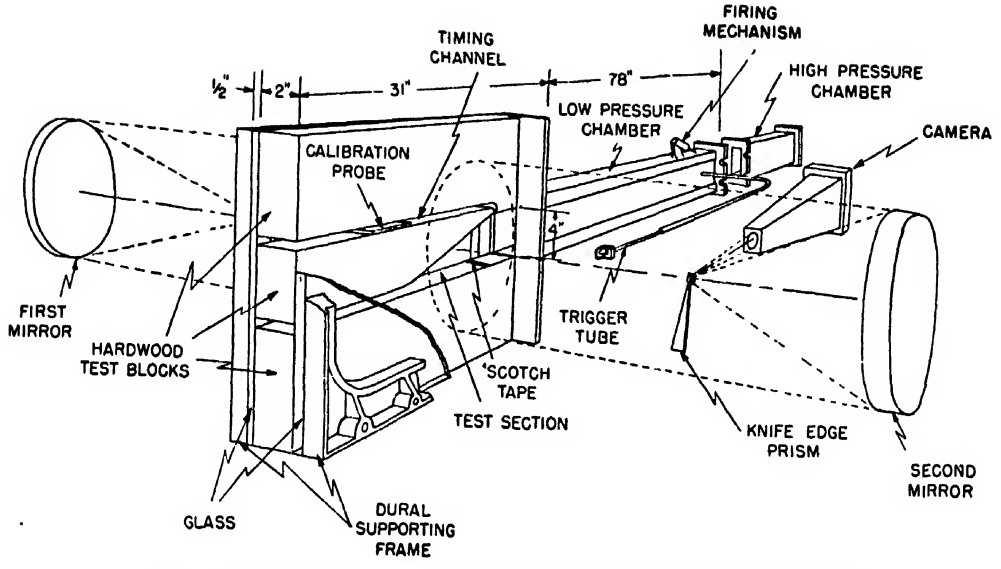

FIG. 1. Schematic drawing of shock tube and schlieren system used in this work.

were used to measure the shock strength and the time instant of the exposure.

APPARATUS

Standard Equipment

The shock tube used in these experiments (see Fig. 1) consisted of a rectangular steel tube 2×4 in. I.D. This tube was partitioned into high and low pressure chambers separated by a cellulose acetate diaphragm which could be pierced by a steel probe. By using various thicknesses of cellulose acetate up to 0.020 in., pressure differences between the chambers as large as 440 in. Hg could be used. In the calibration runs it was found that more consistent shock strengths were obtained if the diaphragm thickness was chosen to be close to its undisturbed bursting point when pierced. The end of the shock tube was equipped with a test section of interchangeable wooden blocks "sandwiched" between plate glass. A conventional schlieren apparatus was used to observe the flow. The spark source for the schlieren apparatus discharged 1.7 μf charged to about 9 kv. Exposures with a rotating mirror established the spark duration to be of the order of 1 μsec. A third trigger electrode was used which was energized via a thyratron.

Aerodynamic Instrumentation

The planned experimental program required the photography of shock waves by the schlieren system at various points during their propagation along the test section. Thus we needed to trigger the spark at controlled times and to measure the strength of the shock wave first for calibration purposes and later for the experimental work. The spark was triggered by a pressure wave which traveled down a small trigger tube (about $\frac{3}{16}$ in. I.D.—see Fig. 1). This trigger tube was connected to an orifice (about 2 in. from the diaphragm) and so received a pulse of high pressure air as the shock passed the orifice. Upon reaching the end of the trigger tube the pressure wave deflected a thin metal diaphragm a few thousandths of an inch to produce an electrical contact. This electrical contact was connected to the grid of the thyratron so as to trigger the spark. The trigger tube actually consisted of two metal tubes telescoping inside each other so that the spark could be triggered with appropriate lags to photograph the shock wave at various points along the test section with a reproducibility of about ±10 μsec. Once one photograph of the shock wave was obtained for a given shock strength, pictures

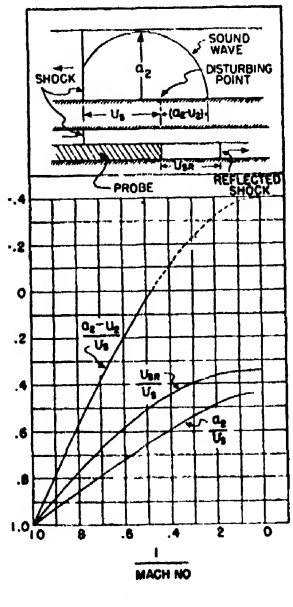

FIG. 2. Velocity ratios used for photographically measured shock strength by the application of weak waves (assumed infinitesimal in these calculations). The velocity ratio of a rearward moving weak wave $(a_1-u_1)/u_s$ was used where the shock strength was high and the velocity ratio of a normally reflected shock was used for measuring the strength of weak shocks, e.g., the timing wave.

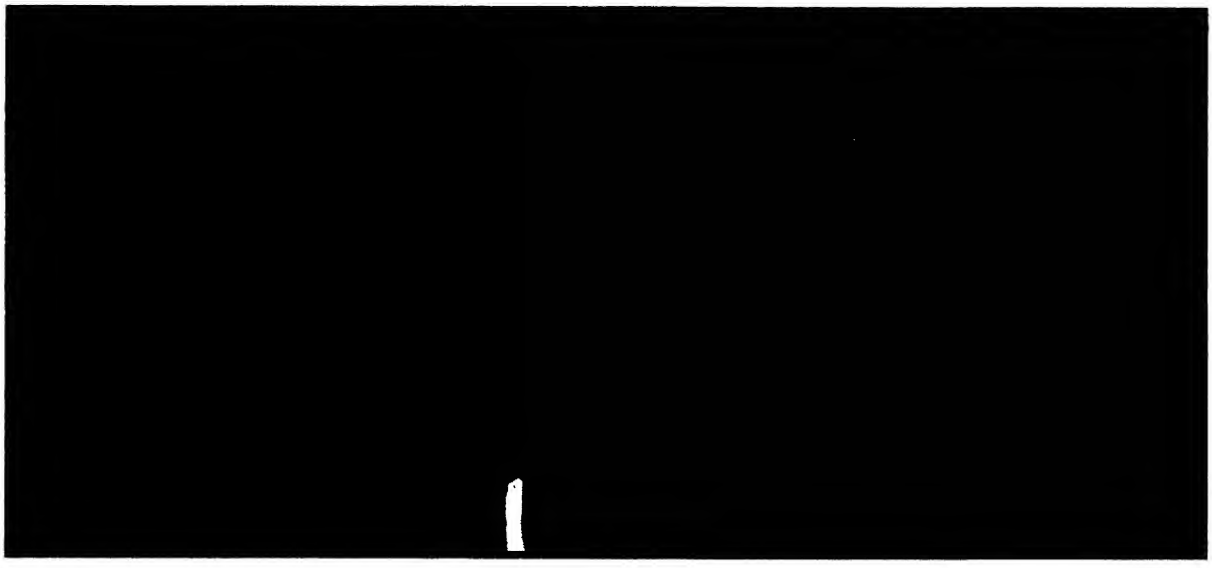

FIG. 3. A schlieren photograph of reflections from a single thickness of Scotch Tape. The left edge of the vertical marker corresponds to the leading edge of the (invisible) Scotch Tape.

at other points in the test section could be obtained by extending or retracting the trigger tube approximately (within five percent) the distance between the new and old shock positions.

A more accurate method of recording the actual instant of exposure was through the use of the timing wave. In Fig. 1 it can be seen that a passage about ½ in. high is included above the test section. This was connected to the main chamber by a narrow slit (0.015 in. wide and one-third the width of the channel). When the main shock passed this slit a very weak wave propagated along this upper channel at slightly greater than the speed of sound. The actual strength of this wave was measured with a calibration probe as will be discussed later. Its position at the instant of exposure was recorded along with the main shock wave on the schlieren photograph. Thus since the velocity of this wave is known from the calibration probe measurement (see below), its position is a measure of the time instant of exposure.

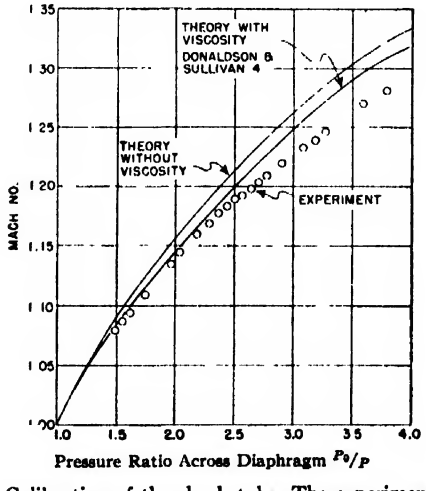

FIG. 4. Calibration of the shock tube. The experimental shock Mach numbers were obtained by the Scotch Tape technique (Fig. 3).

Shock Strength Measurement

Shock strengths were measured in all cases by the comparison of the speed of a reflected wave with the speed of a shock. The simplest technique is to place a piece of ordinary Scotch Tape on the floor of the shock tube in such a way that the passage of a normal shock will produce two weak cylindrical waves. The position of the upstream intersection of the rearward moving cylindrical wave with the wall and the position of a normal shock wave were measured relative to one edge of the Scotch Tape as shown in Fig. 2. The ratio of the distances of these waves from the disturbing point is identical with the ratio of the wave velocities. A photograph of the reflections from a piece of Scotch Tape is shown in Fig. 3. To measure the departure of these reflected waves from sound waves several different thicknesses of Scotch Tape were added to the original to produce stronger reflections. The apparent Mach numbers were plotted against tape thickness and the results extrapolated to zero thickness. No correction for a single thickness of Scotch Tape was required within the experimental scatter of the circles of the calibration on Fig. 4.

In order to calculate the strength of the shock from the ratio of the velocity of the reflected wave to the velocity of the normal shock wave, we need to know the strength of the shock wave in terms of u_2, a_2, and U_S where u_2 is the fluid velocity in the direction of the shock wave motion, a_2 is the velocity of sound behind the

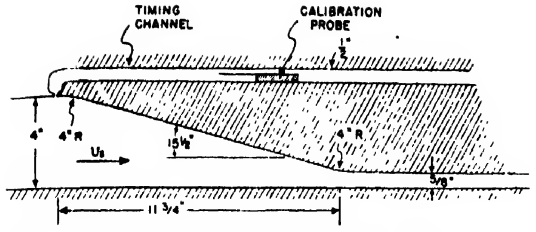

FIG. 5. Converging channel used in experimental work. The timing channel used to determine the exact time of the exposure is also illustrated.

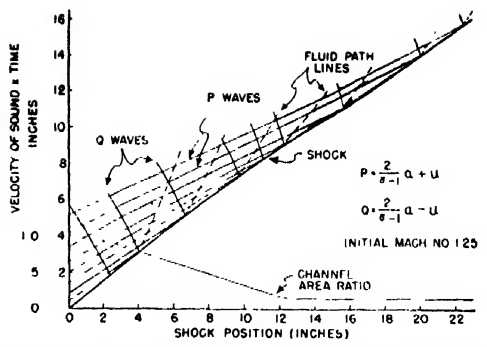

FIG. 6. Typical numerical integration along characteristics of the propagation of a shock wave (followed by no other disturbances) in a converging channel.

shock wave, and U_S is the velocity of the shock. It is desirable to transform to coordinates moving with the shock wave. Using this coordinate system the standard tabulations of the Rankine-Hugoniot relations can be used to give a relation between the shock Mach number and $(a_2-u_2)/U_S$. This relationship is plotted in Fig. 2. When the flow behind the shock becomes supersonic (the dashed curve on Fig. 2), this ratio would probably not be useful as simply measuring the Mach angle of the steady waves from the Scotch Tape. Similarly the wave moving across the channel can be used. In this case we measure the ratio a_2/U_S. This ratio is also plotted in Fig. 2. It can be seen that this ratio does not vary as rapidly with Mach number as the ratio between the upstream moving wave and the shock velocity. Therefore it does not lead to shock strength results as precise as those obtained from the upstream moving wave.

Normal reflection of the shock was used when the Scotch Tape reflection from a weak shock was no longer visible. A probe which is diagrammed in Fig. 2 was employed. In the lower part of this probe the wave was reflected normally whereas in the upper part it proceeded

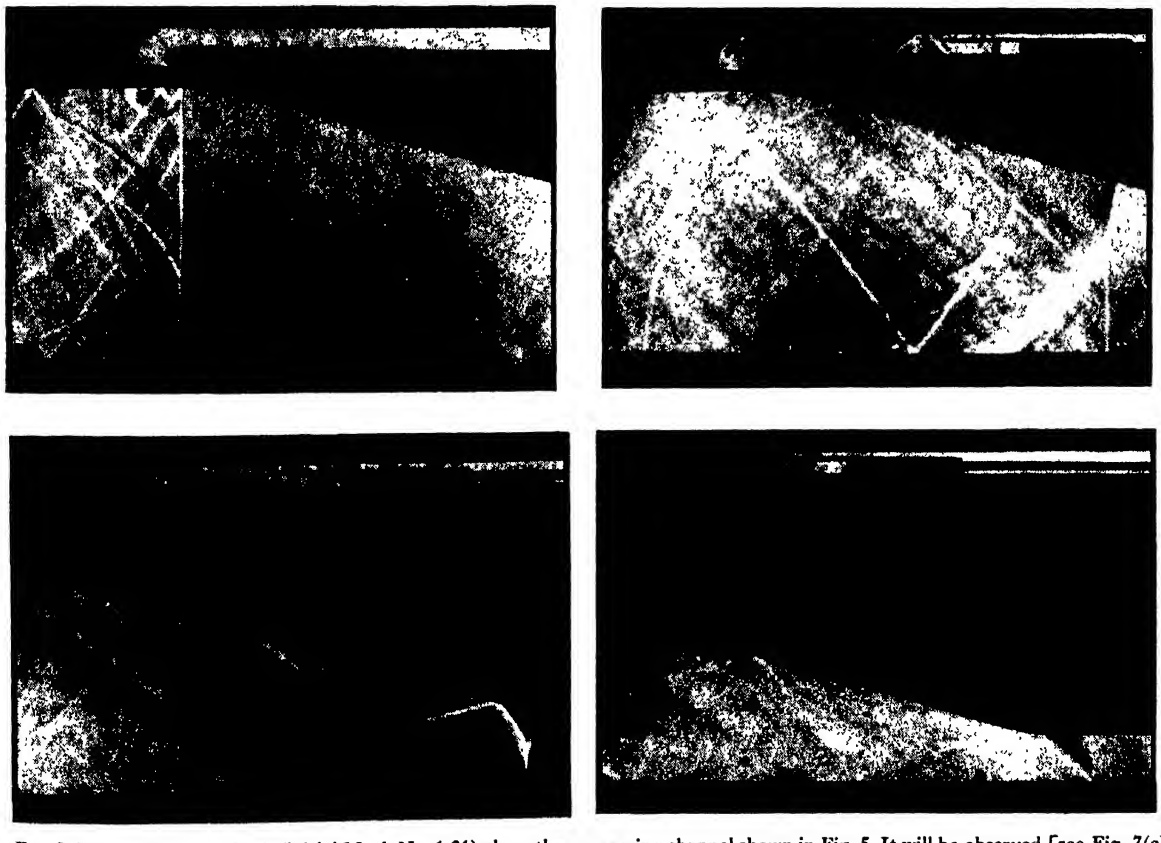

FIG. 7. Propagation of a shock (initial Mach No. 1.21) along the converging channel shown in Fig. 5. It will be observed [see Fig. 7(c)] that the shock rapidly assumes a cylindrical shape and then after a period of adaptation to the converging channel the one-dimensional theory of characteristics should apply.

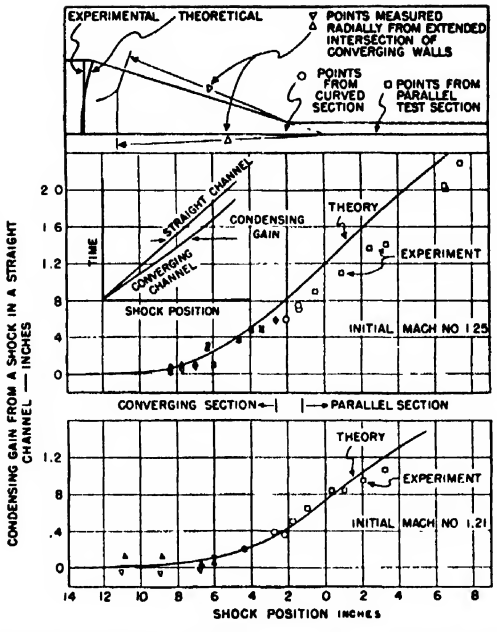

FIG. 8. Comparison of results obtained by numerical integration by the method of characteristics with experimental photographs such as Fig. 7.

with only slight disturbance. The ratio of the speed of the reflected wave to the speed of the initial wave can be used in a manner similar to the above for the determination of the shock strength. This ratio is also plotted in Fig. 2. The normal reflection technique was useful in finding the strength of the timing wave at various points along the timing channel, which had a Mach number of about 1.01.

Calibration of the Shock Tube

Before the shock tube can be conveniently used, a relation must be experimentally determined between the pressure ratio across the diaphragm and the Mach number of the resulting shock wave. This relationship can be determined from simple non-viscous theory by standard methods.[7] A viscous correction has recently been computed by Donaldson and Sullivan[4] which allows for the weakening of the shock wave by the boundary layer formed behind the shock wave. Both of these theoretical calibrations are plotted on Fig. 4. A series of photographs (such as Fig. 3) was taken at various pressure ratios using the Scotch Tape technique for measuring the shock strength. The measured shock Mach number is plotted against the pressure ratio on Fig. 4. It is seen that the Mach number obtained is always somewhat lower than the theory indicates even including wall boundary layer effects. This departure from the theoretical calculation including viscous effects might be expected in view of possible obstructions remaining at the diaphragm and miscellaneous losses due to partial reflections due to roughness in the shock tube and the test section.

APPLICATION TO THE PRELIMINARY STUDIES OF CONDENSING SHOCK WAVES

As was mentioned in the Introduction, our first experiments with the shock tube were directed to the study of the limitations of the one-dimensional method of characteristics for unsteady flows. It is assumed in this theory that conditions are uniform across the channel. On the other hand, if changes in the channel area occur, the effects will be felt first near the wall and only later in the center of the channel. In fact, it is clear from the photographs taken in the test channel that the effects of the wall led to a reflected wave similar to a triple shock intersection. This intersection point divides the shock into two portions, one of which has been affected by the change of wall contour and the other of which has not been affected by this change. We were also interested in determining whether a wave in a converging passage would ultimately assume a cylindrical form, i.e., to see whether the cylindrical form is stable for a condensing shock.

The channel chosen for these experiments is illustrated schematically in Fig. 5. The one-dimensional characteristic theory for this channel was computed by the methods of reference 6, and one such computation is shown in Fig. 6. No viscous effects are included in this calculation and no attempt to correct for departures from one-dimensional flow has been made.

The boundary conditions for the calculation were, first, that the flow is initially at rest with sonic velocity[6] a_o ($P=Q=[2/(\gamma-1)]a_0$) and, second, that no later waves propagated into the test section following the shock (i.e., at the beginning of the convergent section $P=[2/(\gamma-1)]a+u$ is a constant determined from the known initial shock strength).

A series of photographs was taken for two different shock Mach numbers (1.21 and 1.25) and typical photographs from the series for $M=1.21$ are shown in Figs. 7(a)–7(d). The earlier figures can be best described by saying that the effect of the wall deflection was propagated as a triple shock intersection back and forth across the channel. The later figures show that the shock does tend to approach a cylindrical form and thus indicate that the cylindrical form of the shock wave is stable in converging channels for the conditions of these experiments.

A comparison is given in Fig. 8 between the position of the shock wave as determined experimentally and the positions calculated by the method of characteristics. It will be noticed that the two ends of the shock approach the same radial position in about the time the triple shock intersection crosses the channel once.

The Magnetostriction of Permanent Magnet Alloys

E. A. NESBITT
Bell Telephone Laboratories, Murray Hill, New Jersey
(Received April 24, 1950)

In order to obtain a better understanding of the mechanism of coercive force in modern permanent magnets, magnetostriction measurements have been made on various alloys having coercive forces from 50 to 600 oersteds. The results can be summarized by discussing two types of alloys. First are the older carbon-hardening permanent magnets, and for these alloys high coercive force and high magnetostriction occur together. Second are the newer carbon-free permanent magnets and for these alloys high coercive force does not occur with high magnetostriction. In fact for the Mishima alloys having compositions near 29 percent nickel, 12.5 percent aluminum, and 58.5 percent iron, cooled at the rate of 3°C per second (coercive force 400 oersteds), the magnetostriction actually passes through zero. This is contrary to the classical strain theory of coercive force which states that the latter is proportional to the product of the magnetostriction and internal stress. To explain the mechanism of coercive force for these alloys it is necessary to resort to more recent theories.

INTRODUCTION

THE main purpose of this work has been to measure the magnetostriction of permanent magnet alloys having coercive forces from 50 to 600 oersteds, with the hope that the results would aid in understanding the mechanism of coercive force. At the present time the data on magnetostriction in this field are limited, although data of this type on materials of low coercive force are voluminous and have been of great value in interpreting the properties of materials of high permeability.

According to the older theories of Kersten,[1] Becker,[2] Kondorsky,[3] and others, a coercive force occurs when the material has (1) large internal strains that vary from place to place (strain gradients) and (2) large magnetostriction at saturation (change in length from demagnetized state to saturation). This classical strain theory of coercive force is expressed as follows:

$$H_c \doteqdot \lambda_s \sigma_i / I_s$$

where λ_s is the magnetostriction at saturation, σ_i is the amplitude of internal stress and I_s the saturation intensity of magnetization. Because of theoretical and experimental work, the validity of this theory has been questioned.

Néel[4] has developed a theory of coercive force in which he considers fluctuations in the magnetization of the elementary domains. Fluctuations in the *directions* of magnetization are caused by elastic disturbances of the lattice, and fluctuations in *intensity* of magnetization are caused by the presence of inclusions or cavities. Because of these fluctuations there will be magnetic poles throughout the material and associated with them will be energy, the distribution of which will largely determine the positions of the domain walls and their movement with a field.

Stoner and Wohlfarth[5] consider many materials having high coercive force (*magnets*) to be made basically of fine particles (this term including both actual powder grains and atomic segregates or islands in alloys) which act as single magnetic domains. The coercive force of these domains depends on one or more of three types of anisotropy, namely, strain, crystal and shape anisotropy. Strain anisotropy is a function of the strain and the magnetostriction. Crystal anisotropy depends on the crystal structure, and is measured by the anisotropy constant. Shape anisotropy depends upon the shape of the particle in such a way that it is zero for

FIG. 2. Photograph of specimen, box, and winding details.

a material having spherical particles and high for a material composed of long, thin needles. Magnets composed of fine particles of this kind, and having high coercive force, have been produced by Dean and Davis[6] (powdered iron, cobalt, etc.), Guillaud[7] (powdered MnBi, MnAs, etc.), Weil,[8] and others. The theory has been discussed by Néel, and Stoner and Wohlfarth and by Kittel.[9] In the case of iron, the particles must be of the order of 2×10^{-6} cm or smaller in order to act as single magnetic domains.

The measurements here reported make it necessary in the case of some important alloys to resort to the new theories of Néel, and Stoner and Wohlfarth and to reject the older strain theory. For example in some of the Mishima alloys zero magnetostriction was obtained with an accompanying high coercive force and this is incompatible with the strain theory. In other materials such as high cobalt steel the strain theory may still apply.

APPARATUS

The first phase of this work was the development of a new method for measuring magnetostriction which was originally devised by H. J. Williams. The method is a magnetic one and has the desirable feature of recording automatically the change in length of a specimen as a function of the magnetizing force. Figure 1 shows a schematic diagram of this instrument.

The toroidal specimen is rigidly clamped to the brass frame at the point A as shown in Fig. 1. At a point

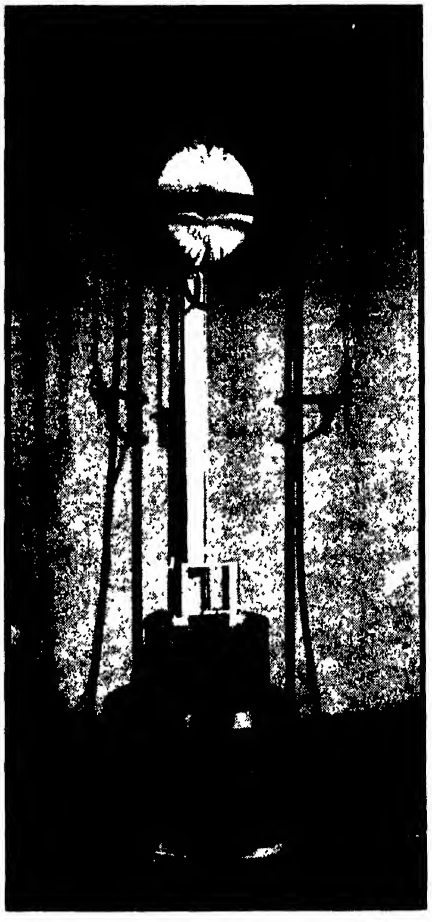

FIG. 4. Photograph of complete assembly of magnetostriction instrument.

diametrically opposite, a brass rod is soldered to the specimen and this rod supports a cylindrical coil C which is suspended in a uniform radial magnetic field supplied by permanent magnets. Any vertical displacement of the cylindrical coil causes a change in the flux linkages of the coil and this is measured by the recorder. The recorder is a Cioffi recording fluxmeter which consists of two elements, one drives a paper drum proportional to the magnetizing force, the other drives the pen across the paper in proportion to the change in flux linkages. In practice the instrument is actuated by

sending current through the magnetizing winding of the specimen. This causes two things to happen. First, sending current through the magnetizing winding also sends current through the recorder and this causes the paper drum to turn by an amount proportional to the magnetizing force. Second, sending current through the magnetizing winding magnetizes the specimen and changes its diameter thus causing a vertical displacement of the cylindrical coil and as a result the pen then moves an amount proportional to the change in flux linkages. Both of these actions occur simultaneously, thus a curve is traced of the change in length of a specimen *versus* magnetizing force.

Figure 2 shows the specimen, the box in which the specimen is suspended but not allowed to touch, the cover for the box and the completely wound specimen. The specimen shown is approximately 4 in. I.D., 4.6 in. O.D., and is either a cast or a machined ring. Specimens 2 in. I.D., 2.5 in. O.D. were also used. The brass extensions are soldered to the specimen, the heavy one fastens to the brass frame, the light one supports the

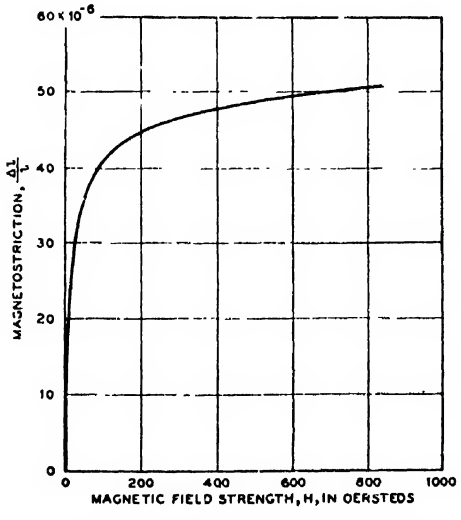

FIG. 5. Longitudinal magnetostriction of Vanadium-Permendur.

cylindrical coil. The box and its cover are watercooled; this is important because it is necessary to keep the temperature of the specimen constant during the measurement. The specimen shown in Fig. 2 is wound with 1850 turns of No. 18 Formex wire. The smaller specimens were wound with approximately 800 turns of No. 19 enameled silk copper wire. It is important to make the windings uniform and continuous in order to avoid magnetic pick-up between the specimen and the cylindrical coil. In some cases it is desirable to have a cylindrical magnetic shield surrounding the toroidal magnetizing winding.

Figure 3 shows the cylindrical coil and its associated bearings for guiding the motion of the coil. The coil is wound with 1600 turns of No. 38 enameled copper wire. The bearings are fitted to have a minimum of frictional

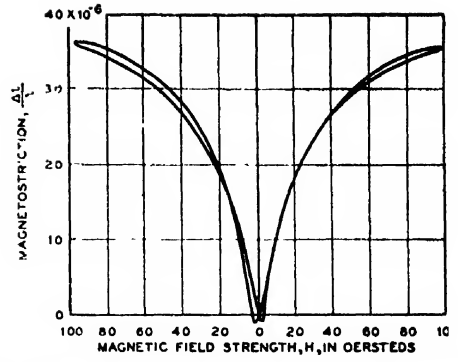

FIG. 6 Magnetostrictive loop of Vanadium-Permendur.

resistance and yet prevent side play of the coil *C*. The coil is placed in the circular gap.

Figure 4 shows the complete assembly of the instrument. The instrument is mounted on a base which is supported by a Julius suspension, part of which can be seen in the photograph. The base is oil damped and the entire instrument enclosed in an air shield (not shown in photograph) since it is important to reduce all mechanical and wind vibrations to a minimum. The rubber tubes shown in the photograph carry water to cool the box containing the specimen. The distance between the specimen and the coil should be at least two feet.

In order to test the accuracy of this new instrument several of the soft magnetic materials were measured since these are freer from cracks, easier to magnetize and chemically more homogeneous. The latter factor is important in measuring magnetostriction because any inhomogeneity in the specimen causes a pole to occur and this results in an undesirable extraneous force between the specimen and the magnetizing coil. Figure 5

shows an actual magnetostrictive trace obtained with this instrument in conjunction with the Cioffi recording fluxmeter, using a specimen of Vanadium-Permendur, an alloy of 49 percent iron, 49 percent cobalt, and 2 percent vanadium. At a field strength of 830 oersteds, a magnetostriction of 51×10^{-6} was obtained. The specimen was approximately 4 in. I.D., 4.5 in. O.D., and had been annealed at 1000°C for 1 hour and slowly cooled. This agrees closely with values obtained by other investigators, for example, on this alloy not containing the vanadium, Honda[10] obtained a magnetostriction of approximately 50×10^{-6} with $H=500$ oersteds. Sometimes it is desirable to take magnetostrictive loops over limited field strengths and Fig. 6 shows that this

[10] K. Honda, *Magnetic Properties of Matter* (Tokyo, 1928), p. 111.

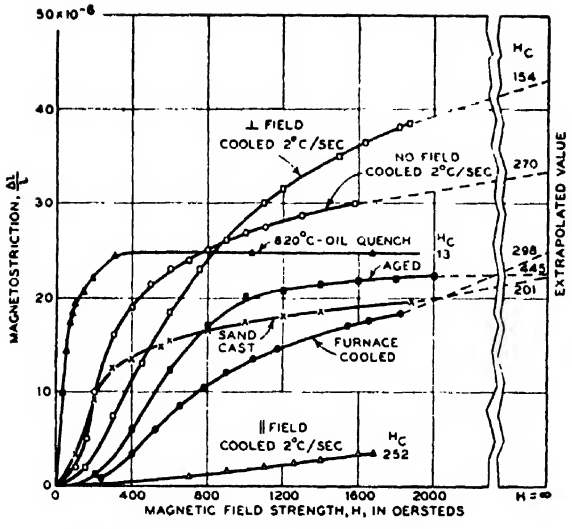

FIG. 8. Magnetostriction of Alnico V for seven different treatments.

instrument is capable of taking symmetrical loops of this type. The specimen is the same as the one used for Fig. 5. The specimen was first magnetized at its remnant value and the magnetizing force then applied in the opposite direction. The magnetostriction dipped slightly then rose to a maximum value of 35.6×10^{-6}, and then as the H was decreased, the magnetostriction decreased to zero. The H was reversed, the magnetostriction dipped again and then rose to a maximum of 36.2×10^{-6} and then as the H was decreased again, the magnetostriction decreased to zero, its starting point.

In many of the experimental curves, the saturation magnetostriction was not reached since magnetizing forces of only about 2000 oersteds were used. It is difficult to saturate completely permanent magnets in their hardened state, and this is especially true when toroidal specimens are used. The use of toroidal specimens has several advantages, however, because by this method one avoids as much as possible the translational forces caused by non-uniform fields and also avoids errors resulting from the forces between free poles. Figure 7 shows trace of the magnetostriction as a function of the magnetizing force for Alnico V and an extrapolated curve (data obtained from trace) of magnetostriction as a function of $(B-H)^2$ for obtaining the saturation magnetostriction. Sometimes it was also necessary to plot $(B-H)$ *vs.* $1/H$ to obtain the saturation magnetization by extrapolation.

The measurement of zero magnetostriction on a polycrystalline specimen does not necessarily mean that the magnetostrictions in the various crystallographic directions are zero. It is possible that a negative magnetostriction in the [111] direction could be balanced somewhat by two positive magnetostrictions in the [100] and [110] directions as is the case in iron. However, an exact balance of these crystallographic magnetostrictions for all values of flux density is unlikely. When the polycrystalline magnetostriction is found to be low at all inductions, it is believed that the magnetostriction is low in all crystallographic directions.

RESULTS

The data obtained may be divided into four categories.

(1) The magnetostriction of Alnico V and its variation with field and heat treatment.

(2) The magnetostriction of alloys having compositions near that of Alnico V.

(3) The magnetostriction of permanent magnet alloys of varying coercivity. The purpose of these experiments is to note any general relationship between magnetostriction and coercive force.

(4) The magnetostriction of several alloys of special interest which cannot be classified as permanent magnets. A specimen of Ferroxcube received from the American Philips Company, through the kindness of Dr. F. Brockman, and specimens of oriented iron-cobalt were measured. An iron-cobalt specimen yielded a magnetostriction of 130×10^{-6} one of the highest values ever reported.

The data for the first three parts are summarized in Tables I–III and they will now be discussed in detail.

Alnico V is probably the most important permanent magnet material. This alloy and associated alloys which are modifications of Alnico V are the only commercial permanent magnets which respond to heat treatment in

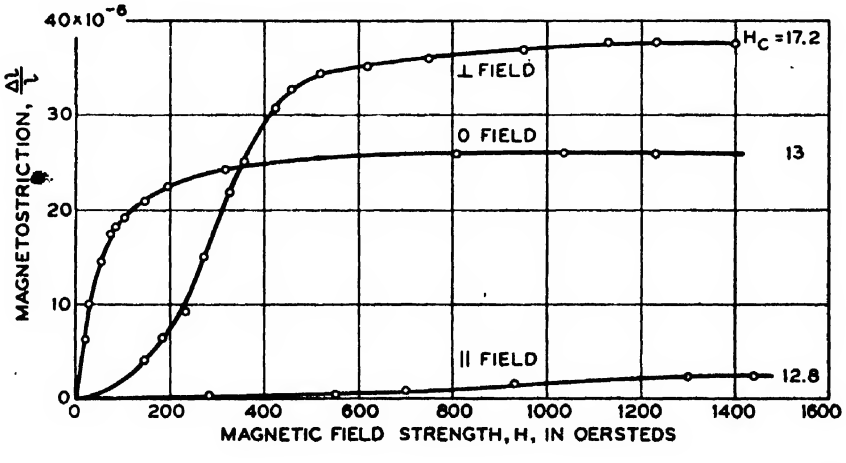

FIG. 9. Magnetostriction of Alnico V quenched from 820°C.

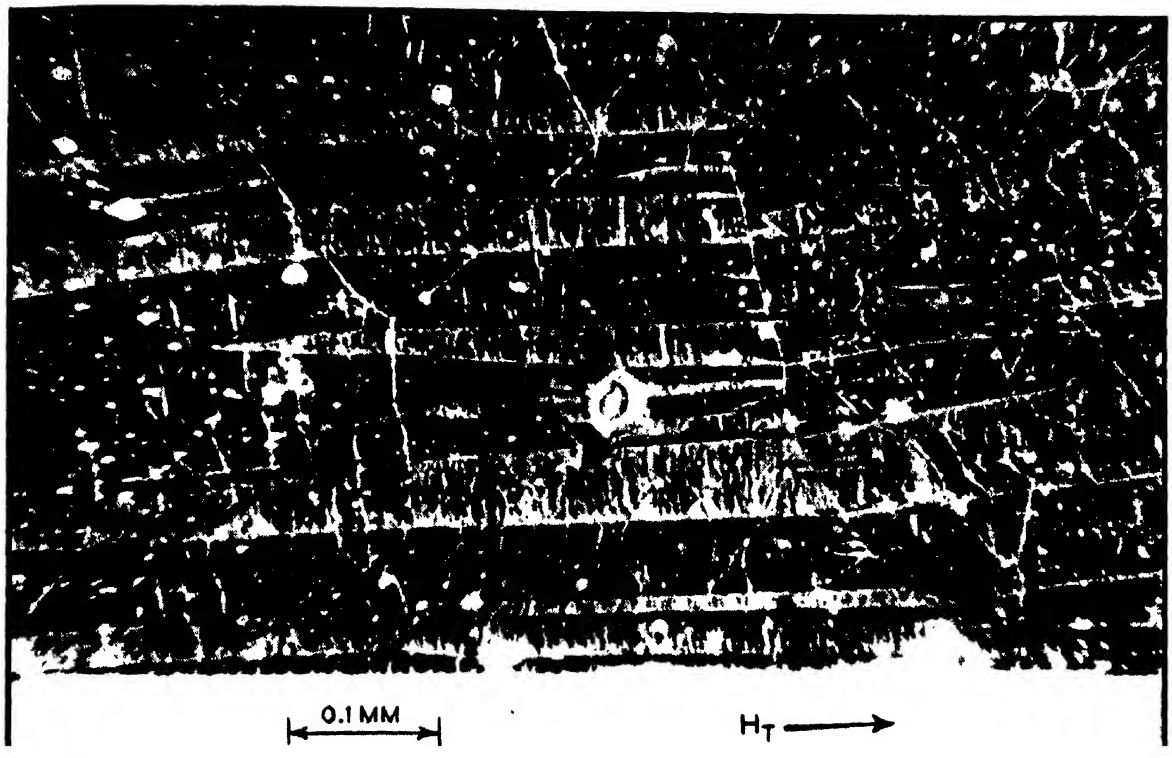

FIG. 10. Powder pattern photograph of Alnico V heat treated in a longitudinal magnetic field, the direction of which is shown by the arrow.

a magnetic field. Suggestions[11] have been made for explaining its response to heat treatment in a field and the nature of its hardening mechanism, and these suggestions have been aided by measurements of magnetostriction.

Figure 8 shows the magnetostriction of Alnico V as a function of magnetizing force for seven different treatments. The saturation magnetostriction values of the quenched, sandcast, and furnace cooled states are respectively 26×10^{-6}, 22.3×10^{-6}, and 25×10^{-6}. In the quenched specimen the precipitation process has not yet begun, in the sandcast specimen the process has not yet advanced to the point for optimum magnet properties while in the furnace-cooled specimen the process has advanced beyond the optimum point. The optimum cooling rate for Alnico V is approximately 2°C per second from 1300°C and the curve for zero field shows the magnetostrictive properties obtained on a specimen cooled at this rate. At an H of 1600 oersteds, the magnetostriction was 30×10^{-6} and the extrapolated value for saturation was 33.5×10^{-6}. The magnetic properties of this specimen are residual induction (B_r) of 11650 gauss, coercive force (H_c) of 270 oersteds, and the B for an H of 1510 oersteds is 16300 gauss. Another specimen of Alnico V (not shown in figure) heat treated in a similar manner had a magnetostriction of 27.5×10^{-6} at an H of 1600 oersteds and an extrapolated value of 35×10^{-6}. These two specimens cooled at the optimum rate yielded the highest magnetostriction for specimens of Alnico V not heat treated in a magnetic field. When Alnico V is completely hardened the saturation magnetostriction is lowered, a value of 21.8×10^{-6} was obtained at an H of 1600 oersteds the extrapolated value was 22.3×10^{-6} as shown in the curve for the aged specimen. The magnetic properties of this specimen were $B_r=9200$ gauss, $H_c=450$ oersteds and a saturation magnetization of 14150 gauss. The results given so far are for Alnico V not heat treated in a magnetic field and a random domain distribution was believed to exist. Specimens of Alnico V heat treated in longitudinal and transverse magnetic fields were also measured. The magnetostriction of the specimen heat treated in a longitudinal field was low as would be expected from the domain theory. A value of only 3.5×10^{-6} at an H of 1680 oersteds was obtained as shown in the curve for the parallel magnetic field. The magnetic properties of this specimen were $B_r=12900$ gauss, $H_c=252$ oersteds and $B=16200$ gauss for an H of 1460 oersteds. The magnetostriction of the specimen heat treated in a transverse field was high as would be expected from domain theory. A value of 36×10^{-6} was obtained at an H of 1600 oersteds and the extrapolated value was 43×10^{-6}. This is higher than that obtained on the specimens cooled at the same rate but with no applied field during the heat treatment. The magnetic properties of the

specimen were $B_r = 5140$ gauss, $H_c = 154$ oersteds, and $B = 15220$ gauss for an H of 1900 oersteds.

Figure 9 compares the magnetostriction of three specimens of Alnico V which were quenched from 820°C. The first specimen was cooled in a transverse field and its magnetostriction was 38×10^{-6}. This value is almost one and one-half times higher than the magnetostriction of the second specimen which was cooled in zero field. This is in exact accordance with domain theory which predicts that a specimen having the domains oriented transversely will have one and one-half times the magnetostriction of a specimen having random domain orientation. The third specimen was heat treated in a longitudinal field and its magnetostriction was 2.5×10^{-6}. This low value is obtained because the longitudinal field orients the domains either parallel or antiparallel to the direction of the applied field and so very little change in length is observed upon magnetization. A powder pattern photograph of the domains in this ring is shown in Fig. 10, taken with H. J. Williams. These large domains or domain aggregates extend around the circumference of the ring in the same direction that the field was applied during heat treatment. As a result of this phase of the investigation, we may say that Alnico V normally has a high magnetostriction and that it varies greatly with heat treatment from 2.5×10^{-6} to 43×10^{-6}. The behavior of the specimens heat treated in a magnetic field conforms with modern domain theory.

The second phase of this work consisted of measuring the magnetostriction of several alloys having aluminum contents in the vicinity of standard Alnico V (8 percent aluminum) to note how the magnetostriction varies with composition. The sum of the aluminum and iron percentages was kept constant. Figure 11 shows seven curves of magnetostriction as a function of magnetizing force for alloys of two, six, and ten percent aluminum. The magnetostriction of the six percent aluminum alloy for sandcast, cooled 2°C per second, quenched, and furnace cooled states, are respectively 25.5×10^{-6}, 25.3×10^{-6}, 19.2×10^{-6}, and 14.2×10^{-6} for an H of 1600 oersteds. With this alloy as with the standard 8 percent aluminum, the magnetostriction depends on heat treatment. Jellinghaus[12] mentioned that alloys containing 5 to 7 percent aluminum have a high Curie point but for some unknown reason fail to respond to heat treatment in a magnetic field. We now know that the 6 percent aluminum alloy also has a substantial value of magnetostriction although its value is only 75 percent that of the Alnico V. Alloys containing only 5 to 7 percent aluminum develop only a fraction of the coercive force of Alnico V. Magnetostriction values of the 10 percent aluminum alloy for the sand cast and furnace cooled states are respectively 17.5×10^{-6} and 12.9×10^{-6} for an H of 1400 oersteds. The furnace cooled specimen has an irregular curve indicating a heterogeneous structure. The magnetization curve has a similar irregularity showing that the magnetostriction is following the magnetization. The magnetostriction of the furnace cooled alloy with 2 percent aluminum was 30.4×10^{-6} at an H of 1600 oersteds and 38×10^{-6} at saturation. This alloy containing only 2 percent aluminum is not in the immediate vicinity of Alnico V and its magnetostriction is due primarily to the magnetic constituents of iron, nickel and cobalt and not to the aluminum.

The third phase of this work consisted of measuring the magnetostriction of a number of permanent magnets having different values of coercive force, as shown in Fig. 12. For tool steel at an H of 1600 oersteds the magnetostriction has a value of approximately -2.8×10^{-6}. This low negative value is also accompanied by a low value of coercive force (45 oersteds). The addition of cobalt to steel (along with several carbide producing elements such as tungsten and chromium) produces a series of permanent magnets of increasing coercivity. The magnetostriction of a low cobalt steel (8.5 percent cobalt) is shown in Fig. 12 and has a value of 14.3×10^{-6}

[12] W. Jellinghaus, Arch. Eisenhüttenw. 16, 247–251 (1943).

at $H=1600$ and a coercive force of 93 oersteds. The best of these cobalt steels is Honda steel and its magnetostrictive curve shown in Fig. 12 yields a value of 33.6×10^{-6} at an H of 1600 oersteds, accompanied by a coercive force of 183 oersteds. Thus we see that in the cobalt steel system for the alloys measured as the magnetostriction increases the coercive force does likewise. This result is consistent with the classical strain theory of coercive force (coercive force is proportional to the product of magnetostriction and stress) if we assume that the stress is substantially constant in these alloys. This seems like a reasonable assumption since the alloys are closely related to each other and their indentation hardness is approximately the same.

Remalloy,[13] a hot workable alloy of iron, cobalt, and molybdenum, and Vicalloy,[14] a hot or cold workable alloy of iron, cobalt, and vanadium, were measured. The magnetostriction of the Remalloy specimen as 11.6×10^{-6} at 1600 oersteds, and the extrapolated value was 17×10^{-6} (Fig. 12). The magnetostriction of the Vicalloy specimen was 26×10^{-6} at 1600 oersteds and the extrapolated value was 34×10^{-6}. The coercive force of the Remalloy was 305 oersteds, the coercive force of the Vicalloy was 320 oersteds while the respective magnetostrictions were 17 and 34×10^{-6}. In this instance, therefore, we have two different alloys with approximately the same coercive force but one alloy has twice the magnetostriction of the other. In addition the magnetostrictions of the Remalloy and Vicalloy specimens were measured in an unhardened state and the values obtained were respectively 24 and 47.5×10^{-6} (Table III). These values are considerably higher than those obtained on the hardened specimens, it being generally true that age-hardening lowers the magnetostriction of an alloy.

The magnetostriction curve for the hardened Alnico V (not heat treated in a field) is replotted in Fig. 12. The magnetostriction was 21.8×10^{-6} at 1600 oersteds and the extrapolated value was 22.3×10^{-6}, and the coercive force was 450 oersteds in the same specimen.

The magnetostriction of the Mishima alloy (29 percent Ni, 12 percent Al, 59 percent Fe), shown in Fig. 12, was so low for its accompanying coercive force of 420 oersteds that it was decided to investigate this system in detail. A series of Mishima alloys were made with nickel held constant at 29 percent and aluminum varying from 8 to 13 percent, and the results obtained are shown in Fig. 13. The magnetostriction of these alloys gradually diminishes with increasing aluminum content and actually passes through zero in the vicinity of 12 to 12.5 percent aluminum. According to the strain theory of coercive force, the coercive force should also pass through zero in this vicinity but the alloys in this range have coercive forces from 400 to 440 oersteds. Evidently the strain theory does not apply to these alloys and in all probability it does not apply to Alnico V since this alloy is directly related to the iron-nickel-aluminum system. The alloys were cooled from 1350°-1300°C at the rate of 2°-5°C per second and their magnetostriction depends to a certain extent upon this heat treatment. This is shown in Table III for the alloy containing 13 percent aluminum. Saturation magnetostriction values for the annealed, cast, aged, and cooled at 5°C per second states are respectively -17.5×10^{-6}, -15.0×10^{-6}, -10.5×10^{-6}, and -6.2×10^{-6}.

A number of the alloys having coercive forces from 50 to 600 oersteds are shown graphically in Fig. 14, in which coercive force is plotted against magnetostriction. In addition to the results shown in Figs. 12 and 13, magnetostriction is plotted for the alloy Cunico (50 percent Cu, 21 percent Ni, 29 percent Co), Vicalloy tape of low magnetic saturation, and two Mishima alloys. Information on the indentation hardness and magnetic saturation are also included. The indentation hardness probably bears some relation to the amplitude of the internal stress. Also in a given material, if all other factors remain the same one would expect the magnetostriction to depend directly on the magnetic saturation. The Cunico specimen has a low value of magnetostriction (7.5×10^{-6}), a low indentation hardness (R.C. 20) and a high coercive force (445 oersteds) and it therefore contributes strongly to the idea that the classical strain

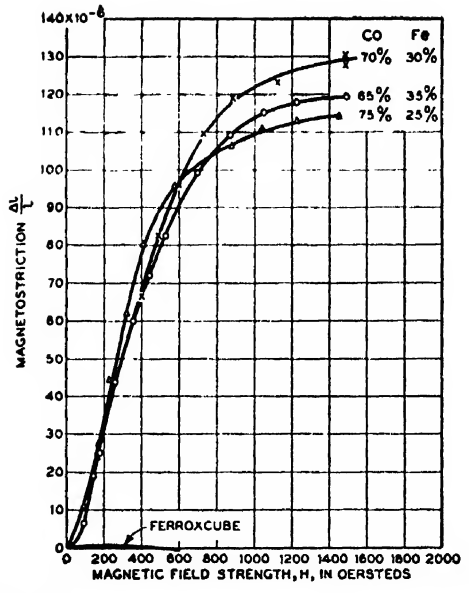

FIG. 15. Magnetostriction of alloys of special interest.

theory does not apply to this alloy. The Vicalloy tape specimen (impregnated in Bakelite) also has low magnetostriction (11×10^{-6}) and low hardness (R.C. 33). The Mishima composition of 23 percent nickel, 12 percent aluminum, and 65 percent iron, cooled from 1300°C at the rate of 5°C per second had the lowest magnetostriction of the alloys actually measured, a value of -1.0×10^{-6} with an accompanying coercive force of 356 oersteds. The magnetostriction of the other Mishima composition (29 percent nickel, 13 percent aluminum and 58 percent iron) is plotted for the sand-cast state, for which the saturation magnetostriction is -15×10^{-6} and the coercive force 560 oersteds.

In Fig. 14 one observes that for the carbon hardening alloys measured there is an approximately linear relation between magnetostriction and coercive force but for the carbon-free alloys measured there is no such relation.
